Abstract

Adaptive optics can effectively correct the wavefront distortion caused by atmospheric turbulence in optical wireless communication systems. As an adaptive optical control algorithm, the mode method has a significant effect on improving the performance of adaptive optical systems. This chapter systematically describes the research progress of Zernike mode method, deformable mirror eigenmode method, Lukosz mode method and Legendre mode method in the field of adaptive optics at home and abroad, introduces the common mode method and correction principle in detail, and briefly introduces the quality evaluation method of wavefront distortion correction in adaptive optics system and the application of mode method in wavefront correction. The research emphasis of mode method is to reduce the error and improve the speed accuracy, which directly affects the ability of wavefront distortion correction, and then affects the performance of adaptive optics system.

Mode method · Adaptive optics · Zernike mode method · Wavefront distortion

Introduction

Adaptive optics can suppress the perturbation of laser signals in atmospheric turbulence transmission [1], with the aim of correcting the wavefront aberration caused by the disturbance of the beam. At present, the common adaptive optics control algorithms mainly include the mode method [2], the control algorithm based on the principle of geometrical optics, and the model-free optimization algorithm, etc. In this chapter, we mainly focus on the Zernike mode method in the mode method, and introduce other mode methods at the same time. The mode method can effectively suppress the wavefront phase aberration, improve the correction speed and correction accuracy of adaptive optics system, and then improve the quality of communication. Therefore, finding a method that can improve and optimize the mode method has great potential for improving the performance of adaptive optics systems.

Research Progress at Home and Abroad

In 1953, Babcock proposed the concept of adaptive optics. He also proposed the idea of using optical elements with variable surface shapes to generate corresponding conjugate wavefronts to compensate for dynamic wavefront errors. This idea laid the foundation for the development of adaptive optics [3].

In 1976, Noll discussed the general properties of Zernike polynomials, such as Fourier transforms, integral representations, and derivatives. The Zernike representation of the Kolmogorov turbulence spectrum is the most commonly used Zernike expression in optics [4].

In 1977, Fried et al. successfully introduced adaptive-optics technology into optical wireless communication systems. The adaptive-optics unit could correct wavefront distortions caused by atmospheric turbulence in real time [5].

In 1979, Jiang developed a 19-unit wavefront-correction system for the Shenguang high-power laser device, which was the first practical device of its kind in the world [6].

In 1990, Nicolas proposed an algorithm that used the Zernike expansion of a random weighted function to simulate an atmospheric-distorted wavefront and introduced and analyzed the algorithm. The results showed that the Zernike polynomial well simulated the wavefront distortion [7].

In 1990, Daniel et al. experimentally verified that the orthogonality of Zernike polynomials makes them very suitable for wavefront fitting and proposed a Zernike-fitting method using a set of orthogonal polynomials. Experimental results showed that this method could speed up the Zernike fitting [8].

In 1995, Hu et al. introduced the eigenmode method for deformable mirrors, described its construction and application principles, and proved its relationship with the direct-slope method. Finally, using a 37-element deformable mirror as an example, the eigenmodes were constructed [9].

In 1996, Glenn et al. provided an expression for non-Kolmogorov turbulence using Zernike polynomials. The results showed that increasing the power-rate index of the three-dimensional phase power-spectral density from two to four resulted in the inclusion of a higher proportion of wavefront energy in the tilt component. For power-law exponents greater than four, the variance of the Zernike coefficients was more dependent on the outer turbulence scale than on the power-law index. The longer the length of the outer turbulence scale, the greater the energy in the tilt term [10].

In 1997, Butts reconstructed the phase as a linear combination of Zernike polynomials and calculated the structural function of the subaperture slope. The results showed that the Zernike spectrum calculated from the data measured by the wavefront sensor was consistent with the standard Kolmogorov turbulence model [11].

In 1999, Marcial et al. studied the properties of Gaussian functions when fitting a wavefront, analyzed a specific set of Gaussian functions, and demonstrated their simple Fourier transform. Two simulated wavefronts were fitted simultaneously and compared with Zernike polynomials. The results showed that, using the Gaussian function, the accuracy of the fitting increased with the number of terms [12].

In 2000, Neil et al. introduced a practical implementation of a closed-loop adaptive-optics system based on a novel wavefront sensor, where a light-spot pattern was generated on the detector plane. The experimental results showed that as the system aberrations were corrected, the Strehl ratio rapidly increased, and the light-spot energy was more concentrated [13].

In 2000, Zhang et al. used circular-domain and annular-domain Zernike polynomials to perform mode-method wavefront-reconstruction experiments on annular laser beams. The center occlusion ratio of the annular laser beam used in the experiment was 1:2. The results showed that if the wavefront-phase distortion of the annular laser beam was mainly composed of low spatial-frequency components, the wavefront could be directly reconstructed using a circular-domain Zernike polynomial. If the wavefront-phase distortion of the annular laser beam contained more high-spatial-frequency components, the annular-domain Zernike polynomial should be used for wavefront reconstruction [14].

In 2001, Hofer et al. used a real-time Shack–Hartmann wavefront sensor, a low-coherence source, and a scanning system to calculate the wavefront-phase root-mean-square value, Seidel aberrations, and average time power spectrum of 32 Zernike coefficients. The results showed that, except for defocus, human-eye aberrations fluctuated, and an adaptive-optics system with a closed-loop bandwidth of 1–2 Hz could accurately correct these aberrations [15].

In 2002, Chang et al. proposed a method for estimating Seidel-aberration coefficients using a two-dimensional discrete-wavelet transform. This method was used to analyze the wavefront of an optical system; it not only obtained more accurate

Seidel-aberration coefficients but also expedited the calculation. The experiment simultaneously fit three simulated wavefronts, and showed the simulation results of spherical aberrations, coma aberrations, astigmatism, and defocus [16].

In 2003, Mahajan expanded a set of Zernike polynomials with aberrations orthogonal to the system aperture; the variance was given by the sum of squares of the aberration coefficients. The experimental results showed that the Zernike polynomial was orthogonal to the circular pupil. For small aberrations, the Strehl ratio of the imaging system depended on the variance of the aberration [17].

In 2004, Upton et al. (2004) used the Gram–Schmidt orthogonalization technique to generate orthogonal hexagonal Zernike polynomials from circular-domain Zernike polynomials and provided the results of the first 17 sixth-order Zernike polynomials. Experiments confirmed that the Gram–Schmidt orthogonalization technique could be extended to any aperture shape [18].

In 2005, Kawashima et al. used a deformable mirror (DM) to compensate for aberrations in the human eye. (The working principle of a DM is to apply a control voltage to each actuator to change the shape of the deformable mirror, to correct a wavefront aberration.) The model-eye aberration measured by the Shack–Hartmann wavefront sensor was extended to a Zernike polynomial. The driving voltage of the deformable mirror was determined, and the human-eye aberration was canceled by using an appropriate voltage for each Zernike polynomial. The results showed that this method could reduce the root-mean-square error of corrected model human-eye aberrations to less than 0.1 μm [19].

In 2005, Seifert et al. studied the wavefront reconstruction of adaptive Shack–Hartmann sensors. The Zernike wavefront reconstruction was studied according to the fitting accuracy, reconstruction time, and noise influence. The experimental results showed that Zernike reconstruction was more suitable for fitting simple wavefronts [20].

In 2005, Yang et al. studied the reasons, conditions, and degree of mode coupling and mode confusion when reconstructing a wavefront using the Zernike mode method, and determined the basic principle of the optimal-reconstruction order. The 19-element Hartmann restoration accuracy was evaluated, and it was concluded that mode coupling was the main factor affecting the accuracy [21].

In 2006, Luo et al. used the Zernike-mode method to experiment with distorted-wavefront reconstruction, and obtained the Zernike optimization order of the distorted-wavefront reconstruction. The relationship between different Zernike orders and the recovery wavefront error was investigated through numerical simulations. The results showed that with an increase in the Zernike order, both the peak–valley (PV) and root-mean-square (RMS) values decreased rapidly. However, when the order exceeded 20, the change was relatively small, and the large number of calculations produced by the increase in the order also resulted in calculation errors [22].

In 2006, Booth proposed an adaptive-optics system that did not use wavefront sensors, but instead represented wavefront-phase distortions with appropriate mathematical models, such as Zernike polynomials. The research results showed that this method was helpful for optimizing control algorithms and was illustrated by the

application of direct-search and hill-climbing algorithms. Moreover, an efficient scheme using a maximization calculation was proposed, which allowed the measurement of N-order Zernike modes using only $N + 1$ intensity measurements [23].

In 2006, Fernandez et al. proposed a new deformable mirror using 52 independent magnetic actuators and studied in detail the ability of the deformable mirror to reproduce different surfaces, particularly Zernike polynomials to the fifth order. A study of the deformable-mirror influence function showed that the deformable mirror had a significant linear response to the applied voltage, and the correction device exhibited high fidelity when generating the surface. The range of Zernike polynomials completely covered common aberrations in the human eye, and even highly distorted eyes had almost perfect aberration correction [24].

In 2007, Martin et al. proposed a wavefront-sensorless adaptive-optics (WSAO) system based on the Lukosz mode (a new form developed after the derivative orthogonalization calculation of its Zernike polynomial) and introduced a scheme that could effectively measure wavefront aberrations represented by a series of modes. The scheme used the expansion of a Lukosz polynomial, based on the representation of aberrations. The experimental results showed that wavefront aberrations of the N-order aberration mode could be corrected with at least $N + 1$ photodetector measurements [25, 26].

In 2007, Rocha et al. measured changes in vision caused by individual Zernike aberrations using different RMS values. Experimental results showed that an electromagnetic adaptive-optics vision emulator could effectively correct and generate wavefront aberrations of up to four orders. Compared to the best eyeglass correction, custom wavefront correction significantly improved vision; and symmetric aberrations (such as defocus and spherical aberrations) were more detrimental to visual performance [27].

In 2007, Durán et al. introduced a scheme using traditional spatial light modulators to compensate for common optical aberrations in the human eye. The experimental results were obtained by correcting aberration distortions in artificial eyes by introducing a single Zernike term or a phase plate with complex ocular-aberration patterns. This was a step toward compensating for eye aberrations using low-cost general-purpose spatial light modulators [28].

In 2007, Qi et al. introduced a Zernike-polynomial fitting method for interference wavefronts. Research results showed that this method obtained the optimal mode combination of the interference wavefront and effectively improved the wavefront-fitting accuracy [29].

In 2008, Yang et al. proposed an adaptive-optics control algorithm that combined a genetic algorithm and the Zernike mode. Experimental results showed that using this algorithm shortened the iteration time and improved the correction speed. The PV and RMS values were reduced from 3.38λ and 0.64λ before the aberration correction to 0.52λ and 0.06λ, respectively. The improvement effect was significant, and the far-field focal spots before and after the correction were more concentrated from dispersion, which was close to the ideal Airy spot [30, 31].

In 2009, Yang et al. conducted a theoretical analysis and discussed the improvement in convergence speed of the stochastic parallel-gradient descent (SPGD)

algorithm based on the Zernike mode. In addition, a 61-element deformable mirror was used as the wavefront corrector to establish a simulation model of an adaptive-optics system.

The results showed that if the system contained only low-order distortion, mode-method optimizations could obtain a better convergence-speed and correction effect. When many high-order components were present, the mode and region methods could be combined, which not only obtained a fast convergence of the mode-method correction, but also maintained the correction ability of the entire system. While the same correction effect was achieved, the convergence speed of the algorithm using the combined optimization of the pattern and region methods was significantly better than the convergence speed based on the region method [32].

In 2009, Wang proposed a wavefront-reconstruction method based on a Walsh series. Because using the Walsh series as a base produced a correlation between the wavefront expansion and the light-field intensity, the wavefront mode coefficient could be obtained by measuring the incident-ray intensity using only a single-mode fiber and phase-spatial light modulator. Because this method only used light-intensity data, the calculation speed was faster than that of the wavefront-reconstruction method using two-dimensional slope information [33].

In 2010, Liu et al. proposed a Zernike-mode gray release graph-reconstruction algorithm for nematic liquid-crystal adaptive-optical systems. The results showed that the PV and RMS values corrected by the mode method were reduced from 2.50λ and 0.610λ to 0.0334λ and 0.00845λ, respectively; they were much smaller than those of the slope method of 0.173λ and 0.048λ, respectively. Compared to the slope method, the Strehl ratio of the system corrected by the mode method was closer to the diffraction limit [34].

In 2010, Mahajan et al. proposed the theory of noncircular-domain wavefront analysis and applied it to a systematic comparison of wavefront analyses of ring-domain and circular-domain Zernike polynomials. The research results showed that unlike ring-domain Zernike coefficients, circular-domain Zernike coefficients usually changed with the number of polynomials in the expansion. Moreover, the wavefronts fitted with a certain number of circular-domain Zernike polynomials were approximately the same as those fitted with the corresponding ring-domain Zernike polynomials [35].

In 2010, Lee proposed an efficient method for estimating the orthogonal-aberration coefficients of noncircular pupils. The method was based on the fact that all the information needed to construct an orthogonal polynomial (via the Gram–Schmidt process) could be obtained numerically using a conventional least-squares process of fitting Zernike polynomials to wavefront data. This enabled the method to obtain the required orthogonal-aberration coefficients using Zernike polynomial fitting. The method was well-suited for real-time wavefront analyses of dynamically changing circular pupils [36].

In 2010, Bueno et al. established a device consisting of a point-diffraction interferometer (PDI) and a Shack–Hartmann wavefront sensor to compare the two complementary techniques when applied to different phase plates. The results showed that under the same experimental and fitting conditions, the maximum

difference in RMS was 0.08 μm when all Zernike terms below order 6 were considered; when the lower-order term was excluded, the difference was reduced to 0.03 μm. The combination of these two techniques enabled the accurate measurement of complex phase distributions, while combining the robustness of the Shack–Hartmann sensor with the high resolution and dynamic range of a PDI [37].

In 2011, Chee et al. proposed a method to improve the accuracy of wavefront fitting. To obtain the coefficients of the Zernike polynomial, a set of discrete orthogonal polynomials needed to be constructed, and the coefficients were calculated by fitting the wavefront data and orthogonal polynomial using the least-squares method. The simulation results showed that, owing to the limitations of the least-squares method, there was a large deviation between the given coefficients and the calculated results [38].

In 2011, Rafael et al. proposed and evaluated complex Zernike polynomials (CZPs) to represent general wavefronts with non-uniform intensity (amplitude) in non-transmissive pupils. The results showed that the CZP provided a fully orthogonal basis capable of representing complex wavefronts, thereby providing a unified general framework. Complex wavefronts require more CZPs; however, they are particularly suitable for nonuniform light beams [39].

In 2011, Yu et al. proposed a simplified Gram–Schmidt method for solving Zernike polynomials; it had high fitting accuracy and was used to analyze the wavefront aberrations of interference fringes captured by interferometer systems. Experiments found that the stability of the Zernike coefficient changed with the Zernike term. When the Zernike term was less than 14, instability could be avoided [40].

In 2011, Feng et al. studied the influence of the order of Zernike polynomials on the fitting accuracy and conducted experiments. The experimental results showed that Zernike polynomials with appropriate orders should be selected to fit the wavefront to improve the fitting accuracy [41].

In 2011, Wang et al. studied the circular Zernike-polynomial pattern method to reconstruct the wavefront. The simulation results showed that the circular Zernike-polynomial mode method could ensure reconstruction accuracy. Moreover, wavefront-reconstruction experiments were performed based on Zernike polynomials with different numbers of terms. The results showed that with a change in the number of terms, the mode coefficients obtained by circular Zernike polynomials changed significantly [42].

In 2012, Chen et al. proposed a generalized ridge-estimation Zernike-mode wavefront-reconstruction algorithm for image restoration. Moreover, the generalized ridge-estimation point-spread function (PSF) and least-squares estimation PSF were compared. The results showed that the generalized ridge-estimation Zernike-mode method could effectively restore the optical wavefront. Using the generalized ridge-estimation PSF, the full width at half height of the restored image was 3.3 pixels with 48 iterations. Using the least-squares estimation PSF, the full width at half height of the restored image was 3.8 pixels with 65 iterations.

The restoration effect of the generalized ridge-estimation PSF was approximately 17% higher than that of the least-squares estimation PSF, which was closer to the

optical diffraction limit of the imaging system. It also reduced the number of iterations, which indirectly proved that the Zernike-mode reconstruction algorithm based on generalized ridge estimation had better PSF reconstruction accuracy [43].

In 2012, Booth et al. used a pattern-based adaptive-optics system to study the aberration correction of mouse embryos imaged in a microscope. The experimental results showed that the method had a fast correction speed and did not require multiple iterations; the real-time performance of the system was greatly improved [44].

In 2012, Hasan et al. studied Zernike polynomials for annular elliptical apertures in Cartesian and polar coordinates. These polynomials formed completely orthogonal bases on annular-elliptical apertures, representing balanced classic aberrations, like circular-field Zernike polynomials in a unit circle [45].

In 2013, Cacao et al. studied quaternionic Zernike spherical polynomials (QZSPs), presented their expressions, and summarized their basic properties. The results showed that the QZSP improved the original Zernike polynomials and was complete and orthogonal in the unit sphere [46].

In 2014, Yang et al. studied a model-based wavefront-detection adaptive-optics system and analyzed the correction effect and correction speed changes under different turbulence conditions. The research results showed that the system could obtain an ideal correction ability close to that of a wavefront-correction device while converging rapidly and had strong adaptability to different aberrations.

When an N-order mode aberration was corrected, the system only needed to measure $N + 1$ far-field light spots, which greatly reduced the number of measurements. This provided a feasible method for a wavefront-detection adaptive-optics system to be used for real-time aberration correction [47].

In 2014, Yan et al. designed an adaptive-optics system based on the deformable-mirror eigenmode method, and analyzed the influence of different orders of eigenmodes on the system-correction effect and closed-loop control stability under different thermal-halo intensities. Numerical-simulation results showed that the deformable-mirror eigenmode method could improve the stability of an AO-system closed-loop control and effectively suppress the occurrence of phase-compensation instability [48].

In the same year, Yan et al. designed an adaptive-optics system to correct the transient thermal-halo effect of collimated light beams. The experimental results showed that for a 69-element deformable mirror, when the order of the reconstructed mode was less than or equal to 37 orders, the greater the order of the reconstructed mode, the better the wavefront-correction effect. However, when the mode order was greater than or equal to 38 orders, the correction effect deteriorated rapidly [49].

In 2014, Yazdani et al. simulated two wavefronts with a typical arbitrary phase distribution. Numerical experiments verified an iterative method for simultaneously reconstructing two unknown interferometric wavefronts. An interferogram on two parallel planes perpendicular to the average propagation direction of these wavefronts was analyzed, and then the unknown wavefronts were calculated using the Zernike polynomial and the SPGD algorithm. The research results showed that

this method could effectively reconstruct two interferometric wavefronts simultaneously. It was verified experimentally to be a fast and accurate method [50].

In 2016, Chao et al. proposed a Gram–Schmidt orthogonalization method to handle the wavefront reconstruction of general aperture types. The method constructed a set of orthogonal basis functions and calculated the expansion coefficients to reproduce the original wavefront. Studies showed that the method was numerically stable, compared with the classic least-squares method, and exhibited superior performance for noncircular apertures. The method was robust to noise and did not cause truncation errors by omitting higher-order terms [51].

In 2016, Wang et al. proposed the use of a deformable-mirror eigenmode instead of the traditional Lukosz mode for a wavefront-sensor adaptive-optics system under point targets. The experimental results showed that after correction with the Lukosz mode, the remaining wavefront-error RMS value was 0.074λ, and after correction with the deformable-mirror eigenmode, the remaining wavefront-error RMS value was 0.042λ. The adaptive-optical correction method without a wavefront sensor, based on the deformable-mirror mode, could effectively correct aberrations with high correction accuracy and better than the traditional Lukosz mode [52].

In 2016, Zhang et al. used a Shack–Hartmann sensor and Zernike-mode reconstruction theory to conduct an experimental analysis of the light quality of a laser output beam. They accurately obtained the PV and RMS values of the wavefront and Zernike aberrations of each order. The far-field light-spot energy distribution was also obtained by further calculation so that the characteristics and quality of the light beam could be comprehensively analyzed. The experimental results showed that the aberration of the laser wavefront was concentrated in the first 10 stages of Zernike aberration [53].

In 2016, Dong et al. used a wavefront-sensorless adaptive-optics system based on the Lukosz mode to dynamically correct aberrations in infrared remote sensors. They used the spectral density of light-spot images at low spatial frequencies as a performance-index function, using 52-unit deformable mirrors for correction. The simulation results showed that the average image-sharpness value during the dynamic correction was 1.436×10^{-5}, and in the unoptimized correction, the average value of the image sharpness was 1.427×10^{-5}. They also verified that the mode-based wavefront sensing adaptive-optical system achieved a faster convergence than the traditional random parallel gradient-descent method [54].

In 2016, Li et al. proposed a wavefront-correction method using a focal-plane image in the field of optical wireless communication. The method divided the focal-plane image into 16 subregions, divided the first 18-order Zernike coefficients into 1736 subspaces, and constructed neural networks with only one hidden layer to successfully estimate the first 18-order Zernike coefficients [55].

In 2017, Wang et al. proposed a wavefront-distortion correction method based on the deformable-mirror eigenmode, and built an experimental system. The experimental results showed that the algorithm converged after three iterative corrections under different turbulence intensities, and the Strehl ratio of the system was higher than 0.8 [56].

In 2018, Liu et al. proposed using the difference Zernike-polynomial fitting (DZPF) method to reconstruct the wavefront from multiple phase differences. Numerical-simulation results showed that, compared with the discrete Fourier transform (DFT) method, the DZPF method maintained higher reconstruction accuracy in a wider shear-ratio range and had better noise immunity. Test experiments of the shear interferometer were also performed. In the wavefront-reconstruction process, the proposed DZPF method was used instead of the DFT method, and the measured RMS value of the shear interferometer was reduced from 0.0054λ to 0.0029λ [57].

In 2018, Wang et al. disclosed an adaptive-optics device based on the eigenmode control of a pyramid wavefront sensor. The eigenmode was used to obtain the transfer-function matrix of the adaptive-optics system, and mode filtering was used to improve the stability of the transfer-function matrix. Thus, it effectively improved the closed-loop stability of the adaptive-optics system. The correction effect of the system could be selected according to the actual situation [58].

In 2018, Ma et al. modified AlexNet [59] (a convolutional neural network for classification). First, the focal-plane and defocus-plane images under different atmospheric-turbulence parameters were generated by simulation. These images were used as the training dataset to train the modified AlexNet model, and the first 35-order Zernike coefficients were output [60].

In 2019, Sun et al. proposed a method for wavefront restoration using the Gram matrix equation and conducted experimental research. The experimental results showed that the method could recover the Zernike coefficient from the wavefront-layer information without pattern coupling. The method could be extended to the ring domain to obtain uncoupled ring-domain Zernike polynomial coefficients [61].

In 2019, Ke et al. used a wavefront-sensorless adaptive-optics system based on deformable-mirror (DM) eigenmodes to correct distorted far-field light spots and deduced a set of DM eigenmodes that conformed to the orthogonal relationship of derivatives. Combined with the principles of Fresnel diffraction and multiphase screen transmission, a system simulation model was established under different atmospheric-turbulence intensities. The results showed that this method could improve the signal-to-noise ratio of the system and effectively correct wavefront distortion caused by dynamic atmospheric turbulence [62].

In the same year, Ke et al. studied a computationally adaptive plenoptic imaging system (CAPIS) to detect optical wavefront distortions and carried out simulation analyses. The results showed that CAPIS technology could accurately detect low-order aberration wavefronts, and the RMS of the wavefront residuals were less than 0.1λ [63].

In 2020, Wu et al. designed an adaptive-optics system based on the deformable-mirror eigenmode and also conducted experimental research. The experimental results showed that, on the premise of ensuring the correction effect, regardless of the turbulence strength, the convergence speed of the system was improved to a certain extent. For the same wavefront aberration, the more deformable mirror units, the fewer required far-field light-spot measurements; the stronger the atmospheric-turbulence intensity, the more units required for deformable mirrors, and the fewer far-field light-spot measurements required [64].

In 2020, Liang et al. studied a wavefront-free adaptive-optics system based on the deformable-mirror eigenmode. Using the influence function of the deformable mirror, a set of deformable-mirror eigenmodes that conformed to the orthogonal derivative was deduced, and the eigenmodes were used as bases for decomposing the wavefront-aberration mode. The experimental results showed that the original wavefront PV value was 1.36 μm, the RMS value was 0.1995 μm, and the PV and RMS values after four corrections simultaneously reached optimal values, which were 0.514 μm and 0.088 μm, respectively. This method effectively corrected static aberrations, improved the energy concentration of far-field light spots, did not use multiple iterations, and had a fast convergence speed. Experiments required multiple measurements of far-field light-spot calculation mode coefficients and could only correct static aberrations well [65].

In 2020, Rodin et al. used convolutional neural networks to train and identify aberration types corresponding to a single Zernike polynomial, based on the intensity pattern of the point-spread function. They used a fast Fourier transform algorithm to simulate the point spread in the focal plane. When training neural networks, the learning coefficient and number of cycles of a dataset of a given size were empirically selected, and from a dataset of 17,000 point-spread function images, a set of 17 Zernike polynomials was obtained. For most types of aberrations, the average absolute prediction error was 0.012–0.017 [66].

In 2020, Wu et al. modified LeNet-5 [67] (a convolutional neural network for classification) and called the modified network a phase-diversity convolutional neural network (PD-CNN). They used a liquid-crystal spatial light modulator to generate the real phase, and experimentally acquired real images of the focal and defocal planes, outputting the first 13 Zernike coefficients. In the experimental verification, the trained neural networks were used to measure a wavefront with a PV value of 1.188λ and an RMS value of 0.226λ. The final recovered PV value was 0.078λ with an RMS value of 0.012λ [68].

In 2020, Hu et al. constructed neural networks based on U-Net [69] (a fully convolutional neural network) and ResNet [70] (a convolutional neural network), and named them SH-Net. The network inputs a light-spot array from the Hartmann sensor and directly outputs the phase map of the wavefront to be measured. It thereby realized an end-to-end mapping from the Hartmann sensor image to the phase map.

In the numerical simulation, the phase screen was generated by multiplying the Zernike-polynomial method and a Gaussian filter by a random-matrix method. In the test group, with the Zernike polynomial method and the random method simultaneously generating the phase screen, the wavefront RMS value restored by SH-Net was only 0.0168λ. In addition, the operational speed of the neural networks was considerable. The average operation time of SH-Net after training was 40.2 ms in actual use [71].

In 2021, Wang et al. proposed a wavefront-decoupling method for liquid-crystal deformable-mirror adaptive-optics systems based on the deformable-mirror eigenmode. The experimental results showed that the RMS of the correction residual after the eigenmode decoupling was 0.09 μm. The resolution of the 700 nm–1700 nm

wide band after decoupling correction increased from 1.1 times the diffraction limit to one times the diffraction limit, which was better than the 1.2 times the diffraction limit of the traditional Zernike mode [72].

In 2022, Cao et al. adopted a residual network as the backbone network and constructed a multi-scale residual mixed-attention network structure. They used the convolution operation to convert the light-intensity image into a feature map and propagated it backward; they extracted features through convolution kernels of different scales, and used the attention mechanism to improve the recognition rate of the network light-spot feature. Finally, the network-loss function was designed to obtain the Zernike coefficient that conformed to the actual wavefront aberration. The results showed that the residual attention network quickly and accurately reconstructed the turbulent phase, effectively correcting the distortion. This provides a guarantee for deep-learning practical applications in AO systems [73].

In 2022, Ning et al. proposed an adaptive-optics wavefront-correction method based on machine learning. This method used a turbulent-pool simulation to generate random disturbances and obtained sample data through wavefront detectors. This simplified the structure of the adaptive-optics system and improved the wavefront-correction accuracy and speed without wavefront sensing [74].

The mode-method application field extends from the optical wireless communication field to the medical field, with many studies and applications in the biomedicine field. In recent years, research on mode methods has mainly focused on error analysis, suppression, and elimination, as well as speed and accuracy. The speed and accuracy of the mode method directly affect the performance of the adaptive-optical system. Therefore, improving the solution speed and accuracy of the mode method will still be a research focus in the future.

For domestic development, most of the few related experiments at the beginning were numerical calculations and simulations. In recent years, new research methods have been proposed, and many new research directions have been added. However, this progress is insufficient. Most domestic development includes simulation analyses of algorithms. Experimental sites and equipments are limited. These are important factors that restrict development in China. The application of the mode method to adaptive optics still needs to be further researched, and improvements in the analysis are needed. Table 24.1 shows the research progress both at home and abroad.

Mode Methods

A mode method selects an appropriate base mode to describe the wavefront error and corrects the wavefront distortion by optimizing the base-mode coefficient [75, 76]. Currently, commonly used base modes include the deformable-mirror eigenmode [77], Zernike mode [4], Lukosz mode [77], and Legendre mode [78]. The base mode needs to satisfy the reciprocal orthogonal relationship [77].

Table 24.1 Research progress at home and abroad

Year	Researcher	Content	Result
1953	Babcock	Proposed the concept of adaptive optics.	–
1976	Noll	Defined the most commonly used Zernike expressions in optics.	The Zernike representation of the turbulent Kolmogorov spectrum was given.
1977	Fried	Introduced adaptive-optics technology into a optical wireless communication system.	The adaptive-optics unit corrected wavefront distortion caused by atmospheric turbulence in real time.
1979	Jiang	Developed a 19-unit wavefront correction system, 21-unit adaptive science system, and 2.16-m telescope infrared adaptive-optics observation system.	–
1990	Nicolas A R	Developed an algorithm for simulating atmospheric distorted wavefronts using a Zernike expansion.	Zernike polynomials simulated distorted wavefronts well.
1990	Daniel M H	Proposed a Zernike-fitting method using a set of orthogonal polynomials.	Expedited Zernike fitting.
1995	Hu	Introduced the deformable-mirror eigenmode method, and attempted to construct an eigenmode in practice.	–
1997	Butts	Reconstructed the phase as a linear combination of Zernike polynomials.	Zernike spectra calculated from wavefront sensor data were consistent with standard Kolmogorov turbulence models.
2000	Neil M A	Practically realized a closed-loop adaptive-optics system for a novel wavefront sensor.	SR increased rapidly with more concentrated light spots.
2005	Kawashima	Compensated for human-eye aberrations using deformable mirrors.	The RMS error of human-eye aberration correction was less than 0.1 mm.
2005	Yang	Created a Zernike-mode method to reconstruct wavefronts.	Mode coupling was the main factor affecting accuracy.
2006	Booth	Developed an adaptive-optics system without a wavefront sensor.	–
2007	Martin	Developed an adaptive-optics system without wavefront sensing based on the Lukosz mode.	The RMS phase error was reduced from 2.01 rad to 0.38 rad.
2008	Yang	Created an adaptive-optical control algorithm combining a genetic algorithm and Zernike mode.	PV and RMS values were reduced from 3.38λ and 0.64λ before correction to 0.52λ and 0.06λ, respectively, afterward.

(continued)

Table 24.1 (continued)

Year	Researcher	Content	Result
2009	Yang	Developed an SPGD algorithm based on a Zernike mode.	SR quickly increased to 0.8, requiring about 120 iterations.
2010	Liu	Created a Zernike-mode reconstruction algorithm for adaptive-optics systems.	Corrected PV and RMS values were much smaller than 0.173λ and 0.048λ.
2012	Chen	Created a generalized ridge-estimation Zernike-mode wavefront-reconstruction algorithm for image restoration.	Recovery was approximately 17% better than least-squares estimates while reducing the number of iterations.
2014	Yang	Designed a mode-based closed-loop control algorithm for adaptive-optics systems without wavefront detection.	Number of measurements was greatly reduced and correction speed was accelerated.
2017	Yu	Developed an adaptive-optics system without a wavefront sensor based on a deformable-mirror eigenmode method.	RMS phase error was reduced from 4.3 rad before correction to 0.26 rad after.
2016	Zhang	Experimentally analyzed the quality of a laser output light beam using a Zernike-mode reconstruction theory.	Laser wavefront aberrations were concentrated in the first 10 levels of Zernike polynomials.
2017	Wang	Developed wavefront-distortion correction based on deformable-mirror eigenmodes.	After correction, the SR was higher than 0.8.
2019	Ke	Created a wavefront-sensing adaptive-optics system based on deformable-mirror eigenmodes.	After six iterations, the system converged, and the SR was basically maintained at about 0.85.
2020	Wu	Created an adaptive-optics system based on a deformable-mirror intrinsic mode.	When $D/r_0 = 5$ and $D/r_0 = 10$, the system convergence speed increased by 2.39 times and 2.33 times, respectively.
2021	Rodin	Obtained the mean absolute error for each aberration of neural networks with a set of 17 Zernike functions using convolutional neural networks.	For most aberration types, the mean absolute error was 0.012–0.019.
2022	Ning	Developed an adaptive-optics wavefront-correction system based on machine learning.	Simplified the structure of the adaptive-optics system, and improved the wavefront-correction accuracy and speed without wavefront sensing.

Zernike Mode

Definition of a Zernike Polynomial

A Zernike polynomial is a set of completely orthogonal bases defined on a unit circle. At present, the most commonly used expression in optics is the Zernike polynomial defined by Noll [4], whose specific expression is

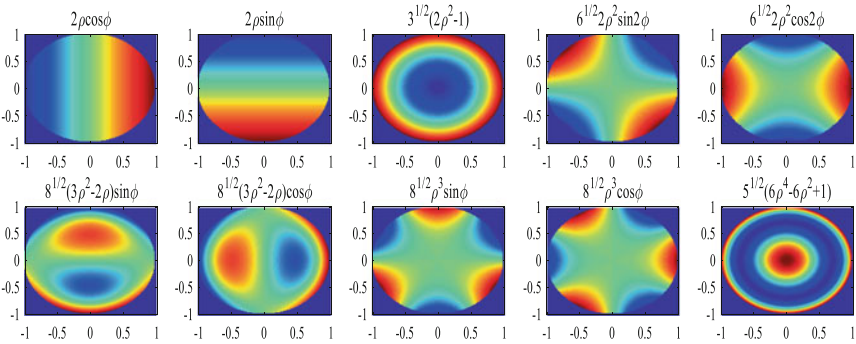

Fig. 24.1 Schematic diagram of the spatial distribution of Zernike modes of orders 2–10 [4]

$$Z_k(\rho,\theta) = \begin{cases} \sqrt{2(n+1)}R_n^m(\rho)\cos(m\theta) & k \text{ is an even number and } m \neq 0 \\ \sqrt{2(n+1)}R_n^m(\rho)\sin(m\theta) & k \text{ is an odd number and } m \neq 0 \\ \sqrt{n+1}R_n^0(\rho) & m = 0 \end{cases} . \tag{24.1}$$

In Eq. (24.1), $0 \leq \rho \leq 1$, $0 \leq \theta \leq 2\pi$, ρ and θ are the parameters of the polar coordinate system, n and m are the radial number and angular direction of the polynomial, respectively, and satisfy $n \geq 0$, $m \geq 0$, $m \leq n$; and n and m are even numbers. k is the serial number of the Zernike polynomial and $Z_k(\rho, \theta)$ is the expression of the Zernike polynomial. $R_n^m(\rho)$ is the radial function of the Zernike polynomial and satisfies

$$R_n^m(\rho) = \sum\nolimits_{k=0}^{\frac{n-m}{2}} \frac{(-1)^k(n-k)!}{k!\left(\frac{n+m}{2}-k\right)!\left(\frac{n-m}{2}-k\right)!}\rho^{n-2k}. \tag{24.2}$$

Figure 24.1 shows a schematic diagram of the spatial distribution of Zernike modes of orders 2–10 obtained by MATLAB simulation.

Physical Meaning of Zernike Polynomials

The correspondence and physical meanings of the Zernike polynomials are listed in Table 24.2 [79]. From the correspondence between the Zernike polynomials and Seidel aberrations, the various aberration components and relative sizes contained in a distorted wavefront can be intuitively analyzed through the Zernike polynomial pattern and its coefficients.

Zernike Polynomials for Simulating Turbulent Phase Screens

Let the wavefront phase be $\varphi(x, y)$ and the coefficient of the Zernike polynomial of item i be a_i. A linear combination of several Zernike polynomials is used to represent an atmospheric-turbulence phase screen, and the expression is shown in Eq. (24.3):

Table 24.2 Correspondence between Zernike polynomials and low-order Seidel aberrations

Modulo ordinal number	Radial number	Angular number	Polar expression	Aberration
1	0	0	1	Translation
2	1	1	$2\rho\cos(\theta)$	Tilt in x direction
3	1	1	$2\rho\sin(\theta)$	Tilt in y direction
4	2	0	$\sqrt{3}(2\rho^2-1)$	Out of focus
5	2	2	$\sqrt{6}\rho^2\sin(2\theta)$	45° astigmatism
6	2	2	$\sqrt{6}\rho^2\cos(2\theta)$	0° or 90° astigmatism
7	3	1	$\sqrt{8}(3\rho^2-2\rho)\sin(\theta)$	Y-axis third-order coma
8	3	1	$\sqrt{8}(3\rho^2-2\rho)\cos(\theta)$	X-axis third-order coma

$$\varphi(x,y)=\sum_{i=1}^{n_Z}a_iZ_i(x,y). \tag{24.3}$$

In Eq. (24.3), a_i is the i-order coefficient of the adopted mode, Z_i is the adopted mode, n_Z is the Zernike polynomial of the former Z term, and $\varphi(x, y)$ is the wavefront phase. The covariance between the i-term and j-term Zernike polynomial coefficients is

$$\begin{aligned}\left\langle a_ia_j\right\rangle=(-1)^{(n_i+n_j-m_i-m_j)/2}\sqrt{(n_i+1)(n_j+1)}\delta_{m_imj}I_{n_in_j}\cdot\\ 2^{4-2\alpha}\pi B(\alpha)c(\alpha)(D_0/r_0)^{\alpha-2},\end{aligned} \tag{24.4}$$

where n_i, n_j, m_i, and m_j are the radial-frequency and angular-frequency numbers corresponding to Zernike polynomials of terms i and j, respectively. D_0 refers to the diameter of the telescope; r_0 is the atmospheric coherence length; and δ_{m_imj} is the expression of Kronecker logic symbols. $I_{n_in_j}$ B (α), c (α), δ_{m_imj} are respectively

$$\begin{aligned}I_{n_in_j}=&\frac{\Gamma\left[(n_i+n_j-\alpha+2)/2\right]}{\Gamma\left[(n_i-n_j+\alpha+2)/2\right]\Gamma\left[(n_j-n_i+\alpha+2)/2\right]}\cdot\\ &\frac{\Gamma(\alpha+1)}{\Gamma\left[(n_i+n_j+\alpha+4)/2\right]}\end{aligned} \tag{24.5}$$

$$B(\alpha)=\frac{\Gamma(\alpha/2)}{2^{2-\alpha}\pi\alpha\Gamma(-\alpha/2)}. \tag{24.6}$$

In Eq. (24.6), α is the absolute value of the refractive-index three-dimensional power-spectral density index term of non-Kolmogorov atmospheric turbulence, which satisfies $3<\alpha<4$. The Γ function is

$$\Gamma(x) = \int_0^{+\infty} t^{x-1} e^{-t} dt, \tag{24.7}$$

where e is an exponential function and t is an intermediate variable of the integral.

$$c(\alpha) = 2\left[\frac{8}{\alpha - 2}\Gamma\left(\frac{2}{\alpha - 2}\right)\right]^{\frac{\alpha-2}{2}} \tag{24.8}$$

$$\delta_{m_i mj} = \left(m_i = m_j\right) \wedge [[(i + j) \in \text{even}] \vee (m_i = 0)] \tag{24.9}$$

In Eq. (24.9), even refers to an even number, $\delta_{m_i mj}$ is a Kronecker logic symbol, $\wedge$ is the "and" operation and $\vee$ is the "or" operation.

We perform a singular-value decomposition on the covariance matrix C_a. Because the covariance matrix has real symmetric positive determinism, its singular-value decomposition can be expressed as

$$C_a = XSX^T, \tag{24.10}$$

where S is a diagonal matrix and the transformation matrix X satisfies $X^{-1} = X^T$. In the simulation, a zero-mean random vector $\dot{d}$ was used with S as the covariance matrix. At this time, the following are obtained:

$$X\vec{d}\left(X\vec{d}\right)^T = X\vec{d}\vec{d}^T X^T = XSX^T = C_a. \tag{24.11}$$

$\dot{a} = X\dot{d}$ is the desired Zernike-polynomial coefficient vector.

The phase screen generated by this method has sufficient low-frequency components and relatively few high-frequency components. Although increasing the number of terms in the Zernike polynomial can solve this problem to a certain extent, it increases the calculation time.

Aberration of a Zernike Term Represents a Face Shape

An aberration means that, in an actual optical system, a single spherical lens or any combination of optical systems can only perfect the image of the paraxial-object point with a fine beam of light. The field of view and aperture increase and the concentricity of the imaging light beam is destroyed, resulting in various imaging defects. A Zernike polynomial is used to represent the surface shape of the optical element. The surface-shape error is

$$\phi(r, \varphi) = \sum_{i=0}^{N} A_i Z_i\left(\frac{r}{a, \varphi}\right), \tag{24.12}$$

where r and φ are the parameters of the surface-shape error, α is the radius of the optical element, Z_i is the Zernike polynomial, and A_i is the Zernike polynomial coefficient.

The definitions for the first 48 Zernike terms are as follows:

- Term 0 is the translation term, which represents the average optical-path difference.
- Terms 1 and 2 are tilt terms in the x and y directions, respectively.
- Term 3 is defocus.
- Terms 4 and 5 represent astigmatism and defocus, respectively.
- Terms 6 and 7 represent coma and tilt, respectively.
- Term 8 represents a spherical aberration.

- Terms 1–3 represent Gaussian or paraxial properties of the wavefront.
- Terms 4–8 represent three-order aberrations.
- Terms 9–17 are five-order aberrations.
- Terms 16–24 represent seven-order aberrations.
- Terms 25–35 represent nine-order aberrations.
- Terms 36–48 represent 11-order aberrations.

1. Tilt:

$$Z_1 = r\cos\frac{\varphi}{a}, Z_2 = r\sin\frac{\varphi}{a}. \tag{24.13}$$

2. Defocus:

$$Z_3 = \frac{2r^2}{a^2} - 1. \tag{24.14}$$

3. Astigmatism:

$$Z_4 = \frac{r^2}{a^2}, Z_5 = \frac{r^2\sin\varphi\cos\varphi}{a^2}. \tag{24.15}$$

4. Coma difference:

$$Z_6 = \frac{(3r^2-2)r\cos\varphi}{a^3}, Z_7 = \frac{(3r^2-2)r\sin\varphi}{a^3}. \tag{24.16}$$

5. Spherical aberration:

$$Z_8 = \frac{6r^4}{a^4} + \frac{6r^2}{a^2} - 1. \tag{24.17}$$

Principle of Zernike-Mode Wavefront-Distortion Correction

The mode method assumes that the distorted wavefront can be represented by a certain pattern [80]. First, the distortion information is converted into performance indicators, which are iteratively optimized using the optimization algorithm. The corrector is continuously deformed to obtain the optimal performance indicators for achieving the correction, which is the purpose of the distortion wavefront [81].

The evaluation function is obtained by calculating the integral of the image power-spectral density in the low-frequency region. According to the literature, the relationship between the image power-spectral density function and wavefront error is approximately [82]

$$g(M_1, M_2) \approx q_0(M_1, M_2) - q_1(M_1, M_2) \iint_p |\nabla \Phi|^2 ds, \tag{24.18}$$

where Φ is the wavefront error, $\nabla\Phi$ is obtained by differentiating Φ, q_0 and q_1 are constants related to the image structure, $\iint_p ds$ represents the integration of the pupil plane, and p refers to the pupil plane. M_1 and M_2 are normalized and represent the value range of the spatial frequency after processing. The wavefront error Φ is expanded through mode Z_i:

$$\Phi = \sum_{i=4}^{N} a_i Z_i. \tag{24.19}$$

In Eq. (24.19), a_i is the i-order coefficient of the adopted mode, Z_i is the adopted mode, and N represents the N-order coefficient. It is expanded to

$$\iint_p \nabla Z_i \cdot \nabla Z_j ds = \begin{cases} 1 & i = j \\ 0 & i \neq j \end{cases}, \tag{24.20}$$

where ∇Z_i and ∇Z_j are obtained by performing layer operations on Z_i and Z. The pupil surface is expressed by the mode coefficient as

$$G = g^{-1} = q_2 + q_3 \sum_{i=4}^{N} {a_i}^2, \tag{24.21}$$

where $q_2 = 1/q_0$ and $q_3 = q_1/q_0$.

The following system of equations can be derived when estimating the correction coefficient of the ith order mode:

$$\begin{cases} G_0 = q_2 + q_3 \sum_{k=i} a_k{}^2 + q_3 a_i{}^2 \\ G_+ = q_2 + q_3 \sum_{k=i} a_k{}^2 + q_3 (a_i + b_i)^2 \\ G_- = q_2 + q_3 \sum_{k=i} a_k{}^2 + q_3 (a_i - b_i)^2 \end{cases}. \tag{24.22}$$

In Eq. (24.22), G_0 is the performance index of the system in the initial state; G_+ and G_- are the performance indicators in the cases of statistical positive and negative bias, respectively; b_i is the offset; and a_i is the i-order coefficient of the adopted model. Solving this equation, we can obtain the correction of the i-order mode coefficient $a_{i,\ \mathrm{corr}}$:

$$a_{i,corr} = -a_i = -\frac{b_i (G_+ - G_-)}{2G_+ - 4G_0 + 2G_-}. \tag{24.23}$$

Lukosz Mode

The Lukosz polynomial is a new form, formed after the derivative-orthogonalization calculation of the Zernike polynomial [83, 84]. Its polar-coordinate expression is given by Eq. (24.24).

$$L_n^m(r,\theta) = B_n^m(r) \times \begin{cases} \cos(m\theta) & m \geq 0 \\ \sin(m\theta) & m < 0 \end{cases}, \tag{24.24}$$

where r and θ are polar-coordinate parameters, m is an integer, and n is a non-negative integer that satisfies $n - m = 2p$, $p = 0, 1, 2, \ldots$.

$B_n^m(r)$ can be expressed by Eq. (24.25):

$$B_n^m(r) = \begin{cases} \frac{1}{2\sqrt{n}} \left[R_n^0(r) - R_{n-2}^0(r) \right] & n \neq m = 0 \\ \frac{1}{2\sqrt{n}} \left[R_n^m(r) - R_{n-2}^0(r) \right] & n \neq m \neq 0 \\ \frac{1}{2\sqrt{n}} R_n^n(r) & n = m \neq 0 \\ 1 & n = m = 0 \end{cases}. \tag{24.25}$$

In Eq. (24.25), $R_n^m(r)$ is the amplitude of the Zernike polynomial, which can be expressed as Eq. (24.26):

$$R_n^m(r) = \sum_{k=0}^{\frac{n-m}{2}} \frac{(-1)^k (n-k)! r^{n-2k}}{k! \left(\frac{n+m}{2} - k\right)! \left(\frac{n-m}{2} - k\right)!} \tag{24.26}$$

where both m and n satisfy the following relationship:

$$0 \le m \le n, n + m = 2p, p = 0, 1, 2 \ldots .$$

Figure 24.2 shows the wavefront diagrams of the Lukosz mode of the first 20 orders, and Table 24.3 is the expression of the first 20 orders.

Deformable-Mirror Eigenmode Method

Definition of the Deformable-Mirror Eigenmode Method

The deformable-mirror eigenmode is a mode with derivative orthogonality, obtained according to the influence function of the deformable mirror itself, which can

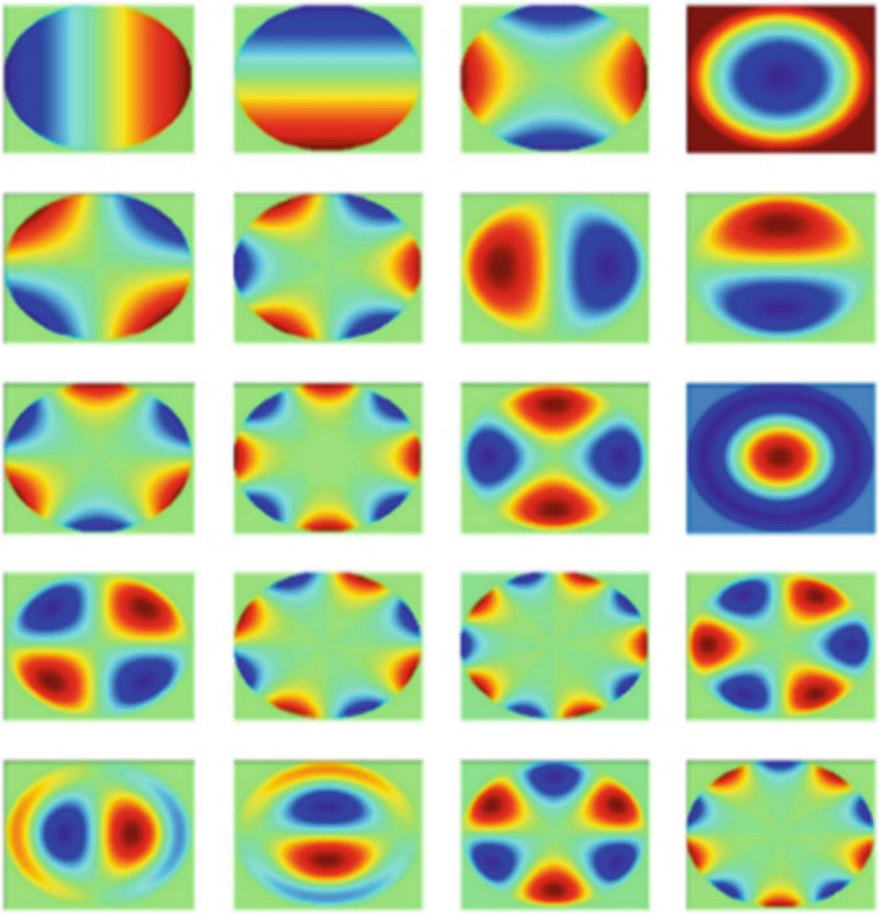

Fig. 24.2 Lukosz-mode wavefront diagrams of the first 20 orders [85]

10	$\frac{\sqrt{3}}{3}r^3\cos 3\theta$	20	$\frac{\sqrt{5}}{5}r^5\cos 5\theta$

perfectly fit the deformable mirror shape. The specific derivation process is as follows [48].

The relationship between the surface shape ψ of the deformable mirror, the influence function ω of the deformable-mirror actuator, and the control voltage matrix C is

$$\psi = \omega \cdot C. \tag{24.27}$$

In Eq. (24.27), ψ is the surface shape of the deformable mirror; C is the control voltage matrix; ω is the influence function of the deformable-mirror actuator.

Then, the coupling matrix Γ between ω can be obtained, which is expressed as

$$\Gamma = \omega^T \cdot \omega, \tag{24.28}$$

In Eq. (24.28), ω^T is the transpose matrix and Γ is the coupling matrix between ω.

We decompose the singular value into

$$\Gamma = U \cdot S \cdot U^T, \tag{24.29}$$

In Eq. (24.29), U is the unitary matrix, U^T is the transpose matrix of U, and S is the diagonal matrix.

According to the characteristics of the unitary matrix, Eq. (24.27) can be expressed as

$$\psi = \omega \cdot U \cdot U^T \cdot C. \tag{24.30}$$

Let $M = \omega \cdot U$ and $C_M = U^T \cdot C$; then, Eq. (24.27) is

$$\psi = M \cdot C_M, \tag{24.31}$$

where M is the deformable-mirror eigenmode matrix and C_M is the coefficient matrix.

Correction Principle of the Deformable-Mirror Eigenmode Method

A distorted light spot is generated by the transmission of a Gaussian beam, the eigenmode of the deformable mirror is deduced as the base, and the system function is calculated to correct the wavefront aberration [86].

System Function

The power-spectral density $S_j(m)$ of the light-spot image at the receiving end is used, and the integral sum in the low-frequency part is used as a system function:

$$g(M_1, M_2) = \int_0^{2\pi} \int_{M_1}^{M_2} S_j(m) m dm d\xi, \tag{24.32}$$

where m is the normalized spatial frequency, $S_j(m)$ is the power-spectral density of the light-spot image, M_1 and M_2 are the value ranges of m [87], ξ is the spatial-frequency direction angle, and $g(M_1, M_2)$ is a system function. $\int_{M_1}^{M_2} S_j(m) m dm$ refers to the integral of the product of the power-spectral density of the light spot in the spatial-frequency range.

After the object passes through the incoherent-imaging optical system, the relationship between the object and the image can be expressed as

$$S_j(m) = |H(m)|^2 S_T(m), \tag{24.33}$$

where $H(m)$ is the optical-transfer function and $S_T(m)$ is the power-spectral density of the object. The relationship between the optical-transfer function (OTF) and the system aberration can be expressed as

$$|H(m)|^2 \approx |H_0(m)|^2 - \frac{1}{\pi} \iint_p (m \cdot \nabla \Phi)^2 ds, \tag{24.34}$$

where $\iint_p ds$ represents the integral of the pupil plane, p refers to the pupil plane, $H_0(m)$ represents the OTF in the ideal state, Φ removes the wavefront aberration after translation and tilt, and ∇ is the layer operator. The system function can then be expressed as

$$\begin{aligned} g(M_1, M_2) &= \int_0^{2\pi} \int_{M_1}^{M_2} S_j(m) m dm d\xi \\ &= \left\{ \int_{M_1}^{M_2} \left\{ |H_0(m)|^2 \int_0^{2\pi} S_T(m) d\xi - \frac{1}{\pi} \int_0^{2\pi} S_T(m) \left[\iint_p (m \cdot \nabla \Phi)^2 ds \right] d\xi \right\} m dm \end{aligned} \tag{24.35}$$

In Eq. (24.35), m is the spatial frequency after normalization, $m = (m \cos \xi, m \sin \xi)$, and $S_f(m)$ is the power-spectral density of the light-spot image. M_1 and M_2 are the value ranges of m, and ξ is the spatial-frequency direction angle. $H_0(m)$ represents the OTF in the ideal state and $S_T(m)$ is the power-spectral density of the object.

It can be seen that substituting $|\nabla\Phi|(\cos\chi, \sin\chi)$ into Eq. (24.29) yields

$$\begin{aligned}\iint_p (m \cdot \nabla\Phi)^2 ds &= \iint_p \{m|\nabla\Phi|[(\cos\xi \cdot \cos\chi) + (\sin\xi \cdot \sin\chi)]\}^2 ds, \\ &= \frac{m^2}{2} \iint_p (\nabla\Phi)^2 [1 + \cos(2\xi - 2\chi)] ds\end{aligned} \tag{24.36}$$

where χ is the spoke angle of $\nabla\Phi$, ξ is the spatial-frequency direction angle, Φ is the wavefront aberration after removing translation and tilt, $\nabla\Phi$ is obtained by differentiating Φ, $\iint_p ds$ represents the integral of the pupil plane, and p refers to the pupil plane.

The desired system-function expression can be obtained by calculation:

$$g(M_1, M_2) \approx q_0(M_1, M_2) - q_1(M_1, M_2) \iint_p |\nabla\Phi|^2 ds \tag{24.37}$$

$$q_0(M_1, M_2) = \pi \int_{M_1}^{M_2} |H_0(m)|^2 a_0(m) m dm \tag{24.38}$$

$$q_1(M_1, M_2) = \frac{\pi}{2} \int_{M_1}^{M_2} a_0(m) m^3 dm \tag{24.39}$$

Correction Coefficient

The system function g is represented by the mode coefficient C_{Mi} as

$$g = q_0 - q_1 \sum_{i=4}^{N} {C_{Mi}}^2, \tag{24.40}$$

where N is the mode order and C_{Mi} is the ith mode coefficient. When the aberration is large, Eq. (24.40) can be expressed as [88]

$$G = g^{-1} = q_2 + q_3 \sum_{i=4}^{N} {C_{Mi}}^2, \tag{24.41}$$

where $q_2 = 1/q_0$ and $q_3 = q_1/{q_0}^2$. Equation (24.41) is also suitable for small aberrations.

The relationship between the eigenmode coefficient of the ith deformable mirror and the system function is as follows:

$$\begin{cases} G = q_2 + q_3 \sum_{k=i} {C_{Mi}}^2 + q_3 {C_{Mi}}^2 \\ G_+ = q_2 + q_3 \sum_{k=i} {C_{Mi}}^2 + q_3 (C_{Mi} + b_i)^2 \\ G_- = q_2 + q_3 \sum_{k=i} {C_{Mi}}^2 + q_3 (C_{Mi} - b_i)^2 \end{cases}, \tag{24.42}$$

where C_{Mi} is the ith mode coefficient and G is the performance index of the system in the initial state.

Solving Eq. (24.42) yields the coefficient correction amount $C_{Mi,\mathrm{corr}}$ of the deformable-mirror eigenmode of the ith order:

$$C_{Mi,\mathrm{corr}} = -C_{Mi} = -\frac{b_i(G_+ - G_-)}{2G_+ - 4G_- + 2G_0}. \tag{24.43}$$

The above process is cycled N times to obtain the correction coefficient matrix $C_{Mi,\mathrm{corr}}$ of the N-order mode. If $C_M = U^T * C$ is known, the required correction voltage can be deduced.

Legendre Mode

Definition of the Legendre Polynomial

The Legendre polynomial [89] is the solution of the Legendre equation under the natural boundary condition: The solution $x = \pm 1$ is kept finite. The specific expression is as follows:

$$L_l(x) = \sum_{k=0}^{l/2} (-1)^k \frac{(2l-2k)!}{2^l k!(l-k)!(l-2k)!} x^{l-2k}, \tag{24.44}$$

where $l \geq 0$ and $[l/2]$ represents the largest integer not exceeding $l/2$. Using Eq. (24.44), the expression of the Legendre polynomial of the first seven orders can be obtained, as shown in Table 24.4.

Two-Dimensional Legendre Polynomials

Because the wavefront phase is distributed in a two-dimensional (2D) space, and the Legendre polynomial is defined in a one-dimensional space, when reconstructing the wavefront on the square domain, the Legendre polynomial needs to be extended to a two-dimensional space. The expansion method

involves multiplying two Legendre polynomials that are independent of each other in the x and y directions [90]:

$$L_{m,n}(x,y) = L_m(x) \times L_n(y), \tag{24.45}$$

where $L_m(x)$ and $L_n(y)$ are the mth and nth Legendre polynomials defined in the x and y directions, respectively.

A Fourier transform is performed on the two-dimensional Legendre polynomial, and the obtained frequency-domain analysis conclusion is the same as that of the Zernike polynomial. That is, as the two-dimensional Legendre order increases, the higher the spatial frequency it can represent. According to Eqs. (24.44) and (24.45), the first 10-order two-dimensional Legendre polynomial expressions can be obtained, as shown in Table 24.5. A schematic diagram of the spatial distribution of the 2D Legendre mode of orders 2–10 is shown in Fig. 24.3.

Unlike the Zernike polynomial, there is no direct connection between each term of the two-dimensional Legendre polynomial and various aberrations; therefore, it is impossible to analyze the distortion wavefront by the size of each coefficient, as can be done with the Zernike polynomial. Various aberration components and relative sizes exist.

Table 24.4 Legendre polynomials of the first seven orders

Serial number	Order	Cartesian coordinate expression
1	0	1
2	1	x
3	2	$(3x^2 - 1)/2$
4	3	$(5x^3 - 3x)/2$
5	4	$(35x^4 - 30x^2 + 3)/8$
6	5	$(63x^5 - 70x^3 + 17x)/8$
7	6	$(231x^6 - 317x^4 + 105x^2–5)/16$

Table 24.5 First 10-order two-dimensional Legendre polynomials

Serial number	$L_{m,n}$	m	n	Expression
1	$L_{0,0}$	0	0	1
2	$L_{1,0}$	1	0	x
3	$L_{0,1}$	0	1	y
4	$L_{2,0}$	2	0	$(3x^2 - 1)/2$
5	$L_{1,1}$	1	1	Xy
6	$L_{0,2}$	0	2	$(3y^2 - 1)/2$

8	$L_{2,1}$	2	1	$(3x^2 - 1)\ y/2$
9	$L1_{,2}$	1	2	$(3y^2 - 1)\ x/2$
10	$L_{0,3}$	0	3	$(5y^3 - 3y)/2$

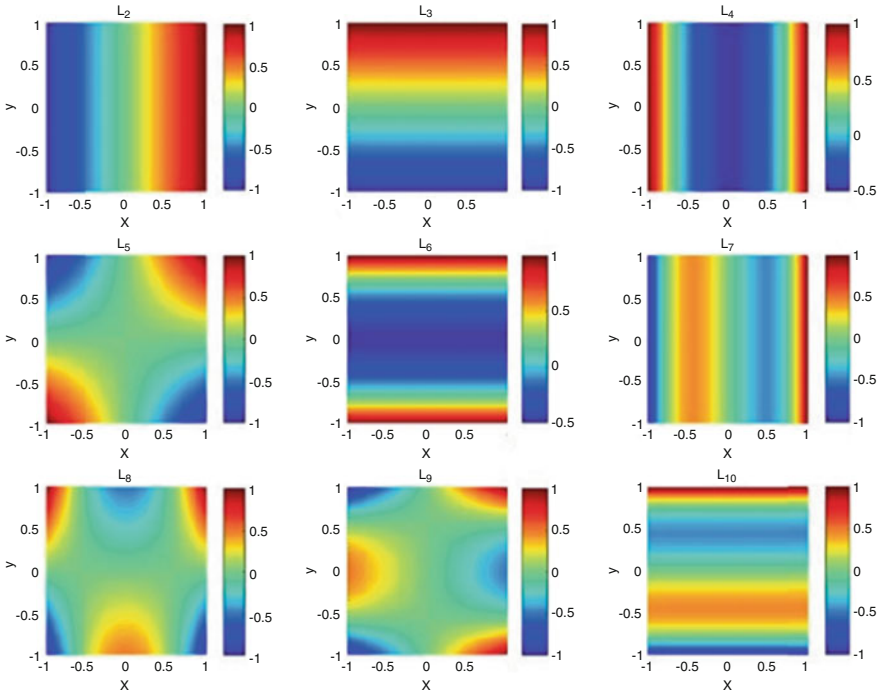

Fig. 24.3 First 10-order two-dimensional legendre polynomials [61]

Orthogonality of Two-Dimensional Legendre Polynomials

Legendre polynomials are orthogonal within their domain [84]. Therefore,

$$\int_{-1}^{+1} L_m(x)L_n(x)dx = \begin{cases} 0 & (n \neq m) \\ \dfrac{2}{2n+1} & (n = m) \end{cases}, \tag{24.46}$$

where m and n are polynomial orders. When the Legendre polynomial is extended to a two-dimensional space, if two two-dimensional Legendre polynomials are integrated in their domain, then, according to their extended definitions and the orthogonality of the Legendre polynomial, we can obtain

$$\int_{-1}^{1}\int_{-1}^{1} L_{m,n}(x,y)L_{k,l}(x,y)dxdy = \int_{-1}^{1} L_m(x)L_k(x)dx \int_{-1}^{1} L_n(y)L_l(y)dy, \tag{24.47}$$

where $L_{m,\,n}(x,\,y)$ and $L_{k,\,l}(x,\,y)$ are two-dimensional Legendre polynomials.

Wavefront-Distortion Correction Quality-Evaluation Method

An adaptive-optics system compensates and corrects the distortion of the optical wavefront. Its purpose is to correct the wavefront phase at each position in the optical receiving aperture to the same value. For point-target imaging, when the undistorted plane light wave is imaged through the optical system, the phase of each position in the optical receiving aperture is exactly the same, as shown in Fig. 24.4a. At this time, the light spot acquired on the imaging focal plane has the highest energy concentration and maximum light intensity, and the imaging effect at this time is the optical diffraction limit of the imaging system. The corresponding imaging light spot is called an Airy spot, as shown in Fig. 24.4b.

In contrast, if the light wave is distorted, the phase of each point in the optical receiving aperture is different, the energy concentration of the light spot obtained at this time decreases, the intensity of the center position of the light spot decreases, and the radius of the light spot increases. Therefore, the correction quality of the point light source imaging by the adaptive-optics system can be evaluated from three aspects: the phase difference of each point in the optical receiving aperture, the imaging light-spot radius, and the spot-center position intensity. The corresponding indicators are the wavefront-phase RMS error, optical diffraction-limit multiple, and spot Strehl ratio (SR).

The wavefront-phase RMS error describes the degree of fluctuation of the phase value of each point in the optical receiving aperture. The calculation method is as follows:

$$\mathrm{RMS} = \sqrt{\frac{1}{N}\sum_{i=1}^{N}[\varphi(x,y) - \langle\varphi(x,y)\rangle]^2}, \tag{24.48}$$

where $\varphi(x, y)$ is the wavefront phase and $\langle\varphi(x, y)\rangle$ is the average value of $\varphi(x, y)$.

The optical diffraction-limit multiple is the multiple of the light-spot radius obtained by the distorted incident-ray wave after passing through the imaging system, relative to the optical diffraction-limit light-spot radius. Let the intensity distribution of the imaging light spot be $I(x, y)$; then, the corresponding light-spot radius R can be calculated by the following expression:

$$\mathrm{R} = \frac{\iint\sqrt{(x-\bar{x})^2 + (y-\bar{y})^2}I(x,y)dxdy}{\iint I(x,y)dxdy}, \tag{24.49}$$

where $(\bar{x}, \bar{y})$ is the light-spot centroid coordinate. The smaller the optical diffraction-limit multiple, the higher the energy concentration of the light spot and the better the imaging quality. The Strehl ratio is defined as the ratio of the maximum intensity of

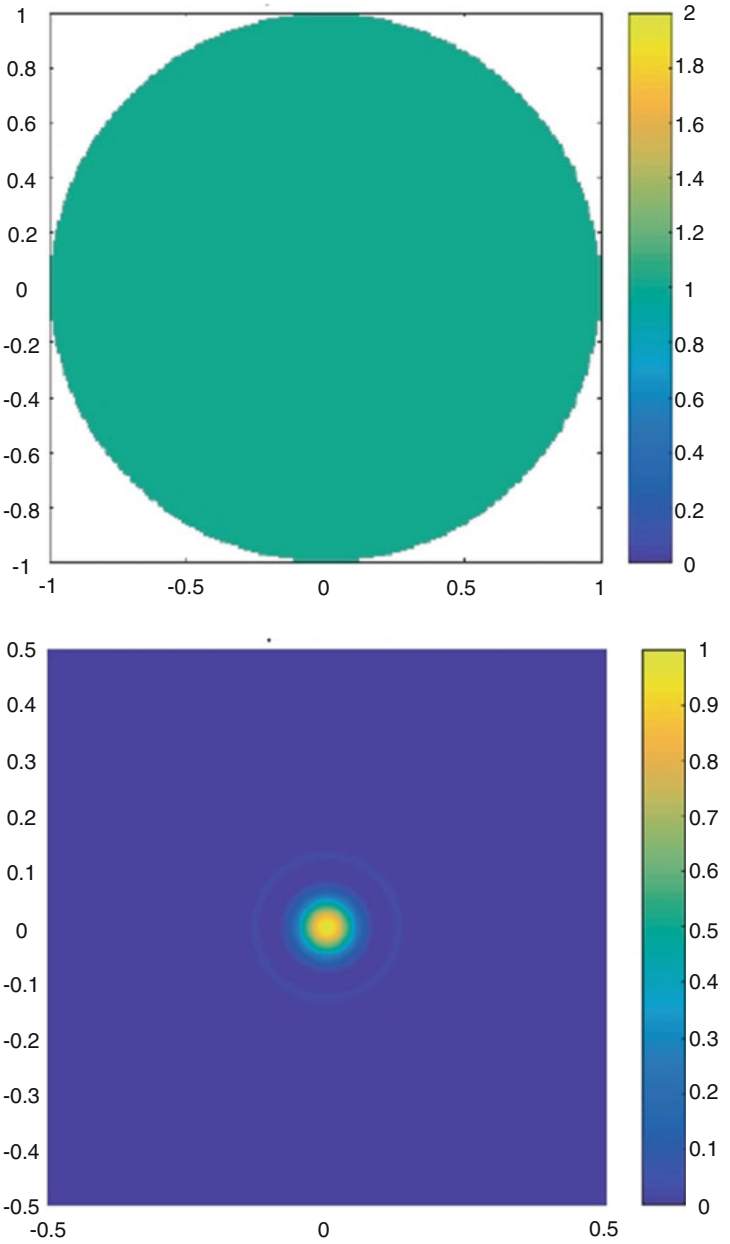

Fig. 24.4 Wavefront phase and imaging light spot without wavefront distortion [91]. (**a**) Wavefront-phase distribution. (**b**) Imaging light-spot intensity distribution

the actual imaging light spot to the maximum intensity of the ideal imaging light spot, as follows:

$$\mathrm{SR} = \frac{\max[I(x,y)]}{\max[I_0(x,y)]}. \tag{24.50}$$

In Eq. (24.50), x and y represent the coordinate values, $I(x, y)$ is the light-intensity distribution of the actual light spot with wavefront distortion, and $I_0(x, y)$ is the light-intensity distribution of the ideal imaging light spot without wavefront distortion. Max represents the maximum value. When the phase of the distorted wavefront $\varphi(\rho, \theta)$ is known, the Strehl ratio can also be calculated using the following expression:

$$\begin{aligned}\mathrm{SR} &= \frac{1}{\pi^2}\left|\int_0^{2\pi}\int_0^1 \exp[j\varphi(\rho,\theta)]\rho d\rho d\theta\right|^2 \\ &= \frac{1}{\pi^2}\left|\int_0^{2\pi}\int_0^1 \sum_{n=0}^{\infty}\frac{[j\varphi(\rho,\theta)]^n}{n!}\rho d\rho d\theta\right|^2,\end{aligned} \tag{24.51}$$

where $\varphi(\rho, \theta)$ is the distortion-wavefront phase. When $\varphi(\rho, \theta)$ is smaller, the higher-order terms of the third order and above in the Taylor expansion of Eq. (24.51) can be ignored so that

$$\begin{aligned}\mathrm{SR} &= \left|1 + j\langle\varphi(\rho,\theta)\rangle - \frac{1}{2}\langle\varphi^2(\rho,\theta)\rangle\right|^2 \\ &\approx 1 - \left[\langle\varphi^2(\rho,\theta)\rangle - \langle\varphi(\rho,\theta)\rangle^2\right] \approx \exp\left(-\mathrm{RMS}^2\right).\end{aligned} \tag{24.52}$$

When the Strehl ratio of the light spot is greater than 0.8, the quality of the imaging light spot is higher and the wavefront distortion is better corrected. If the imaging target is an extended target with a larger size, the intensity distribution of the light spot imaged by the point light source must be regarded as the point-spread function of the imaging system, i.e.,

$$f(x,y) = I(x,y) * h(x,y), \tag{24.53}$$

where $I(x, y)$ is the intensity distribution of the imaging target, $h(x, y)$ is the point-spread function of the imaging system, $f(x, y)$ is the imaging result of the target after passing through the optical system, and * is the convolution operator. The imaging result corresponding to the Airy spot is used as a reference image for the quality evaluation. Common metrics include the peak signal-to-noise ratio (PSNR) and structural similarity. The method for calculating the peak signal-to-noise ratio is as follows:

$$\mathrm{PSNR} = 10\log_{10}\left\{\frac{\left(2^k-1\right)^2}{\mathrm{MSE}[f(x,y),I(x,y)]}\right\}, \tag{24.54}$$

where k represents the number of bits in the image and MSE[$f(x, y)$, $I(x, y)$] is the mean-squared error between the imaging screen $f(x, y)$ and the reference image $I(x, y)$. Let the sizes of both images be $N_x \times N_y$, then, the mean-squared error is calculated as

$$\mathrm{MSE}[f(x,y),I(x,y)] = \frac{1}{N_x N_y}\sum_{x=0}^{N_x-1}\sum_{y=0}^{N_y-1}[f(x,y)-I(x,y)]^2. \tag{24.55}$$

The structural similarity is calculated as

$$\mathrm{SSIM}[f(x,y),I(x,y)] = \frac{\left(2\mu_f\mu_I+c_1\right)\left(2\sigma_{fI}+c_2\right)}{\left(\mu_f^2+\mu_I^2+c_1\right)\left(\sigma_f^2+\sigma_I^2+c_2\right)}, \tag{24.56}$$

where μ_f, μ_f^2, and μ_I, μ_I^2 are the mean and variance of the imaging picture and reference image, respectively, and σ_{fI} is the covariance between the two images. The values of parameters c_1 and c_2 are $(k_1L)^2$ and $(k_2L)^2$. $k_1 = 0.01$ and $k_2 = 0.03$, where L is the image pixel value and SSIM is the structural similarity.

Application of Mode Methods to Wavefront Correction

Application of Zernike Mode

Ke Xizheng et al. from Xi'an University of Technology studied the detection of optical wavefront distortion using a computationally adaptive plenoptic imaging system (CAPIS) [63]. As shown in Fig. 24.5, the RMS value of the single-order

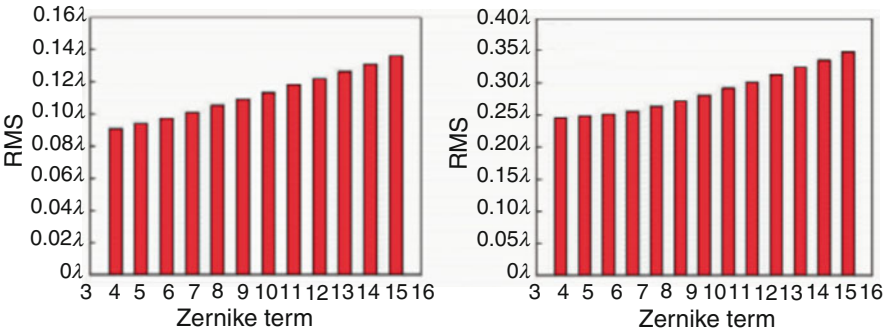

Fig. 24.5 RMS values of Zernike aberration detection results [63]. (**a**) Single-order aberration. (**b**) Combined aberration

aberration reconstruction is smaller and the accuracy is higher, whereas the RMS value of the combined aberrations is larger. It can be concluded that the effect of single-order aberration reconstruction is better than that of combined aberrations.

Ke and Zhang of Xi'an University of Technology designed an adaptive-optics system based on a double-fuzzy adaptive PID control algorithm [92]. Figures 24.6, 24.7, and 24.8 show the distribution curves of the Zernike coefficient values and wavefront PV values after wavefront correction with dual-fuzzy control under different parameters. Figure 24.6a shows the Zernike coefficient value and Fig. 24.6b shows the PV value. Experiments showed that the adaptive dual-fuzzy PID method can effectively correct the wavefront-distortion signal, improve the system response speed, and reduce the parameter-adjustment difficulty.

Application of the Deformable-Mirror Eigenmode Method

Ke and Li of Xi'an University of Technology built a wavefront-sensorless adaptive-optics (WSAO) experimental system based on the deformable-mirror eigenmode method to correct distorted light spots [62]. As shown in Fig. 24.9, after correction, the light spots become more convergent and the energy becomes more concentrated. This system can effectively correct the wavefront distortion caused by dynamic turbulence. As shown in Fig. 24.10, the system converges after six iterations, and the SR value is maintained at approximately 0.85.

Summary

This chapter systematically summarized the research progress on mode methods in the field of adaptive optics at home and abroad, pointed out their research directions, and provided a comparison of the research progress. It included an optical-system wavefront-distortion correction quality-evaluation method and the application of mode methods in wavefront-distortion correction.

It can be seen from the above discussion that the mode method is relatively mature, theoretically, in adaptive optics, and is developing in more directions. Astronomical observations and adaptive-optics system wavefront-distortion corrections are both application scenarios, as is medical human-eye aberration compensation.

In terms of research, methods based on the Zernike mode and deformable mirror eigenmode both exist. The research focus of mode methods is mainly on reducing errors and improving speed and accuracy, which are directly related to the size of the wavefront-distortion correction capability, which in turn affects the performance of the adaptive-optics system; thus, these aspects are still future research directions.

To further optimize the performance of a model-based adaptive optics system, the following adjustments can be made:

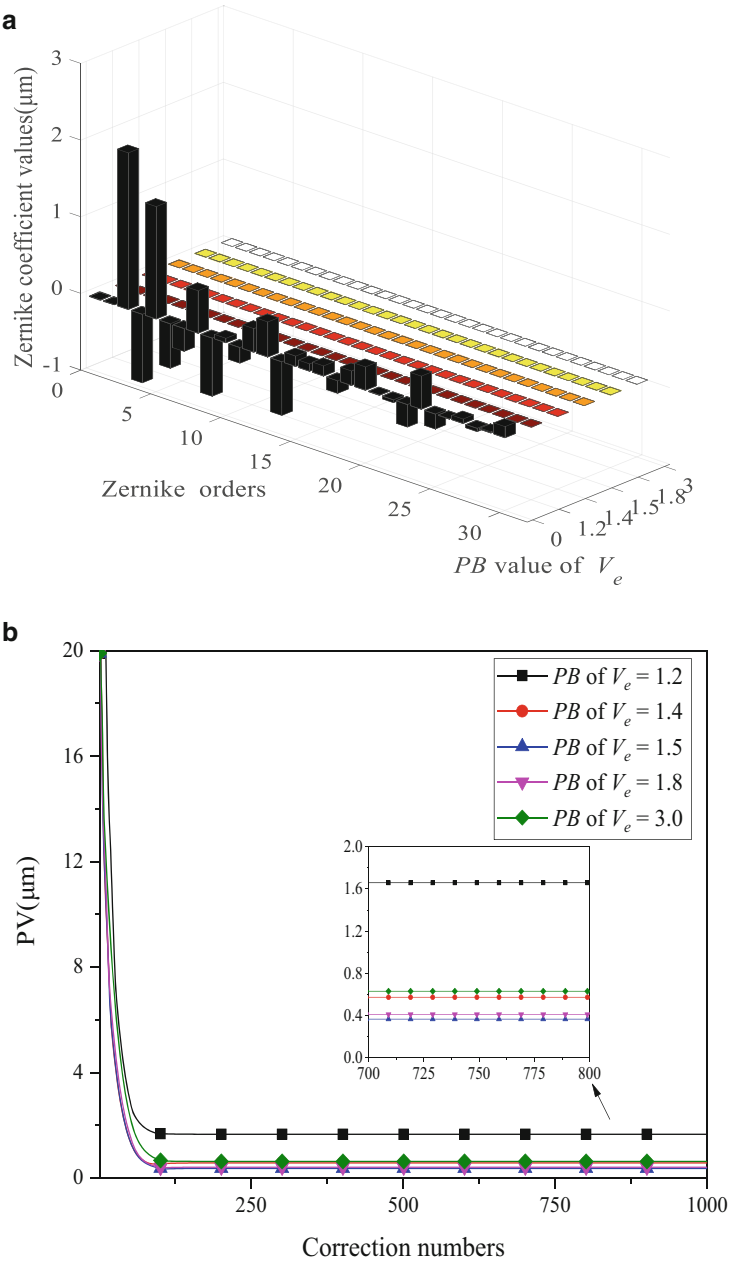

Fig. 24.6 Distribution of the Zernike coefficient value and PV value after correction of different control voltages [92] (**a**) Zernike coefficient values; (**b**) PV values

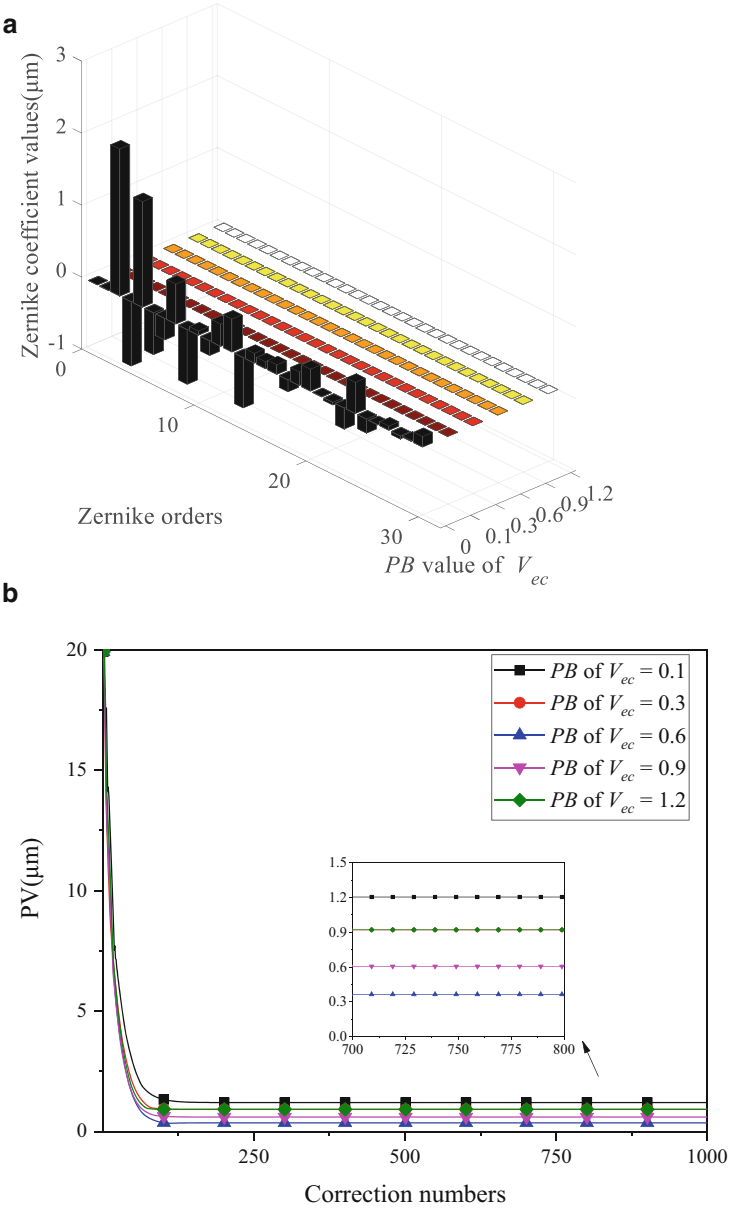

Fig. 24.7 Distribution of the Zernike coefficient value and PV value after correction of the first derivative of different control voltages [92] (**a**) Zernike coefficient values; (**b**) PV values

1. When performing algorithm operations, software programs may require a long time. Hardware, such as digital signal processing (DSP) chips and ARM microprocessors, can be used to reduce the system running time and improve the system performance.
2. A model-free algorithm and a pattern method can be combined, and a new hybrid algorithm can be proposed for specific research.
3. The mode method includes a variety of base modes. Different modes can be applied to a system for research, to analyze the differences in the correction results of different modes, and improve these differences as much as possible.

In recent years, some researchers have used deep-learning techniques (such as residual networks, convolutional neural networks, and attention mechanisms) to obtain Zernike mode coefficients that conform to actual wavefront aberrations, and the obtained mode coefficients have high accuracy. Applying deep-learning technology to adaptive optics is a new research direction; however, the current related research is still insufficient and requires more in-depth study.

Abstract

Wavefront distortion caused by atmospheric turbulence can be described as different types of aberrations, such as piston, tilt, defocusing, astigmatism, coma, etc. Dual-deformable mirrors can have mutual coupling effects that help correct the effects of wavefront distortion. In this study, a fast-steering mirror (FSM) and a deformable mirror (DM) were used to form a dual-deformable-mirror wavefront-correction system, and a decoupling algorithm that could correct any specified aberration was proposed. In this decoupling algorithm, both the FSM and the DM are controlled using the mode method, and specific aberrations are corrected based on a limited matrix. The DM-compensation ability is directly characterized by the mode coefficients of the aberrations; thus, it can independently correct any order of aberration and effectively reduce the coupling effect of the wavefront-correction system. An experiment using an adaptive-optical dual-deformable-mirror wavefront-correction system was conducted to verify the proposed decoupling algorithm. When the FSM corrects the first- and second-order aberrations, and the DM corrects the third-, tenth-, and 25th-order aberrations, the coupling coefficients are approximately 1.117×10^{-3}, 1.824×10^{-2}, and 7.81×10^{-3}, respectively, and the magnitude of the coupling coefficients

Introduction

The woofer–tweeter system is a typical dual-deformable-mirror wavefront-correction system [1] consisting of a large-stroke, low-spatial-frequency deformable mirror (woofer) and a small-stroke, high-spatial-frequency deformable mirror (tweeter). These two deformable mirrors work together to improve wavefront correction.

However, when both deformable mirrors work simultaneously, coupling effects occur, which can waste the correction ability of some deformable mirrors. If this phenomenon cannot be effectively suppressed, coupling errors will gradually accumulate; eventually, the coupling will completely consume the stroke of the deformable mirror. When the aberration to be corrected in the system changes, the deformable mirrors affected by coupling have difficulty effectively compensating for the aberration, leading to a decrease in the system correction ability [2]. Therefore, coupling compensation for deformable mirrors has become an important research direction for dual-deformable-mirror wavefront-correction systems, in terms of aberration-compensation ability and stability.

To fully utilize the advantages of adaptive-optics dual-deformable-mirror wavefront-correction systems, it is crucial to further improve their performance and eliminate the potential coupling between the deformable mirrors. Numerous scholars have addressed this issue, using different approaches proposed over the years. These decoupling algorithms have been successfully applied to various adaptive-optical dual-deformable-mirror wavefront-correction systems, significantly reducing the coupling effects between the mirrors.

Nonetheless, few decoupling algorithms are available for dual-deformable-mirror wavefront-correction systems that combine a fast-steering mirror (FSM) and a deformable mirror (DM), in which each aberration order cannot be independently controlled or corrected. Different application scenarios have varying requirements for different types of aberrations; hence, specific aberrations can be corrected according to the actual requirements to meet the diverse needs of different application scenarios, improve the system performance, and lay the foundation for large-aperture telescope applications.

This article proposes a decoupling algorithm to address the issues associated with the coupling between the FSM and DM in a dual-deformable-mirror wavefront-correction system. The algorithm utilizes the mode method to control both deformable mirrors, with the initial control voltage for the deformable mirror obtained

directly from the Zernike coefficient. The final control voltage of the deformable mirror is then determined using a proportional-integral (PI) controller, enabling the independent correction of any order aberration while avoiding cross-coupling effects. This approach significantly improves the performance and flexibility of the system, and can greatly enhance its capabilities.

Domestic and Foreign Research Progress

In 1990, Jiang et al. proposed a new algorithm based on a direct-slope gradient, derived a control decoupling matrix, and decoupled a deformable-mirror driver by adding appropriate fitting terms. The correctness of the algorithm was verified through computer simulations and experiments [3].

In 2002, Vorontsov et al. proposed a decoupled stochastic parallel gradient-descent optimization algorithm for adaptive optics, which achieved a fast convergence speed by partially decoupling the control channels of the adaptive system. The results showed that the phase distortion could be compensated with only 10–20 iterations [4].

In 2005, Hu et al. proposed a limited correction algorithm that decoupled the aberration of dual-deformable mirrors by solving the extended slope-response matrix of the deformable mirror. The numerical simulation of this algorithm showed that the correction effect of the dual-deformable-mirror adaptive-optical system was better than that of the finite-stroke single-deformable-mirror adaptive-optical system, and it avoided the production of deformable mirrors with both large-stroke and high-spatial-frequency characteristics [5]. Owing to the different response functions of each actuator, in 2009, Hu also proposed a decoupling algorithm based on an actual dual-deformable-mirror adaptive-optical system, verifying the feasibility of decoupling the two deformable mirrors in the system [6].

In 2006, Conan et al. proposed a control method based on distributed-mode decoupling to correct turbulence aberrations that increased with the increase of the telescope aperture. This method analyzed the mathematical characteristics of the influence function of wavefront correctors and solved for a series of distributed modes with good orthogonality between different wavefront correctors. It controlled the wavefront correctors to operate according to these specific modes, thereby suppressing the coupling between them and effectively eliminating coupling errors between different wavefront correctors [7].

In 2008, Zou et al. proposed a regional wavefront-control algorithm that used Lagrange-damping least-squares to suppress the correlation between two deformable mirrors [8].

In 2009, Ye et al. [9] proposed a closed-loop control method for a single-wavefront sensor and multiple deformable mirrors in an adaptive-optical system. It used an aberration-decoupling control algorithm to decompose the wavefront distortion and correct different deformable mirrors. The low-order deformable mirror (19-unit deformable mirror) used the mode method to correct low-order aberrations,

whereas the high-order deformable mirror (127-unit deformable mirror) used the direct-slope method to correct the residual aberrations.

A numerical simulation of the joint closed-loop operation of multiple deformable mirrors was conducted. A tilted mirror was used to correct wavefront tilt aberrations; 19 deformable mirrors were used to correct defocus aberrations; 61 deformable mirrors were used to correct Zernike aberrations before the 20th order, excluding tilt and defocus aberrations; and 127 deformable mirrors were used to correct other higher-order aberrations. The simulation results showed that this method enabled the joint closed-loop operation of multiple deformable mirrors, significantly improving the adaptive-optical correction ability. Multiple experiments were conducted using a dual-deformable-mirror adaptive-optical system. After multiple repeated experiments, the closed-loop working state of the system was stable and the repeatability was good, proving the effectiveness of the method and obtaining good applications in practical systems.

In 2010, Sredar et al. proposed a dual-deformable-mirror decoupling control method based on response-matrix orthogonalization. This method explored the coupling relationship between different deformable-mirror response matrices through mathematical derivation and used a matrix operation to remove the coupling components between the deformable-mirror response matrices, thereby orthogonalizing different deformable-mirror response matrices. This method was applied to a dual-deformable-mirror laser-scanning ophthalmic imaging system to verify its effectiveness [10].

In 2012, Lei et al. proposed a decoupling control algorithm based on mode decomposition. This method used the aberration-mode coefficient as the variable to be optimized and used different-order aberration-mode coefficients to control different deformable mirrors for aberration compensation, thereby decoupling the control of dual-deformable mirrors. The beam quality was better than that obtained using a single-deformable mirror for correction [11].

In 2013, Liu et al. proposed a decoupling control algorithm based on Zernike mode decomposition. The algorithm first decoupled the slope measured by the wavefront sensor using the Zernike mode, and then generated a control vector for the low-order deformable mirror using low-order Zernike coefficients to eliminate the high-order mode. In addition, the control vector of the high-order deformable mirror was reset through the constraint matrix to avoid accumulating coupling errors. Experiments showed that this algorithm effectively compensated for phase distortion and significantly suppressed the coupling between low- and high-order deformable mirrors [12].

In 2014, Li et al. proposed a constraint correction algorithm (CCA) for a combined deformable-mirror adaptive-optics (CDM-AO) system and analyzed its decoupling principle. The calibration results of this system were compared with those of traditional adaptive-optical systems. The simulation results showed that this system corrected different aberrations with different characteristics, had better calibration performance, and eliminated the coupling components of low-order deformable mirrors in high-order deformable mirrors. The coupling efficiency of this system was also analyzed and numerically evaluated, indicating that the algorithm

could improve the coupling efficiency of free-space optical (FSO) communication systems [13].

In 2015, Zhou et al. proposed an algorithm based on dual-deformable-mirror voltage decoupling. This algorithm used inertial components as controllers for low-order deformable mirrors and integral components as controllers for high-order deformable mirrors. Simulations and experimental results showed that this algorithm effectively corrected large-scale low-order aberrations and high-spatial-frequency aberrations in adaptive-optical systems. It significantly improved the correction efficiency, effectively reduced system residuals, and improved the performance of adaptive-optical systems [14].

In 2016, Liu et al. proposed a region-decoupling algorithm for controlling dual-deformable mirrors. The low-order deformable mirror is controlled using traditional slope-based correction methods, whereas the control vector of the high-order deformable mirror is generated by the response matrix of the residual wavefront and then reset through a constraint matrix to avoid coupling with the low-order deformable mirror. By comparing this algorithm with traditional regional-decoupling algorithms through simulations, the results showed that the proposed algorithm effectively suppressed coupling errors. The experimental system verified that this algorithm not only effectively compensated for phase distortion but also suppressed coupling errors and improved the system performance [2].

In 2018, Cheng et al. proposed a slope-based decoupling algorithm to simultaneously control two deformable mirrors in adaptive-optical systems. The basic principle of this algorithm was to directly use a Hartmann wavefront sensor to measure the response matrix of the low-order deformable mirror to construct a slope orthogonal basis. It then selectively allocated significant low-order aberrations to the low-order deformable mirror through the slope orthogonal basis and allocated the remaining aberrations to the high-order deformable mirror. By constructing a constraint matrix based on the response matrix and the slope orthogonal basis of the high-order deformable mirror, the control vector of the high-order deformable mirror was reset. Numerical simulation results showed that this algorithm fully utilized the compensation ability of low-order deformable mirrors, released the stroke of high-order deformable mirrors to compensate for high-order aberrations, and better suppressed coupling errors [15].

In the same year, to verify the effectiveness and practicality of the aforementioned algorithm, Cheng et al. established a typical dual-deformable-mirror adaptive-optical system. Theoretical model simulations were conducted for this system, and the results showed that the algorithm could selectively correct distorted wavefronts of different spatial frequencies for two deformable mirrors, effectively suppressing the cross-coupling between them [16].

In 2018, Cheng et al. proposed a projection-based decoupling algorithm. This algorithm utilized the response matrix of low-order deformable mirrors to construct a slope orthogonal basis and assigned different spatial-frequency aberrations to two deformable mirrors. Moreover, the control-voltage vector of the high-order deformable mirror was projected onto the slope orthogonal basis, and the coupling between the high-order and low-order deformable mirrors was calculated. The high-order

deformable mirror obtained the control-voltage vector after eliminating the coupling effect, thereby suppressing the cross-coupling between the two deformable mirrors. Correction experiments were conducted on static and dynamic aberrations. The results showed that the algorithm could effectively suppress the cross-coupling between the two deformable mirrors [17].

In 2020, Cheng et al. proposed a decoupling control algorithm to apply dual-deformable-mirror adaptive-optical systems to a generalized irregular-pupil region. This algorithm constructed a slope orthogonal basis based on the response matrix measured by the Hartmann sensor, and assigned aberrations of different spatial frequencies to the deformable mirror. It also used the slope orthogonal basis and improved response matrix of the higher-order deformable mirror to construct a constraint matrix to reset the control-voltage vector of the higher-order deformable mirror to remove the coupling effect between the higher-order and lower-order deformable mirrors. Numerical simulations were conducted to validate the algorithm, and showed that it better suppressed the cross-coupling between low-order and high-order deformable mirrors [18].

To solve the collaborative control problem of dual wavefront correctors in generalized irregular-pupil regions, Kong et al. proposed a decoupling control algorithm based on numerical orthogonal polynomials (NOP) in 2021. Through numerical simulations and experiments, it was shown that this algorithm eliminated cross-coupling between dual-wavefront correctors and exhibited better performance [19].

In 2021, Yang et al. used a dual-deformable-mirror combination control for fiber power coupling to improve the efficiency of space optical-fiber coupling [20]. In the same year, Wang et al. proposed a global-decoupling control algorithm to achieve high-precision control of two correctors simultaneously. This algorithm utilized the eigenmode orthogonal basis and response matrix of the deformable mirror to construct a constraint matrix for the two correctors, thereby constructing a global-decoupling control matrix. Numerical simulations showed that this algorithm performed well in simultaneously correcting different spatial-frequency aberrations and suppressing cross-coupling between dual correctors, fully utilizing and improving the correction ability of deformable mirrors [21].

In 2022, Wang et al. proposed an intrinsic-mode wavefront-decoupling algorithm to control the decoupling of dual correctors in liquid-crystal deformable-mirror adaptive-optical systems and prevent the loss of correction ability caused by coupled aberrations. The simulation and experimental results showed that, after correcting 55 intrinsic modes, the root-mean-square of the residual aberration was 0.09 μm. After decoupling correction, the root-mean-square value of the residual aberration decreased by 0.02 μm. At 0.7–0.95 μm, the uncoupled imaging resolution in the visible band was 11.04 μm. After decoupling, the imaging resolution was 9.84 μm, which was approximately 1.1 and one times the diffraction-limit resolution, respectively [22].

In 2023, Liu et al. proposed a dual-deformable-mirror decoupling control method based on pattern-projection suppression, which eliminated the low-order correction components in high-order deformable mirrors through projection suppression, thereby enabling efficient collaboration between the two deformable mirrors. Theoretical analysis and simulation results showed that, compared with traditional

decoupling algorithms for wavefront-sensorless adaptive-optical systems, this decoupling control method had good coupling suppression and aberration correction and high practical engineering value [23].

A summary of the above research progress was made, and the research progress of dual-deformable-mirror decoupling technology is presented in Table 25.1.

Wavefront-Correction Principle with Dual-Deformable Mirrors

Principle of a Dual-Deformable-Mirror Correction System

The working principle of the dual-deformable-mirror correction system is illustrated in Fig. 25.1. The system consists of three parts: a wavefront sensor, wavefront controller, and two wavefront correctors [24]. When a light beam propagates in the atmosphere, the wavefront is distorted by atmospheric turbulence. It is corrected using a wavefront corrector.

In the dual-deformable-mirror correction system used in this study, the wavefront distortion was graded and corrected by two wavefront correctors. Wavefront corrector 1 is generally an FSM or a large-stroke, low-spatial-frequency DM (commonly referred to as a woofer) responsible for correcting low-order aberrations. Wavefront corrector 2 is generally a small-stroke, high-spatial-frequency DM (commonly referred to as a tweeter), which is responsible for correcting high-order aberrations [1].

The system utilizes wavefront sensors to measure the wavefront of the received beam in real time and feeds the measured wavefront information back to the wavefront controller. The controller calculates the control voltage of the wavefront corrector using a control algorithm and provides real-time control signals for the wavefront corrector. The wavefront corrector receives a real-time control voltage from the wavefront controller, fits the surface shape to correct the wavefront distortion, and improves the communication quality of the dual-deformable-mirror wavefront-correction system.

Principle of the Separation Coefficient Algorithm

The distorted wavefront caused by the interference of atmospheric turbulence can be expanded using Zernike polynomials. The expression for wavefront $\phi(\rho)$ is [25, 26]

$$\phi(\rho) = \sum_{i=1}^{\infty} a_i Z_i(\rho), \tag{25.1}$$

where a_i represents the ith-order Zernike coefficient and $Z_i(\rho)$ represents the ith-order Zernike polynomial [26]. This study uses the Zernike polynomial defined by Noll in polar coordinates, whose expression is [27]

Table 25.1 Research progress in dual-deformable-mirror decoupling technology

Year	Scholars	Research progress
1990	Jiang Wenhan et al.	A new algorithm based on a direct-slope gradient was proposed, and a control decoupling matrix was derived to verify the effectiveness of the algorithm
2002	Vorontsov et al.	A decoupled random parallel gradient-descent optimization algorithm for adaptive optics was proposed, which quickly converged
2005	Hu Shijie et al.	A limited correction algorithm was proposed to decouple the aberrations of dual-deformable mirrors by solving the extended slope-response matrix of the deformable mirror
2006	Conan et al.	A control method based on distributed-mode decoupling was proposed, which effectively eliminated coupling errors between different wavefront correctors
2008	Zou Weiyao et al.	A regional wavefront-control algorithm was proposed that utilized the Lagrange-damping least-squares method to suppress the correlation between two deformable mirrors
2009	Hu Shijie et al.	A decoupling algorithm based on an actual dual-deformable-mirror adaptive-optical system was proposed, and the feasibility of decoupling two deformable mirrors in the system was verified
2009	Ye Weihong et al.	A closed-loop control method with a single-wavefront sensor and multiple deformable mirrors for adaptive-optical systems was been proposed; its effectiveness was demonstrated and applied to practical systems
2010	Sredar et al.	A dual-deformable-mirror decoupling control method based on response-matrix orthogonalization was proposed and applied to a dual-deformable-mirror laser-scanning ophthalmic imaging system, and the effectiveness of the method was verified
2012	Lei Xiang et al.	A decoupling control algorithm based on pattern decomposition was proposed to control the decoupling of dual-deformable mirrors; the beam quality was better than using only a single-deformable mirror for correction
2013	Liu Wenjin et al.	A decoupling control algorithm based on Zernike mode decomposition was proposed, which effectively compensated for phase distortion and significantly suppressed the coupling between low-order and high-order deformable mirrors
2014	Li Zhaokun et al.	A constraint-correction algorithm was proposed, which eliminated the coupling components of low-order deformable mirrors in high-order deformable mirrors
2015	Zhou Rui et al.	A voltage-decoupling algorithm based on dual-deformable mirrors was proposed, which significantly improved the correction efficiency, effectively reduced the system residual, and improved the performance of the adaptive-optical system
2016	Liu Wenjin et al.	A region-decoupling algorithm was proposed to control dual-deformable mirrors. This algorithm not only effectively compensated for phase distortion, but also suppressed coupling errors and improved the system performance
2018	Cheng Tao et al.	A slope-based decoupling algorithm was been proposed, which had better performance in suppressing coupling errors

(continued)

Table 25.1 (continued)

Compared with traditional decoupling algorithms for wavefront-sensorless adaptive-optical systems, this decoupling control method had good coupling suppression and aberration correction, and high practical engineering value

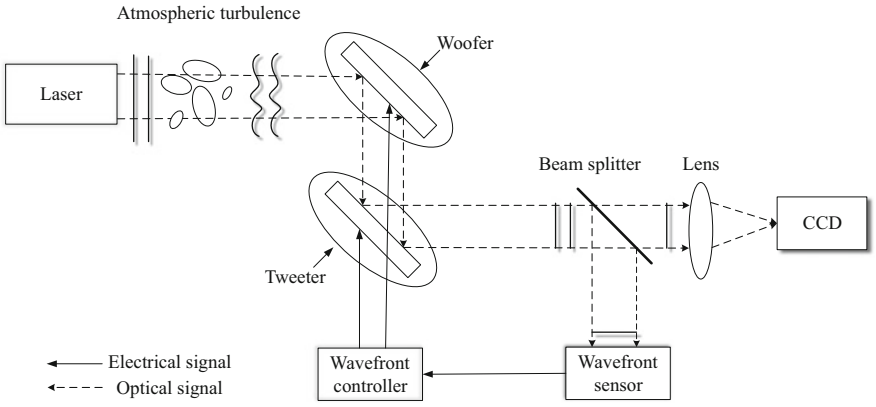

Fig. 25.1 Schematic diagram of a dual-deformable-mirror wavefront-correction system

$$Z_i = \begin{cases} \sqrt{n+1}R_n^m(\rho)\sqrt{2}\cos(m\theta) & m \neq 0 \text{ and } m \text{ is even} \\ \sqrt{n+1}R_n^m(\rho)\sqrt{2}\sin(m\theta) & m \neq 0 \text{ and } m \text{ is odd} \\ \sqrt{n+1}R_n^m(\rho) & m = 0 \end{cases}, \tag{25.2}$$

where (ρ, θ) is the polar coordinate. The integers m and n represent the angular and radial levels, respectively, and the relationship between them is as follows:

$$\begin{cases} m \le n \\ n - |m| = k \quad k \in N \end{cases}. \tag{25.3}$$

The radial polynomial $R_n^m(\rho)$ is defined as [28]

$$R_n^m(\rho) = \sum_{s=0}^{\frac{n-m}{2}} \frac{(-1)^s (n-s)!}{s![(n+m/2)-s]![(n-m/2)-s]!} \rho^{n-2s}. \tag{25.4}$$

The lower-order modes of the Zernike polynomials in the circular domain are consistent with the Seidel aberrations, and the specific expressions for the aberrations represented by the first 15 orders of the Zernike polynomials are listed in Table 25.2.

Assuming that the influence function of the ith actuator of the DM is f_i, it can generally be measured using a Zygo interferometer or wavefront sensor. The jth-order Zernike mode is denoted as Z_j. The cross-correlation matrix C_{fz} between the influence function of the DM and the Zernike modes can be represented as [23]

$$C_{fz}(i,j) = \int f_i(r) Z_j(r) d^2 r. \tag{25.5}$$

Similarly, the expression for calculating the autocorrelation matrix C_{ff} between the influence functions of the DM actuator is as follows [23]:

$$C_{ff}(i,j) = \int f_i(r) f_j(r) d^2 r, \tag{25.6}$$

where C_{ff} is the autocorrelation matrix of the influence functions of the deformable-mirror actuator.

According to Eqs. (25.5) and (25.6), the conversion matrix T from the Zernike mode coefficient to the control voltage of the DM can be obtained as [23]

$$T = C_{ff}(i,j)^{-1} \cdot C_{fz}(i,j), \tag{25.7}$$

where C_{fz} is the cross-correlation matrix obtained from Eq. (25.5). C_{ff} is the autocorrelation matrix obtained from Eq. (25.6). C_{ff}^{-1} is the inverse of matrix C_{ff}; then, the expression of the control voltage to be loaded each time by the DM is [23]

$$v = T \cdot a, \tag{25.8}$$

where $a = [a_1, a_2, \ldots, a_n]^T$, the dimension is $n \times 1$, and n is the order of the Zernike polynomial. T is the transformation matrix between Zernike mode coefficients and

15	(4, −4)	$\sqrt{10}\rho^4\sin 4\theta$	$\sqrt{10}(4xy^3-4x^3y)$	Quatrefoil aberration

DM control voltages. $v = [v_1, v_2, \ldots, v_P]^T$ is the initial control voltage of the DM and P is its number of actuators.

The Shack–Hartmann wavefront sensor (SH-WFS) can measure the slope; its slope matrix is represented as

$$S = Z \cdot a, \tag{25.9}$$

where $S = [S_{x1}, S_{x2}, \ldots, S_{xm}, S_{y1}, S_{y2}, \ldots, S_{ym}]$ is the slope matrix directly measured by the SH-WFS. The dimension is $2m \times 1$ and m is the number of subapertures of the SH-WFS. Z is the wavefront-reconstruction matrix and the dimension is $2m \times n$. $a = [a_1, a_2, \ldots, a_n]^T$, the dimension is $n \times 1$, and n represents the order of the Zernike polynomial.

According to the wavefront-reconstruction principle of the Zernike mode method [29], the Zernike coefficients can be reconstructed using the measured slope S, as follows:

$$a = Z^{+} \cdot S, \tag{25.10}$$

where Z^{+} is the generalized inverse matrix of Z.

The mode-coefficient expression for correcting the aberrations with a low-order DM is as follows:

$$a_w = I_w \cdot a = I_w \cdot Z^{+} \cdot S, \tag{25.11}$$

where $a_w = [a_{w1}, a_{w2}, \ldots, a_{wn}]^T$ is the mode coefficient assigned to the low-order DM for aberration correction. I_w is an $n \times n$ diagonal matrix, which is also known as the limiting matrix for low-order aberrations. For example, if the low-order DM corrects first- and second-order aberrations, the expression for I_w is as follows:

$$I_w = \begin{bmatrix} 1 & & & & & \\ & 1 & & & & \\ & & 0 & & & \\ & & & \cdots & & \\ & & & & 0 & \\ & & & & & 0 \end{bmatrix}. \tag{25.12}$$

Based on Eq. (25.8), the initial control voltage of the low-order DM can be directly calculated. The expression is

$$v_w = T_w \cdot a_w = T_w \cdot I_w \cdot Z^{+} \cdot S, \tag{25.13}$$

where $v_w = [v_{w1}, v_{w2}, \ldots, v_{wh}]^T$ is the final control voltage of the low-order DM, and h is its number of actuators. T_w is the conversion matrix between the Zernike mode coefficient and the control voltage of the low-order DM, as calculated by Eqs. (25.5), (25.6), and (25.7). a_w is the mode coefficient, calculated using Eq. (25.11), that the low-order DM will use to correct aberrations.

After obtaining the initial control voltage of the low-order DM using Eq. (25.13), a PI controller is used to solve the final control voltage of the low-order DM and send it to the low-order DM for operation. To accurately calculate the control voltage of the low-order DM, its final control-voltage expression at time k is

$$V_w(k) = k_{i_w} \cdot V_w(k-1) + k_{p_w} \cdot v_w(k-1), \tag{25.14}$$

where k_{i_w} is the integral-gain coefficient of the PI controller, and k_{p_w} is the proportional-gain coefficient of the PI controller. $V_w(k) = [V_{w1}, V_{w2}, V_{w3}, \ldots, V_{wh}]^T$ $V_{w2}, V_{w3}, \ldots, V_{wh}]^T$ is the final control voltage of the low-order DM and h is its

number of actuators. $v_w(k-1)$ is the previously calculated initial control voltage of the low-order DM.

In addition, the mode-coefficient expression for correcting aberrations in the high-order DM is as follows:

$$a_t = I_t \cdot a = I_t \cdot \mathrm{Z}^{+} \cdot S, \tag{25.15}$$

where $a_t = [a_{t1}, a_{t2}, \ldots, a_{tn}]^T$ is the mode coefficient assigned to the high-order DM for aberration correction. This is the $n \times n$ diagonal matrix, also called the limiting matrix of higher-order aberrations. For example, if a high-order DM only corrects third-order aberrations, the expression for I_t is as follows:

$$I_t = \begin{bmatrix} 0 & & & & & \\ & 0 & & & & \\ & & 1 & & & \\ & & & \cdots & & \\ & & & & 0 & \\ & & & & & 0 \end{bmatrix}. \tag{25.16}$$

According to Eq. (25.8), the initial control voltage of the high-order DM can be directly calculated; its expression is

$$v_t = T_t \cdot a_t = T_t \cdot I_t \cdot \mathrm{Z}^{+} \cdot S, \tag{25.17}$$

where $v_t = [v_{t1}, v_{t2}, \ldots, v_{tt}]^T$ is the final control voltage of the high-order DM, and t is its number of actuators. T_t is the conversion matrix between the Zernike mode coefficient and the high-order DM control voltage, calculated using Eqs. (25.5), (25.6) and (25.7). a_t is the mode coefficient of the high-order DM calculated using Eq. (25.15), which corrects for aberrations.

After obtaining the initial control voltage of the high-order DM using Eq. (25.17), a PI controller is used to solve the final control voltage of the high-order DM and send it to the high-order DM for operation. To accurately calculate the control voltage of the high-order DM, its final control-voltage expression at time k is

$$V_t(k) = k_{i_t} \cdot V_t(k-1) + k_{p_t} \cdot v_t(k-1), \tag{25.18}$$

where k_{i_t} is the integral-gain coefficient of the PI controller, and k_{p_t} is the proportional-gain coefficient of the PI controller. $V_t(k) = [V_{t1}, V_{t2}, V_{t3}, \ldots, V_{tt}]^T$ is the final control voltage of the high-order DM and t is its number of actuators. $v_t(k-1)$ is the initial control voltage of the high-order DM calculated at the previous moment.

Using Eqs. (25.14) and (25.18), the final control voltages of the low-order and high-order DMs can be calculated to obtain the corrected wavefront phase. The corrected wavefront phase is denoted as ϕ^k, and the iterative phase expression after the kth correction is

$$\phi^{k+1} = \phi^k + \left(V_w^k \cdot f_w\right) + \left(V_t^k \cdot f_t\right), \tag{25.19}$$

where f_w is the influence function of the low-order DM, and f_t is the influence function of the high-order DM.

In practical applications, the measurement and calculation of Z, Z^+, T_w, T_t, f_w, and f_t can be completed in advance and saved for future use, allowing for quick and efficient access during the calibration process. This decoupling algorithm not only streamlines the program's performance by reducing its running time and storage space but also significantly enhances the computational efficiency. This decoupling algorithm provides the flexibility to independently correct any order of aberration, while also enabling the independent correction of each order of aberration. This makes it highly adaptable to different types of dual-deformable-mirror systems and enables efficient and accurate wavefront correction for a wide range of applications.

The peak-to-valley (PV) value represents the difference between the maximum and minimum values of the wavefront phase, indicating the maximum level of wavefront-phase defects. However, this approach ignores the proportion of this part of the overall wavefront. Therefore, evaluating the wavefront quality based solely on the PV value is not sufficiently rigorous. However, the root-mean-square (RMS) value focuses more on the overall wavefront-phase information. It reflects the degree of deviation of all the points on the wavefront from their ideal positions. Therefore, combining the PV and RMS values can more accurately represent the wavefront condition.

This study used PV and RMS values to evaluate the level of wavefront distortion [30]. Based on the phase compensation of the two deformable mirrors, the coupling coefficient (c) was used to quantitatively describe the coupling effect of the adaptive-optics dual-deformable-mirror correction system [12]. A c value closer to 0 indicates a smaller coupling effect between the woofer and tweeter, whereas a c value closer to 1 indicates a larger coupling effect.

Numerical Simulation Analysis

Experimental data were analyzed in the laboratory of Xi'an University of Technology to further validate the algorithm proposed in this study. The transmitting end of the data measurement was positioned in Building 5 of Xi'an University of Technology, whereas the receiving end was located in Building 2. The slope data of the wavefront distortion were measured using a Shack–Hartmann wavefront sensor.

According to the wavefront-reconstruction principle [29], the wavefront-reconstruction matrix was inverted and the product of the slope data measured by the Hartmann wavefront sensor was obtained (i.e., Eq. 25.10) to obtain the initial Zernike coefficient of the wavefront distortion, as shown in Fig. 25.2a. Given the Zernike-coefficient value of the wavefront distortion, the phase of the wavefront distortion can be calculated by substituting it into Eq. (25.1), as shown in Fig. 25.2b, which displays the phase diagram of the wavefront distortion.

Next, a dual-deformable-mirror wavefront-correction system consisting of an FSM (woofer) and a 69-unit DM (tweeter) was used to correct the wavefront-

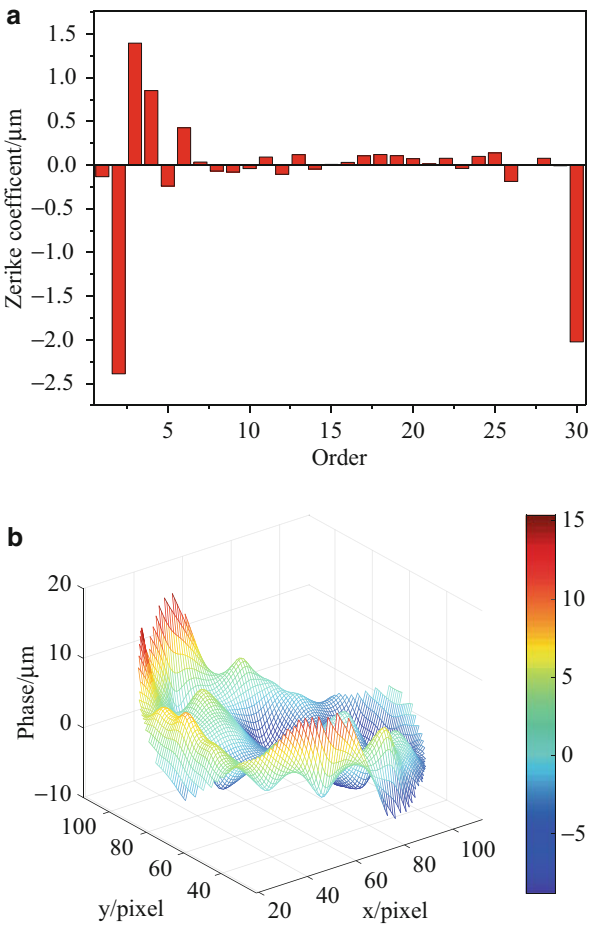

Fig. 25.2 Initial wavefront distortion. (**a**) Zernike coefficient; (**b**) wavefront-distortion phase diagram

distortion data measured in the experiment. The FSM corrected the second-order aberration, the DM corrected the thirtieth-order aberration, and the parameters of the PI controller were set to $k_{i_w} = 0.999$, $k_{p_w} = 0.1$, $k_{i_t} = 0.999$, and $k_{p_t} = 0.1$. Figure 25.3 shows the wavefront-phase diagrams corrected by the FSM and DM, as well as the wavefront-phase diagrams corrected by working together.

Figure 25.3 shows the phase diagrams of the FSM and DM after correcting the aberrations individually and in combination. Specifically, Fig. 25.3a illustrates the wavefront-phase diagram after correction with the FSM, whereas Fig. 25.3b shows the residual wavefront-phase diagram after correction with the DM. Figure 25.3c depicts the residual wavefront-phase diagram after both the FSM and DM were employed for correction.

As shown in Fig. 25.2a, the second- and thirtieth-order aberrations had the largest Zernike coefficients, indicating that they contributed significantly to the total

wavefront aberration. Therefore, the FSM was used to correct the second-order aberration, whereas the DM corrected the thirtieth-order aberration.

By comparing Fig. 25.2b with Fig. 25.3b, it is evident that the tilt degree of the corrected wavefront-distortion phase diagram is minimal, indicating that the residual wavefront after correction has a minimal proportion of tilt aberrations. However, when the DM was used to correct the thirtieth-order aberration without compensating for the second-order aberration, as shown in Fig. 25.3b, there was a degree of tilt in the corrected wavefront-phase diagram. As shown in Fig. 25.3c, there is a significant difference between the corrected wavefront-phase diagram and the initial distorted wavefront-phase diagram. By evaluating the PV and RMS values, it can be concluded that the wavefront-correction ability of the proposed algorithm is accurately reflected, demonstrating that the decoupling algorithm independently corrects the specified aberrations.

In a dual-deformable-mirror wavefront-correction system, the deformation generated by two deformable mirrors is typically used to correct the wavefront aberration. However, when the two deformable mirrors are coupled, their deformations can affect each other, leading to an unwanted coupling effect. To evaluate this effect, the coupling coefficient is employed as an important indicator.

The correction amounts of the FSM and DM were calculated based on the FSM and DM control voltage. By substituting these correction amounts into the coupling-coefficient expression [12], the value of the coupling coefficient between the FSM and DM can be solved.

The coupling-coefficient diagram is presented in Fig. 25.4, where the black line represents the coupling-coefficient curve for second-order aberrations corrected by the FSM and the second- and thirtieth-order aberrations corrected by the DM. It is observed that a coupling effect exists between the two mirrors with a coupling coefficient of about 4.8×10^{-1}, indicating an order of about 10^{-1}.

In the proposed algorithm, a finite matrix was used to constrain the Zernike coefficients. By modifying the elements on the diagonal of the matrix defined by Eqs. (25.12) and (25.16), it was ensured that only the second-order aberration was corrected by the FSM, whereas only the thirtieth-order aberration was corrected by the DM. As shown by the red line, this results in a coupling coefficient value around 10^{-5}, indicating that the algorithm effectively suppressed the coupling effect between the FSM and DM.

Experimental Research

In adaptive-optics systems, the FSM is usually regarded as a special DM that only compensates for tilt aberrations. To verify the importance of the theoretical results, an experimental platform for a dual-deformable-mirror wavefront-correction system was built indoors to correct the wavefront distortion. The experimental setup is illustrated in Fig. 25.5.

The beam was emitted by a 650-nm semiconductor laser and extended and collimated through a 4f system composed of lenses L_1 and L_2. The collimated

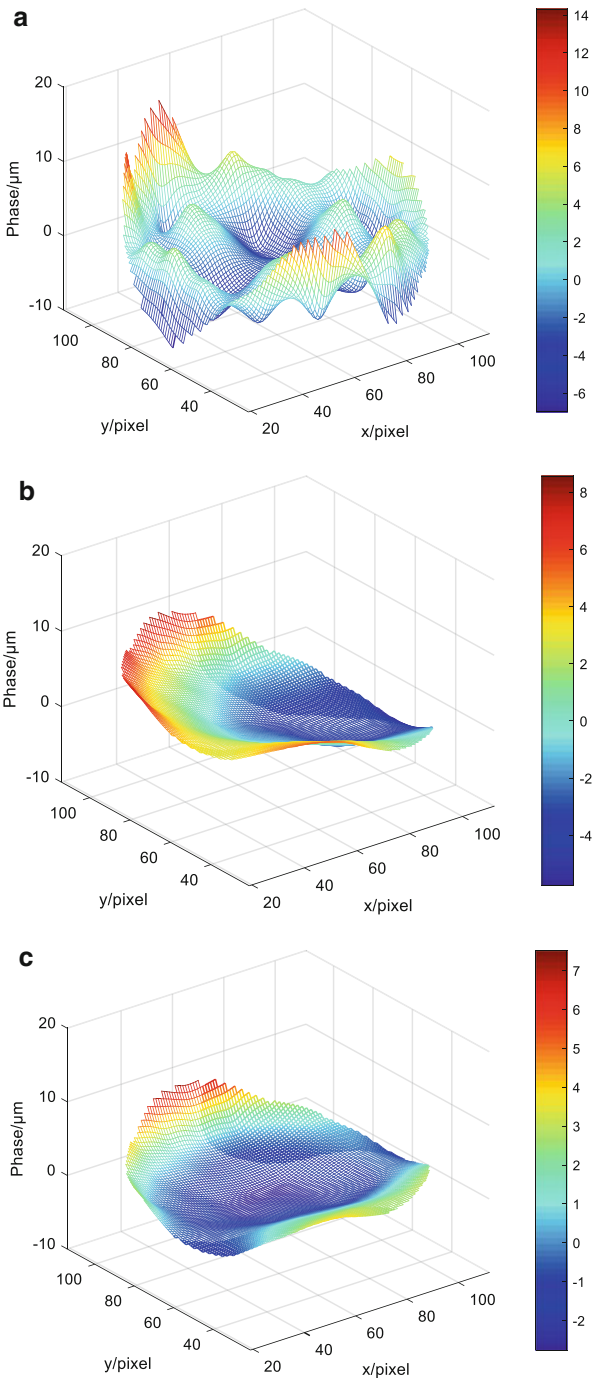

Fig. 25.3 Wavefront-phase diagrams. (**a**) After FSM correction; (**b**) after DM correction; (**c**) after both FSM and DM correction

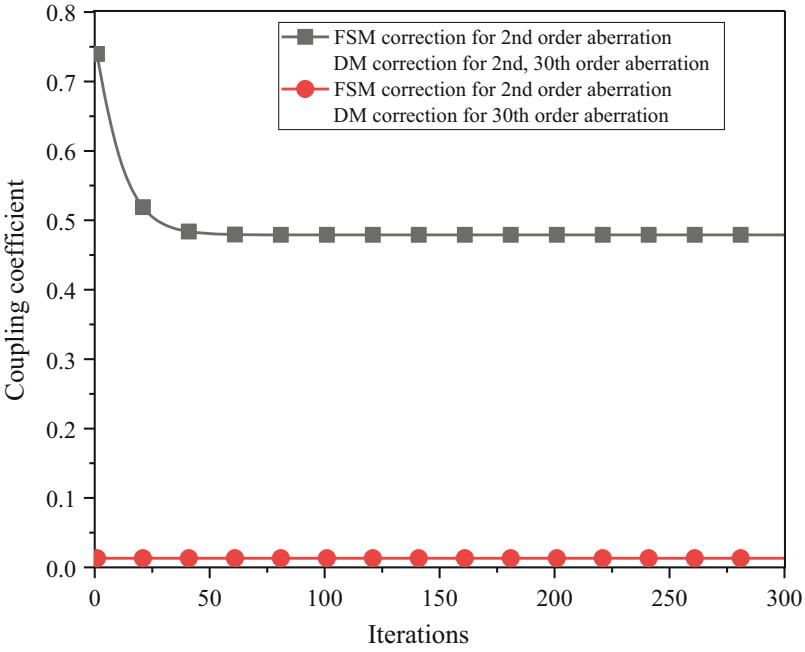

Fig. 25.4 Coupling-coefficient curves between FSM and DM

beam was incident on the surface of the FSM and then on the surface of the DM. The FSM and DM corrected the specified aberrations as needed. The beam corrected by the FSM and DM was incident onto a 4f system composed of lenses L_3 and L_4 for beam reduction.

The wavefront sensor detected the focal point of lens L_4 and transmitted the detected wavefront information to a wavefront controller (computer). The computer calculated the control voltage using an appropriate control algorithm, and sent it to the FSM and DM for closed-loop correction of the distorted wavefront over multiple iterations. This formed a typical adaptive-optics dual-deformable-mirror closed-loop correction system.

According to the experimental diagram shown in Fig. 25.5, the experimental parameters of the PI controller were $k_{i_w} = 0.999$, $k_{p_w} = 0.1$, $k_{i_t} = 0.999$, and $k_{p_t} = 0.1$. The decoupling algorithm studied in this article was used for indoor experiments. Figure 25.6 shows the coupling-coefficient curve between the FSM and DM.

Figure 25.6a presents the coupling-coefficient curve when the FSM corrects only the first- and second-order aberrations, and the DM corrects only the third-order aberrations. The approximate trend of the curve indicates that the coupling coefficient is approximately 1.117×10^{-3}. Figure 25.6b displays the coupling-coefficient curve when the FSM only corrects the first- and second-order aberrations, and the DM only corrects the tenth-order aberrations, with a coupling

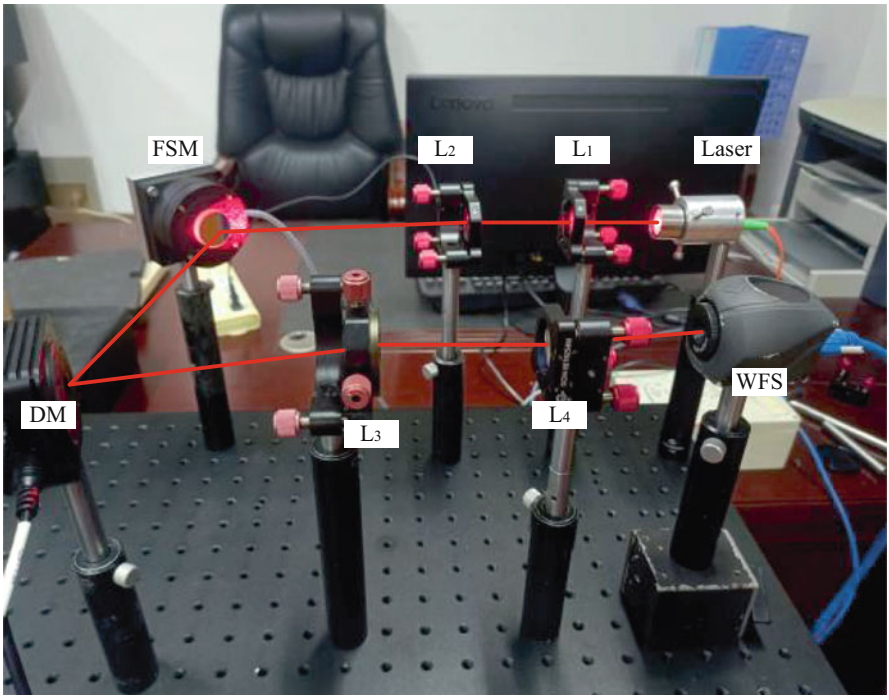

Fig. 25.5 Experimental diagram of a typical adaptive-optics dual-deformable-mirror wavefront-correction system

coefficient of approximately 1.824×10^{-2}. Figure 25.6c shows the coupling-coefficient curve when the FSM only corrects the first- and second-order aberrations, and the DM only corrects the 25th-order aberrations, with a coupling coefficient of approximately 7.81×10^{-3}.

Experiments demonstrated that the decoupling algorithm was effective in suppressing the coupling effect between the FSM and the DM. It performed graded correction of aberrations, selectively allocated any order of aberrations for correction, and independently corrected any order of aberrations. The coupling coefficients reached levels of 10^{-2} and below, effectively suppressing the coupling effect between the FSM and DM.

Coupling Analysis

The coupling coefficient is calculated from the directional cosine of the woofer and tweeter phase compensations. This coefficient represents the degree of correlation between them [31]. Through research, the coupling effect of the dual-deformable-mirror wavefront-correction system can be effectively reduced, independently correcting each order of aberration and any order of aberrations, as well as correcting

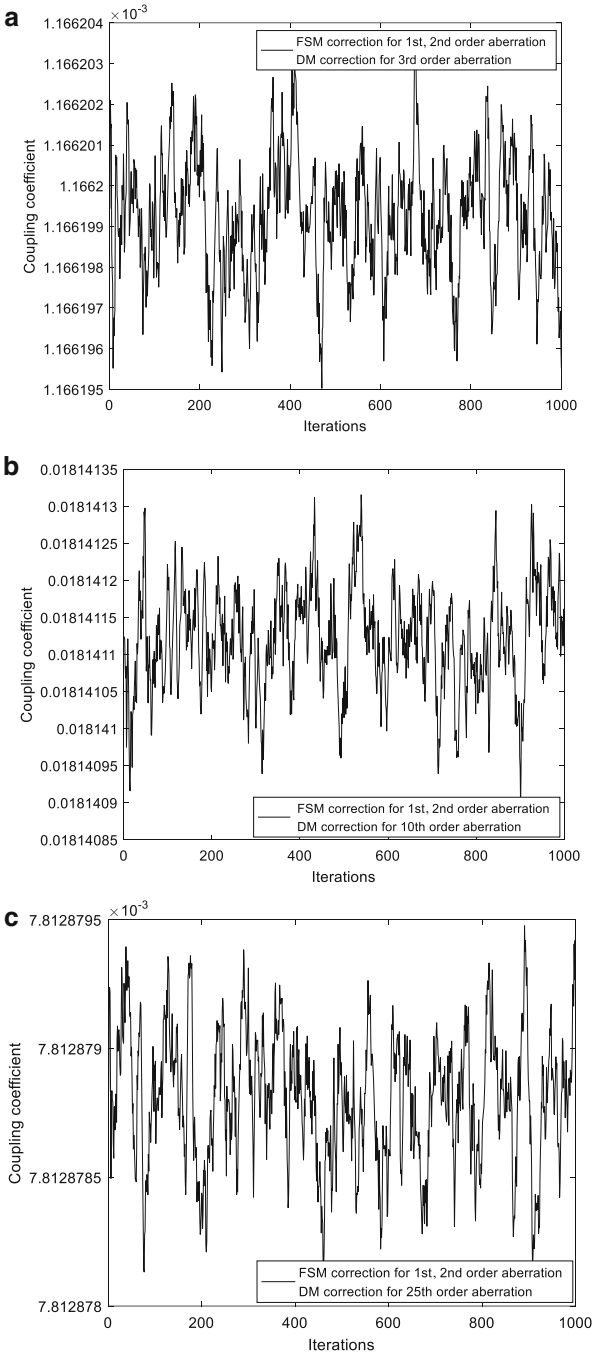

Fig. 25.6 Coupling-coefficient curves between FSM and DM

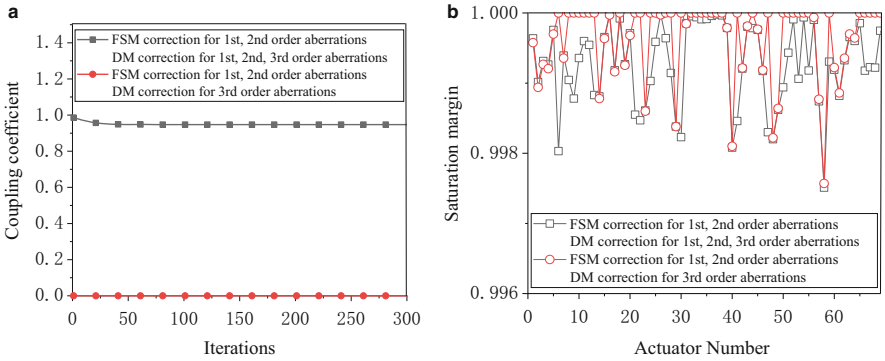

Fig. 25.7 (**a**) Coupling-coefficient curve. (**b**) Saturation margins of DM actuators

specific targeted aberrations in different scenes. This makes the dual-deformable-mirror wavefront-correction system more widely applicable and lays the foundation for its application in large-aperture telescopes.

For example, when correcting third-order aberrations, the mode coefficients of the aberrations are 0.657761 μm, 2.42713 μm, and 0.0423 μm. Figure 25.7 shows the saturation margin of the DM actuator and the coupling-coefficient curve between the FSM and DM.

Figure 25.7a shows the coupling-coefficient curve between the FSM and DM. Figure 25.7b shows the saturation margin of the DM actuator. The black line in Fig. 25.7a represents the coupling-coefficient curve when correcting the first- and second-order aberrations of the FSM and the first-, second-, and third-order aberrations of the DM. The red line represents the coupling-coefficient curve when correcting the first- and second-order aberrations of the FSM and the third-order aberration of the DM.

The black line in Fig. 25.7b represents the saturation margin of the DM actuator, which corresponds to the black line shown in Fig. 25.7a. The red line represents the saturation margin of the DM actuator, which corresponds to the red line in Fig. 25.7a. As indicated by the black line in Fig. 25.7b, the saturation margin of some of the DM actuators decreases rapidly, which reduces the ability to correct aberrations and affects the correction of higher-order aberrations. This seriously affects the stroke of the DM actuator, resulting in wasted resources and increased costs. Therefore, a decoupling study of the dual-deformable-mirror wavefront-correction system is crucial.

Conclusion

In this study, a decoupling algorithm was proposed for a dual-deformable-mirror wavefront-correction system. The algorithm utilized Zernike coefficients to directly represent the compensating ability of the deformable mirror and enabled the

independent correction of each order of aberration. Based on the expression for the coupling coefficient in a typical dual-deformable-mirror wavefront-correction system, this study analyzed the coupling effect of correcting different aberrations and drew the following conclusions:

1. A typical dual-deformable-mirror wavefront-correction system can independently correct various orders of aberrations as well as specific targeted aberrations in different scenes, thereby effectively suppressing the coupling effect between deformable mirrors.
2. The algorithm proposed in this study is simple and feasible, and was verified to be applicable to a dual-deformable-mirror wavefront-correction system with a wavefront sensor. This study has great practical significance in engineering and provides an important reference for practical applications.

Abstract

Phase-locked loop (PLL) plays an important role in wireless communication navigation, radar, and other fields. It affects the data processing rate of the whole system and the extraction of clock phase information. The optical phase-locked loop (OPLL) has the advantages of high-speed real-time reception, low power consumption, and strong ability to resist background light interference and Doppler frequency shift, and is the key circuit module of coherent optical communication system. Its performance directly affects the performance of optical communication system. The research of optical phase-locked loop is mainly aimed at optimizing and improving its parameters. This chapter reviews

the research progress of the technology from electric phase-locked loop to optical phase-locked loop. Based on an introduction to the principle and key components, the classification and parameters of the electric phase-locked loop and optical phase-locked loop are introduced in detail, and the performance of various optical phase-locked loops is compared. This chapter summarizes the optical phase-locked loop technology in wireless coherent optical communication systems, and finally prospects its future development direction, which can provide reference for the research and development of phase-locked loop technology in different fields.

Keywords

Wireless communication · Optical communication · Coherent optical communication · Phase-locked loop

Introduction

Traditional phase-locked loop technology was first applied in receiving systems for wireless communication. The clock phase is extracted from the received signal, and the local clock and the received-signal clock are synchronized through feedback control [1]. Optical phase-locked loop (OPLL) technology originated from coherent optical communication systems [2, 3]. Compared with the intensity modulation/direct detection (IM/DD) communication mode in an optical communication system, the sensitivity of coherent communication can be improved by 20 dB to 23 dB.

Coherent detection is the best solution for achieving high system sensitivity and suppressing out-of-band noise [4]. Coherent optical communication can be divided into homodyne and heterodyne coherent reception, depending on whether the frequencies of the signal light and local light are consistent. The sensitivity of homodyne coherent reception is 3 dB higher than that of heterodyne reception [5].

In homodyne coherent reception, the phases of the signal light and the local oscillator light should be strictly synchronized, which requires the communication system to be able to control the laser frequency. As a closed-loop optical-band control system [6], an optical phase-locked loop can match the phases of two beams of light; thus, an optical phase-locked loop becomes the core technology of a coherent receiver.

Development of Phase-Locked Loops

Development of Electric Phase-Locked Loops

In 1665, Huygens [7] proposed the concept of a synchronous oscillator by observing the spontaneous weak coupling of a pendulum. This was the first concept of phase-locking. Limited by the level of scientific and technological development at that time, the academic community did not focus on the concept of phase-locking.

In 1919, Vincent and Appleton [8] discussed the phase-locking concept in the literature and proposed a method to synchronize oscillators. In the 1930s, radio technology was in the early development stages and some mathematical theories of phase-locked loops appeared [9]. In 1932, French De Bellescize [10] published the theory of synchronous detection; then, he provided a mathematical description of a phase-locked loop, and applied it to synchronous detection.

In 1940, researchers first applied phase-locked loops (PLL) to television sets [11]; they effectively suppressed the screen jitter caused by external noise interference, improved image-synchronization performance, and made TV pictures clearer. By 1947, phase-locked loop technology was widely used in TV horizontal synchronous circuits [12].

In the 1950s, Jaffe and Rechtin [13] applied phase-locked loop technology in a missile-tracking filter device and theoretically analyzed the phase-locked loop, including the noise effect. The Soviet Union launched the first artificial earth satellite in 1957, and phase-locked loop technology was first applied in this field, opening the human space era [14]. In 1965, an analog-integrated phase-locked loop [15] was developed using analog-circuit technology, which greatly reduced the cost of phase-locked loop circuits.

In the 1970s, phase-locked loops appeared in digital–analog hybrid systems [16]. Some circuits in the loop structure were digitized, whereas the rest were still composed of analog circuits. The charge-pump phase-locked loop (CPPLL) proposed by Gardner [17] in 1980 is a typical digital–analog hybrid phase-locked loop. In 1988, Johnson et al. [18] designed a phase-locked loop structure based on a CMOS voltage-control delay, which dynamically adjusted the clock period, improved the loop stability, and enhanced the anti-noise performance of the system as a whole.

In 1993, Riley [19] proposed a fractional frequency-division phase-locked loop structure to improve the accuracy of the output frequency. This fractional frequency division was achieved using a Δ-Σ accumulator modulator. With the development of digital circuits, in 2003, Staszewski [16] proposed the structure of an all-digital phase-locked loop (ADPLL). In the twenty-first century, with the development of electronic communication, the structure of phase-locked loops has improved from single loops to composite loops, and has been developing toward low power consumption, high frequency, and wide range.

Development of Optical Phase-Locked Loops

Since Enlog et al. [20] first used a He–Ne laser to perform laser phase-locked experiments in 1964, many structural implementation schemes have been developed for optical phase-locked loops; for example, researchers have successfully conducted homodyne and heterodyne phase-locked laser experiments, and phase-locked experiments with distributed Bragg reflection lasers.

In 1977, Mengali et al. [21] analyzed the performance of an optical phase-locked loop driven by a photodetector current in an optical receiver and analyzed the loop-tracking characteristics of pulse-amplitude modulation and sine-wave modulation.

In 1983, Steele [22] designed a heterodyne optical phase-locked loop structure based on GaAlAs semiconductor lasers. The experimental results showed that the locking range of the optical phase-locked loop reached 40 MHz.

From 1985 to 1986, Kazovsky [23, 24] researched various types of optical phase-locked loops, including heterodyne decision-driven, homodyne balanced-detection, and homodyne decision-driven phase-locked loops.

In 1989, Germany launched a solid-state laser communication system (SOLACOS) [25] that used the Costas optical phase-locked loop as the terminal model to realize one-way communication between low-orbit satellites and synchronous-orbit satellites.

In 1990, the European Space Agency (ESA) demonstrated simulated space experiments using a coherent-reception terminal with the Costas loop, based on binary phase-shift keying (BPSK) modulation with a transmission rate of 140 Mbit/s [26].

In 1990, Kazovsky et al. [27] conducted a coherent-reception experiment on a balanced optical phase-locked loop using a Nd:YAG laser. The sensitivity of the receiver was 25 photons/bit when the phase-shift keying homodyne transmission rate was 140 Mbit/s, and 332 photons/bit when the transmission rate was 2 Gbit/s. In the same year, Kahn et al. [28] used an external-cavity semiconductor laser to conduct an experiment on a BPSK homodyne balanced phase-locked loop system. The receiver sensitivity was 83 photons/bit when the transmission rate was 4 Gbit/s.

Schopflin et al. [29] conducted an experimental coherent-reception study based on a Costas phase-locked loop. The experimental results showed that the sensitivity could reach 11 photons/bit at a communication rate of 140 Mbit/s and 21 photons/bit at 565 Mbit/s. Norimatus et al. [30, 31] carried out an experiment based on a Costas phase-locked loop receiver. When the transmission rate was 5 Gbit/s, the measured sensitivity was 93 photons/bit. They then carried out an experimental study on a decision-driven phase-locked loop. When the transmission rate was 10 Gbit/s, the corresponding sensitivity was 297 photons/bit.

Before modulating the data signal, Wandemoth [32] added a zero-bit signal as the synchronization bit every eight bits, thus improving the structure of the optical phase-locked loop and obtaining a synchronization-bit phase-locked loop. The sensitivity measured in the experiment was 20 photons/bit when the communication rate was 565 Mbit/s. As shown in Table 26.1, a relationship between the communication bandwidth and coherent-detection sensitivity has been experimentally proven.

In 1991, Bopp et al. [33] used a receiver based on a Nd:YAG solid laser to conduct a communication experiment using BPSK zero-difference detection and differential phase-shift keying (DPSK) modulation based on a Costas phase-locked loop. The communication rate reached 600 Mbit/s.

In 1992, Hornbachner et al. [34] used a Costas phase-locked loop to conduct a phase-synchronization experiment between the input signal and the local optical signal. Compared to the limitation of ideal shot noise, the sensitivity of the receiver was improved by 5.9 dB.

In 1995 and 1996, Wang et al. [35, 36] successively carried out long-distance communication experiments based on homodyne balanced and homodyne Costas

Table 26.1 Various homodyne coherent-detection experiments based on optical phase-locked loops

Year	Author	Type of optical phase-locked loop	Communication rate	Detection sensitivity (photons/bit)
1990	Kazovsky	Balanced loop	140 Mbit/s 2 Gbit/s	25 332
1990	Kahn	Balanced loop	4 Gbit/s	83
1990	Schopflin	Costas loop	140 Mbit/s 565 Mbit/s	11 21
1990	Norimatus	Costas loop Decision-driven loop	5 Gbit/s 10 Gbit/s	93 297
1991	Wandemoth	SyncBit loop	565 Mbit/s	20
1992	Hornbachner	Costas loop	140 Mbit/s	28
2005	Herzog	Third-order dither loop	400 Mbit/s	36

loops, and theoretically analyzed the performance of an optical amplifier in an optical phase-locked loop system under the effect of noise.

In 1996, the European Space Agency implemented a new generation of inter-satellite coherent optical communication projects called short-range optical inter-satellite links (SROIL) [37]. The receiver used BPSK homodyne coherent-detection technology as the modulation mode. When the transmission distance was 4000 km, the transmission rate of the receiver was 1.5 Gbit/s, and the measured bit-error rate was approximately 10^{-9}. The project also carried out medium-long distance inter-satellite laser communication experiments, and the receiver used BPSK homodyne coherence technology. When the transmission distance was 6000 km, the measured transmission rate was 6.5 Gbit/s.

In 1999, Djordjevic [38] studied an optical heterodyne system based on phase-shift keying (PSK) and a Costas phase-locked loop for multichannel frequency-division multiplexing. In 1999, Kudielka and Klaus [39] designed an optical phase-locked loop receiver that combined the advantages of synchronous bit and residual carriers. The receiver did not require complex electronic equipment or a special modulation circuit for the transmitter.

In 2002, the Deutsche Zentrum für Luft- und Raumfahrt (DLR) and TESAT jointly launched a laser communication terminal for the SAR-X (LCTSX) project. This project used a Costas optical phase-locked loop homodyne coherent-optical communication system with a laser wavelength of 1064 nm [40]. The error rate of the system was approximately 10^{-9}.

In 2004, Camatel et al. [41] proposed a subcarrier optical phase-locked loop to improve a decision-driven phase-locked loop, which was implemented based on external modulation.

In 2005, Smutny et al. [42] investigated Costas phase-locked loop receiving technology with BPSK modulation on a communication optical terminal. They achieved a transmission rate of 6.75 Gbit/s, with a 6000-km transmission distance, and a measured bit-error rate of 10^{-8}.

In 2005, Herzog et al. [43] investigated a third-order oscillatory optical phase-locked loop supported by the ESA project. The experimental results showed that the communication rate was 400 Mbit/s and the reception sensitivity reached 36 photons/bit.

In 2005, Zhang et al. [44] introduced a control system to correct the laser phase in optical phase locking, locked the phases between the independent elements of the array laser, and effectively suppressed the laser-phase noise.

In 2006, Camatel et al. [45] used a subcarrier optical phase-locked loop to detect the zero-difference coherence of amplitude shift keying (ASK) and phase-shift keying (PSK) modulated signals. They tested the coherent communication between ASK and PSK at a transmission rate of 2.5 Gbit/s using a 10-Gbit/s PSK transmission system.

In 2006, the German TESAT Research Center launched a plan to establish a low-earth orbit (LEO) to geosynchronous earth orbit (GEO) inter-satellite laser link with a transmission rate of 2 Gbit/s using BPSK-modulation homodyne coherent-detection technology. The link was further extended to GEO–GEO and GEO–ground laser links [46, 47], which had transmissions rate of up to 2 Gbit/s.

In 2006, the National Intelligence and Communications Institute of Technology (NICT) of Japan developed a real-time coherent receiver model [48]. The front end of the receiver included a 90° optical hybrid, two tunable lasers, and two balanced optical detectors. The system demodulated coherent optical signals at a rate of 3 Gbit/s.

In 2007, Yariv et al. [49] proposed a new control system consisting of a multistage optical phase-locked loop to control the beam frequency and phase, and locked the phases of two 1064-nm semiconductor lasers.

In 2007, the German TerraSAR-x satellite LCTSX orbited the Earth at a polar orbit of 514.8 km. LCTSX adopted an optical coherent receiver based on a homodyne BPSK optical phase-locked loop [50] with a data-transmission rate of 5.5 Gbit/s.

In 2007, Zhang et al. [51] proposed a new optical phase-locked loop mechanism for clock extraction. It was based on the four-wave mixing effect of an electric absorption modulator (EAM). It was experimentally determined that the system could extract the clock information of a 40/80 Gbit/s optical time-division multiplexing optical-data signal.

In 2007, Quan et al. [52] established a new type of optical phase-locked loop, which was based on the four-wave mixing effect of a voltage-controlled optical pulse source and an optical fiber; the extinction ratio of the phase detector was greater than 30 dB.

In 2008, Camatel et al. [53] built a subcarrier optical phase-locked loop homodyne receiver based on BPSK modulation, and demonstrated a nonlinear-subcarrier optical phase-locked loop based on a decision-drive scheme. The performance of the decision-driven receiver was 3 dB better than that of the pilot-carrier receiver based on 8B/10B coding.

In 2008, the United States' Near Field Infrared Experience (NFIRE) satellite and Germany's TerraSAR-X satellite completed a LEO–LEO inter-satellite communication test. The system had a communication rate of 5.625 Gbit/s and used a BPSK-

modulation Costas phase-locked loop homodyne-detection structure [50]. Since then, the NFIRE satellite of the United States conducted a satellite–ground laser-communication link with a European ground station, with a communication rate of 5.625 Gbit/s, which was the first satellite–ground coherent-laser link test in the world [54].

In 2009, Ristic et al. [55] successfully integrated the core of an optical phase-locked loop using photonic integrated-circuit technology. In 2009, optical inter-satellite communication based on the TESAT laser communication terminal (LCT) in Europe operated on a LEO satellite for more than 2 years [56]. The communication terminal used a modulation scheme based on homodyne BPSK and achieved a bit-error rate of 10^{-9} at a full-duplex data rate of 5.625 Gbit/s. LCT not only shows its characteristics in LEO–LEO inter-satellite links but can also be used in LEO–ground link communication to study the propagation of beams in the atmosphere.

In 2009, Xu et al. [57] proposed a balanced homodyne receiver using Costas-loop feedback to detect weak coherent states and used an experimental BPSK-modulation device to conduct an optical carrier phase-tracking experiment.

In 2009, Wang [58] studied a coherent-optical communication homodyne BPSK system, completed an efficient optical homodyne detection and communication signal-demodulation experiment, and analyzed the noise performance of balanced and decision-feedback optical phase-locked loops. To reduce the phase difference between the signal light and the local oscillator light caused by phase noise, the optical phase-locked loop needs a larger bandwidth, but the larger the loop bandwidth, the greater the noise. In addition, shot noise will bring additional phase-locked errors.

In 2010, Steed et al. [59] studied a tunable coherent terahertz source based on a hybrid-integrated optical phase-locked loop. The system had the potential to generate signals up to 1.8 THz, the linewidth of the heterodyne signal between the lasers was less than 1 kHz, and the offset frequency was less than −80 dBc/Hz when the phase noise was at 10 kHz.

In 2010, Yariv et al. [60] researched composite phase-locked technology based on distributed-feedback (DFB) lasers, using optical phase modulators to expand the bandwidth of the loop and reduce residual phase errors. This experiment improved the coherence between master and slave lasers in an optical phase-locked loop.

In 2010, Sakamoto et al. [61] proposed a new structure for a digital Costas optical phase-locked loop, based on a subcarrier optical phase-locked loop, to realize the real-time homodyne demodulation of BPSK signals with a transmission rate of 40 Gbit/s.

In 2010, Du [62] analyzed optical phase-locked loop technology and backward phase-synchronization and correction technology, based on frequency-offset extraction, and adopted this technology to keep the quadrature-in-phase branch signal strictly orthogonal, thus eliminating phase noise at the transmitter.

In 2011, the NICT of Japan designed optical-injection phase-locked loop technology. The phase-locked loop used the structure of the Costas phase-locked loop [63]. The experiment showed that when the signal laser frequency changed more

than 9 GHz at a frequency-deviation rate of up to 1 Hz, the 10 Gbit/s BPSK link successfully maintained a stable frequency and a phase-locked state, meeting the requirements of LEO-to-optical-ground-station coherent links.

In 2011, the Japan Aerospace Exploration Agency (JAXA) [64] designed a homodyne coherent receiving terminal based on BPSK modulation, which was applied in a laser-link experiment between GEO and LEO satellites in a geosynchronous orbit. The transmission rate was up to 2.5 Gbit/s, and the demodulation sensitivity was measured to be −49.1 dBm when the initial frequency offset was ±7.5 GHz.

In 2011, Steed et al. [65] conducted a heterodyne optical phase-locked loop experiment. They used a custom-designed feedback circuit to lock the phase noise of a heterodyne signal between two lasers with a 1553-nm emission wavelength and 1.1-MHz linewidth below −90 dBc/Hz and a frequency offset greater than 20 kHz. The variance of the phase error was 0.04 rad^2 in a 10-GHz bandwidth.

In 2011, Qiu [66] carried out a theoretical analysis and mathematical modeling experiments on a Costas optical phase-locked loop and studied the loop-stability problem. The results showed that with an increase in the loop-damping coefficient, the loop-acquisition speed would be accelerated. When the damping coefficient was 0.64, the maximum value of the normalized oscillation frequency was 0.74. In this case, the loop stability was the best.

In 2011, Ding [67] designed an optical phase-locked loop system based on a ring laser. Through simulation analysis, it was found that when the total gain of the loop was 2.7 MHz, the system could lock the phase for a short time. The locking time was generally a few seconds, with a minimum of approximately 1 s.

In 2012, Park et al. [68] established a highly integrated 40-Gbit/s coherent-optical receiver based on a Costas phase-locked loop structure and experimentally achieved a 1.1-GHz loop bandwidth and 120-ps loop delay. In 2012, Lu et al. [69] first proposed a highly integrated optical phase-locked loop with a phase/frequency detector and a single sideband mixer and measured its loop bandwidth up to 400 MHz.

In 2012, Mizutori et al. [70] implemented a 12.5-Gbit/s BPSK zero-difference decision-drive loop experiment with a 3-kHz linewidth outer-cavity semiconductor laser. The performance of this phase-locked loop enabled the sensitivity of the receiver to match that of a digital coherent receiver.

In 2012, Xu [71] designed a fully digital optical phase-locked system with a feedback control circuit for an atomic interferometer using an external-cavity semiconductor laser. The phase-locked loop achieved a loop bandwidth of 570 kHz and a residual phase variance of 0.14 rad^2.

In 2012, Peng et al. [72] used an optical phase-locking method to track the frequency of two semiconductor DFB lasers with a 1550-nm wavelength. The frequency difference between the master and slave lasers was constant at 11 GHz.

In 2013, JAXA studied a homodyne coherent-optical receiving system based on a BPSK Costas ring. The receiver also had good stability in the presence of a ±7.5-GHz doppler-frequency shift and successfully established a GEO–LEO data link

with a transmission rate of 7.2 Gbit/s [73]. The measured bit-error rate was 10^{-6} and the sensitivity was −43 dBm.

In 2013, Ding et al. [74] studied an optical phase-locked loop device for locking the frequency of coherent lasers. In the experiment, when the beat signal was 6.834 GHz, it had a bandwidth of −3 dB at 1 Hz.

In 2013, Meng et al. [75] designed an optical phase-locked loop using a digital phase-locked loop chip with a frequency-locking bandwidth of 1–7 GHz. In the experiment, the magnitude of the beat-signal noise was reduced from megahertz to hertz.

In 2014, Balakier et al. [76] investigated the properties and performance of an integrated balanced optical phase-locked loop used to generate tunable millimeter/THz waves, such as tunability and long-term frequency locking.

In 2014, Shi et al. [77] conducted an experiment with a Costas optical phase-locked loop with a transmission rate of 5 Gbit/s BPSK and measured a sensitivity of −41.4 dBm when the bit-error rate was 10^{-9}.

In 2014, Yue [78] conducted an experiment on a homodyne coherent-optical communication system with a balanced phase-locked loop. When the communication rate was 1.25 Gbit/s, the measured communication sensitivity was −51 dBm and the error rate was 9.72×10^{-5}.

In 2015, Koga et al. [79] studied a Costas-ring homodyne receiver with a 20-Gbit/s communication rate and quadrature phase-shift keying (QPSK) modulation mode, based on the concept of an optical synchronization network.

In 2015, Zhang et al. [80] designed a digital optical phase-locked system based on a Costas loop. When the frequency-difference range was within 140 MHz, the lock-in time could reach 1 h. A tracking experiment was conducted with a 20-MHz/s Doppler frequency shift.

In 2015, Jiang [81] proposed a heterodyne optical phase-locked loop based on the internal modulation of ultra-narrow linewidth lasers, and a phase-locking experiment of 100-μW strong light and 10-nW weak light for 10 h was successfully conducted.

In 2016, Wang et al. [82] designed an optical phase-locked loop with a frequency discrimination and control subsystem. The experimental results showed that the optical phase-locked loop locked the phase within 0.2 ms, and accurately tracked the sinusoidal phase jitter with an amplitude of $\pm\pi/2$ at a 1-kHz jitter frequency.

In 2016, Ma et al. [83] designed an optical phase-locked loop circuit based on an ADF41020 phase-locked loop chip to lock two laser beams with frequency differences ranging from 4 to 18 GHz.

In 2017, Wang et al. [84] demonstrated a method based on a balanced phase-locked loop for fast laser-frequency acquisition and conducted a phase-locked experiment with a large initial-frequency difference. When the frequency acquisition range was 164 MHz, the measured acquisition and locking time was 440 ms.

In 2017, Chang et al. [85] conducted research on optical phase-locked loop technology for inter-satellite high-speed coherent laser communication. When using BPSK for modulation, when the transmission rate was 5 Gbit/s, the measured sensitivity reached −41.4 dBm, and the receiver error rate was 10^{-7}.

In 2017, Zhou et al. [86] designed a coherent receiver based on a Costas optical locking ring with an auxiliary acquisition and locking circuit. It compensated for the Doppler shift caused by the relative motion of satellites in real time. The sensitivity of the receiver was -39.5 dBm and the bit-error rate was 10^{-9} when the communication rate was 10 Gbit/s. In 2018, they [87] further proposed the structure of a Costas covariance coherent receiver with 90° mixed signals in space optics. The results showed that the sensitivity of the Costas coherent receiver with an optimal signal power-distribution ratio was close to the ScatterNet noise limit.

In 2018, Ashtiani et al. [88] studied a high-resolution optical-frequency synthesizer with an integrated electro-optical phase-locked loop. It could generate optical signals with a subhertz-tuned resolution of 192 THz, within the range of 5 THz, with a coarse-tuned resolution of 20 MHz and a fine-tuned resolution of 1 Hz.

In 2018, Wang et al. [89] added an adjustable advanced phase-shifting circuit and adjustable-gain unit into the single-loop feedback loop of the optical phase-locked loop. They determined that the residual phase noise of the optical phase-locked loop was as low as 0.012 rad^2, which can reduce the laser linewidth from 2 MHz to 10 kHz.

In 2018, Liu et al. [90] simulated the phase-locking process of an optical phase-locked loop by building a BPSK zero-difference coherent-optical communication system model. The results showed that the Costas optical phase-locked loop could lock the phase of the signal light to approximately 1 μs when the frequency difference was less than 50 MHz.

In 2018, Yue et al. [91] adopted an improved Costas optical phase-locked loop and a digital control algorithm to suppress the phase error and track the Doppler shift to realize zero-error detection. The experimental results showed that the receiver-sensitivity loss caused by the phase error was approximately 1 dB. The receiver could track the Doppler shift at 100 MHz/s.

In 2019, Tao [92] established a pulse-laser balanced phase-locked loop model, based on broadband-laser phase-locked technology, and analyzed that the loop-capture frequency band could reach 120 MHz. They then built a loop experimental platform and measured the loop delay as only 1.2 ns; the loop bandwidth reached 40 MHz, thus, realizing laser phase locking.

In 2019, Liu [93] proposed a Costas phase-locked loop broadband-tuning method based on an acousto-optic frequency shifter. In the 10-GHz capture range, the loop bandwidth was 1.5 MHz, and 1×10^{-8} was the measurement standard. When the communication rates were 10 Gbit/s and 5 Gbit/s, the measured sensitivities were -38.7 dBm and -41.4 dBm, respectively.

In 2019, Pan et al. [94] conducted an experiment on a Costas phase-locked loop based on the BPSK signal. When the phase difference between the in-phase branch signal and the quadrature branch signal output by the balance detector was 90°, the signal light and local oscillator light could be locked quickly. This experiment could better demodulate the baseband signal in the input signal light.

In 2020, Wang [95] designed a multi-stage compound-loop control system based on a Costas optical phase-locked loop and completed a BPSK signal-demodulation

experiment with a communication rate of 10 Gbit/s. The system had a bit-error rate better than 10^{-7} and the system had fast-acquisition capability.

In 2020, He [96] established a closed-loop acquisition model of a homodyne coherent-optical communication system, and experimentally measured the frequency-discrimination range as ±2.5 GHz at a communication rate of 5 Gbit/s.

In 2021, Wang [97] designed a balanced optical phase-locked loop for distributed-feedback semiconductor lasers, based on real-time data acquisition and identification. The experimental results showed that loop locking reduced the laser linewidth from 4 MHz to 20 kHz.

In 2021, Huo [98] adopted homodyne laser phase-locked loop technology to conduct coherent-detection experiments on laser-pulse echoes. The results showed that the loop reduced the initial frequency difference between the pulse laser and local oscillator laser to less than 2 MHz for a differential frequency signal within the range of 110 MHz. In addition, the loop-capture range was 112 MHz and the loop bandwidth was 539 MHz.

In 2022, Zhang et al. [99] studied a high-stability laser-frequency stabilization method, based on an optical phase-locked loop. They used the optical phase-locked loop system to investigate the frequency-offset locking of a tunable external-cavity semiconductor laser to the optical frequency comb. After the loop locking, the beat frequency fluctuated within the range of ±0.3 Hz; after the system locking, the beat-frequency linewidth was compressed from 500 kHz to 2 kHz.

In 2022, Fang et al. [100] proposed to use optical phase-locked loop technology in coded synthetic-aperture laser radar to suppress the random phase noise of the system itself. The system worked at 1550 nm and its modulation bandwidth was 1.25 GHz.

Electronic Phase-Locked Loops

Basic Structure of an Electronic Phase-Locked Loop

A phase-locked loop (PLL) synchronizes the output signal and input reference signal in terms of frequency and phase [16]. When the phase-locked loop is locked, the phase difference between the oscillator output signal and reference signal is constant or zero [101].

Figure 26.1 shows the basic circuit of a phase-locked loop, including three basic units: a phase detector (PD), loop filter (LPF), and voltage-controlled oscillator (VCO). To double the clock frequency, the PLL adds a frequency divider between the output circuit of the voltage-controlled oscillator and the input circuit of the phase detector. It is sometimes added after the reference-frequency clock circuit [102] to obtain more output-frequency points.

The working principle of the electric phase-locked loop is as follows. The phase detector compares the phase of the feedback-clock signal with the reference-clock signal, thus obtaining the phase-deviation information. After the signal is processed by the loop filter, the high-frequency component of the signal is eliminated and a

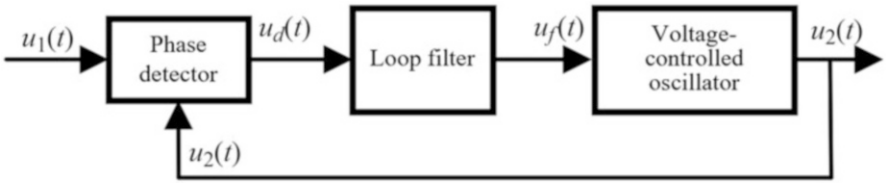

Fig. 26.1 Basic block diagram of a phase-locked loop

voltage signal is generated, which is used to control the frequency of the voltage-controlled oscillator.

One part of the output frequency of the voltage-controlled oscillator is used as the output signal. The other part is used as the feedback-clock signal and is then sent to the phase detector, thus forming a complete phase-locked loop. After the loop stabilizes, the frequency phases of the reference signal and oscillator output signal match [103].

1. Phase detector: The phase detector compares the phase difference between the input signal and the reference signal, and reflects the difference through voltage or current. The average voltage characteristic curve of the output signal is proportional to the phase difference of the input signal.
2. Loop filter: The loop filter retains the DC control signal output by the phase detector of the previous stage and simultaneously removes high-frequency burrs and noise. The number of zeros and poles in the loop affects the loop bandwidth and the phase margin of the phase-locked loop structure.
3. Voltage-controlled oscillator: This module converts the DC-voltage control signal into an AC oscillation signal [104]. This circuit is responsible for generating the output signal. It has an important impact on the output-frequency range of the phase-locked loop and the out-of-band noise.

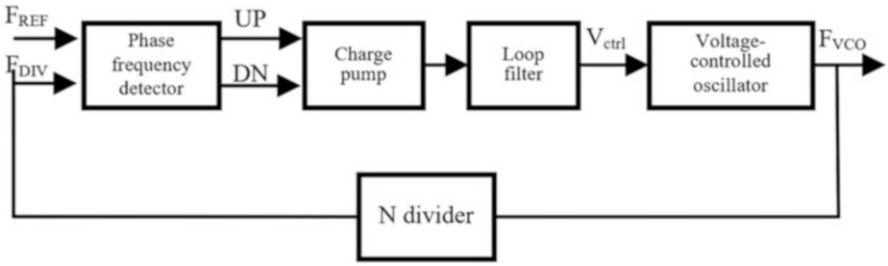
Classification of Electric Phase-Locked Loops

Different Circuit Structures

Analog Phase-Locked Loops

All parts of an analog phase-locked loop are analog circuits. The analog phase-locked loop is also called a linear phase-locked loop (LPLL) because in the ideal state, when the phase-locked loop works stably, each component-circuit unit works linearly [105]. The loop characteristics of analog phase-locked loops are mainly determined by the characteristics of the phase detector, which plays an important role in signal modulation and demodulation.

Figure 26.2 shows the basic structure of an analog phase-locked loop, which mainly consists of five analog-circuit modules: a phase-frequency detector (PFD),



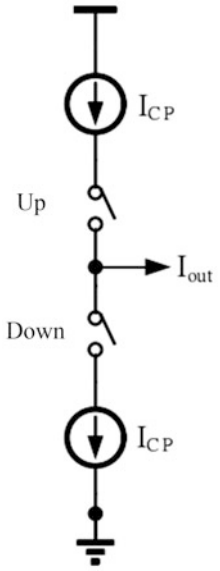


Fig. 26.2 Analog phase-locked loop structure

Fig. 26.3 Schematic diagram of the charge pump

charge pump (CP), loop filter (LPF), voltage-controlled oscillator (VCO), and frequency divider.

In an analog phase-locked loop, the frequency divider divides the output signal. The charge pump converts the output signal of the previous stage into an electric charge and charges and discharges the capacitor in the next stage. Figure 26.3 shows a schematic diagram of the charge pump. The circuit uses two switches to control the current source. The switch signal is the output signal of the frequency and phase detectors. The charge pump directly affects the performance of the entire phase-locked loop.

Following is the working process of the analog phase-locked loop shown in Fig. 26.2. The phase detector compares the phases of the input signal and the output

signal of the frequency divider to generate UP and DN signals, which adjust the charge pump to charge or discharge the loop filter. The high-frequency noise in the output signal of the charge pump is removed in the loop filter. Then, a stabilized signal is generated to adjust the frequency of the output signal of the voltage-controlled oscillator to lock the phases. This is repeated until the entire loop is completely locked; that is, the phase-locked loop system as a whole can be regarded as a negative-feedback system.

All-Digital Phase-Locked Loops

An all-digital phase-locked loop does not contain passive components. Its structure is shown in Fig. 26.4. In the all-digital phase-locked loop, the converter replaces the frequency and phase detector and the charge-pump unit in the traditional phase-locked loop. The converter compares the phases of the reference clock and the feedback clock, obtains the phase-difference signal, and converts it into a digital signal.

The converter in the all-digital phase-locked loop has three different structures: a phase-to-digital converter (PDC), frequency-to-digital converter (FDC), and time-to-digital converter (TDC). The phase-error quantization function of a time-to-digital converter is unique to all digital phase-locked loops. The time-to-digital converter can effectively convert the time to a digital signal, and the clock information can be easily extracted [106]. However, it is difficult to extract from the phase-to-digital and frequency-to-digital converters.

A digital loop filter (DLF) replaces the loop filter. Its function is the same as that of the loop filter in a traditional phase-locked loop. It processes the digital signal output by the converter, filters the noise and high-frequency components, generates the control word, and sends it to the next oscillator. The digital filter directly affects the locking speed and stability of the entire system; therefore, the performance of the loop can be changed by adjusting the parameters of the filter.

The all-digital phase-locked loop oscillator differs from the traditional phase-locked loop oscillator. Its control signal is a digital signal rather than an analog voltage; therefore, it is called a digitally controlled oscillator (DCO). The DCO receives the phase-difference signal generated from the time-to-digital converter to change the output oscillation frequency. The DCO generates an output signal with a specific frequency range and precisely locks its frequency through a phase-locked loop.

Classification of All-Digital Phase-Locked Loops

At present, there are many ways to implement all-digital phase-locked loops; however, the design is primarily based on two types of phase-locked loops [108]. One places the time-to-digital converter in the forward path, which is called a Type-I all-digital phase-locked loop. The other places the time-to-digital converter in the feedback path, which is called a Type-II all-digital phase-locked loop.

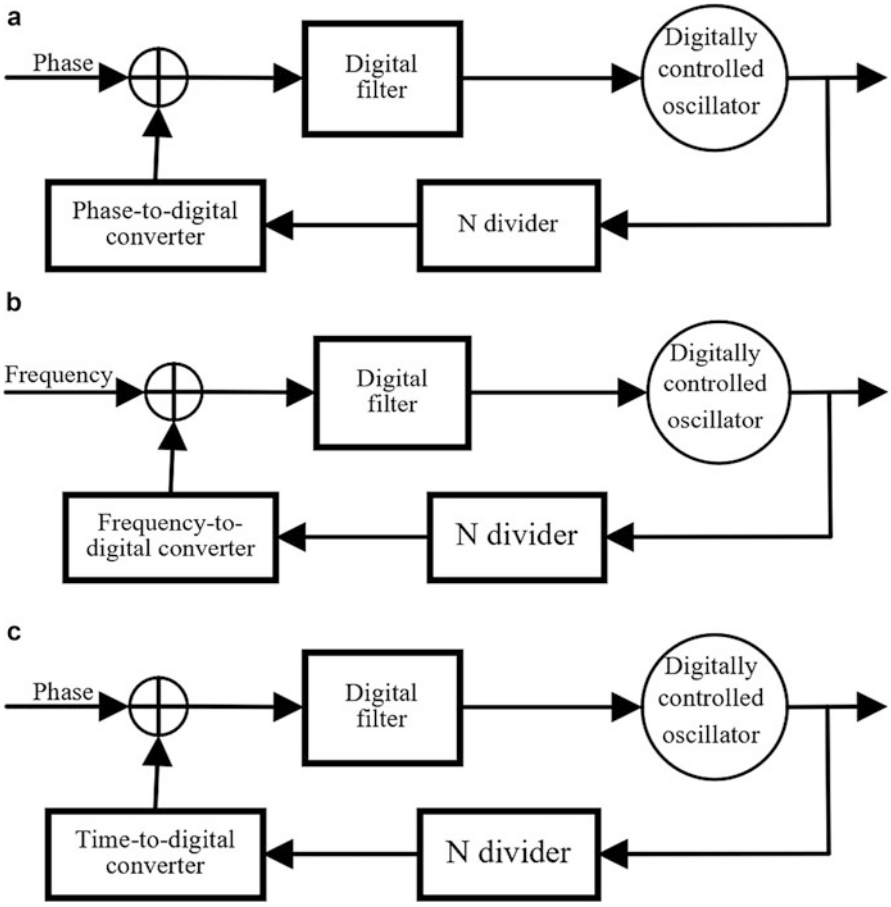

Fig. 26.4 Three all-digital phase-locked loop structures [107]. (**a**) PDC structure (**b**) FDC structure (**c**) TDC structure

Type-I All-Digital Phase-Locked Loop

As shown in Fig. 26.5, the circuit consists of a time-to-digital converter, digital filter, digitally controlled oscillator, and *N* divider. It was developed from the traditional analog phase-locked loop, with mature technology, good dynamic characteristics, and a simple structure. It is applicable to situations in which the frequency or phase must be quickly captured. When the loop is locked, there is a constant phase difference between the reference and output signals. However, the in-band phase noise is high, and the performance is poor.

Following is the working principle of Fig. 26.5. The time-to-digital converter compares the difference between the rising and falling edges of two input signals and quantizes them into the next level of the digital signal input. The digital filter adopts an infinite impulse response (IIR) filter, which is composed of an adder, D trigger, and shift register. Its function is similar to that of the loop filter. After removing the

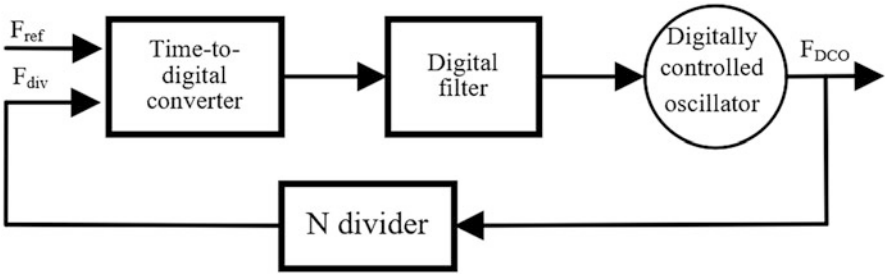

Fig. 26.5 Type-I all-digital phase-locked loop (TDC in forward path) [108]

high-frequency noise, the output signal of the digital filter is used as the input control signal of the digitally controlled oscillator.

The digitally controlled oscillator uses a MOS capacitor to determine the frequency resolution, whereas a voltage-controlled oscillator uses the C-V characteristic of the varactor to realize high-precision tuning. A digitally controlled oscillator uses delta–sigma modulation (DSM), which can reach or even exceed the tuning accuracy of a voltage-controlled oscillator.

The structure of the *N*-frequency divider is generally similar to that of the analog phase-locked loop. It can also be applied to digital circuits. The divided signal is fed back to the time-to-digital converter for comparison, and the entire process is repeated until the all-digital phase-locked loop is completely locked.

Type-II All-Digital Phase-Locked Loop

As shown in Fig. 26.6, the Type-II all-digital phase-locked loop differs from the traditional phase-locked loop in structure. The circuit structure includes a time-to-digital converter, digital integrator, digital filter, digitally controlled oscillator, and high-speed counter. Compared with the Type-I all-digital phase-locked loop, the time-to-digital converter is placed in the feedback path to measure the phase difference between the rising or falling edge of the digitally controlled oscillator and the reference clock, which is then converted to digital.

The phase difference between the output signal and the reference signal of the Type-II PLL is approximately zero, and it is often used in high-precision frequency synthesis and clock recovery fields. Its disadvantage is that there is significant quantization noise. Because the input signal of the high-speed counter and time-to-digital converter is the output frequency of the digitally controlled oscillator, the output of the digitally controlled oscillator consumes a large current and high power, and the circuit design and implementation of this type of phase-locked loop are relatively complex.

Following is the working principle of Fig. 26.6. A high-speed counter is included in the feedback channel. When the reference-clock edge arrives, the counter records the integral part of the output-clock phase of the digitally controlled oscillator, and the time-to-digital converter records the fractional part of the clock phase. Thus, the overall digital phase signal of the digitally controlled oscillator is obtained by adding the output of the counter and the time-to-digital converter.

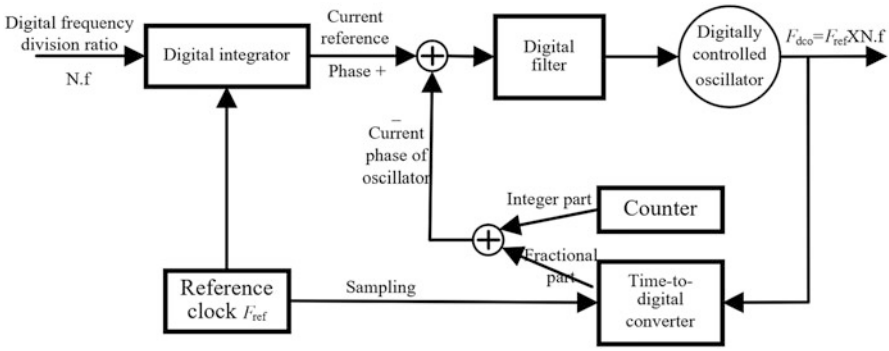

Fig. 26.6 Type-II all-digital phase-locked loop (TDC in feedback channel) [108]

The phase of the reference clock is also converted into a digital phase signal by a digital integrator, and the digital value of the current phase difference is then calculated by comparing the two output digital signals. This value is then passed into the digital filter to filter the noise and is finally used for the output-frequency control of the digitally controlled oscillator.

Digital–Analog Hybrid Phase-Locked Loop

Owing to a further reduction in the process size, the internal-leakage current of the component increases, and the periodic vibration of the clock frequency of the analog phase-locked loop also increases. For leakage current, long-period jitter, and other problems, the all-digital phase-locked loop can be used; however, the resolution of the digitally controlled oscillator in the all-digital phase-locked loop is limited, and there is high flicker noise, which increases jitter; thus, a digital–analog hybrid phase-locked loop is generally used.

To reduce flicker noise in the digital-circuit structure, the fractional frequency division is generally used to replace the digitally controlled oscillator in the digital–analog hybrid phase-locked loop structure [109].

A charge-pump phase-locked loop (CPPLL) is a typical digital–analog hybrid phase-locked loop. Its characteristics include a wide linear range, short acquisition time, and small lock-phase difference. The charge-pump phase-locked loop is shown in Fig. 26.7. Its structure consists of a frequency and phase-frequency detector (PFD), charge pump (CP), loop filter (LPF), and voltage-controlled oscillator (VCO). Compared to the analog phase-locked loop, the only difference is that the phase detector unit uses a digital charge-pump phase detector.

The charge-pump phase-locked loop can filter the jitter from the output of the all-digital phase-locked loop without considering the impact of the leakage current. The jitter of the digital–analog hybrid phase-locked loop is also improved in the clock-output cycle. The disadvantage of the charge-pump phase-locked loop is that the anti-interference performance is poor, and it is vulnerable to noise and other factors. Moreover, its compatibility with the digital module is poor, so its performance level is not too high.

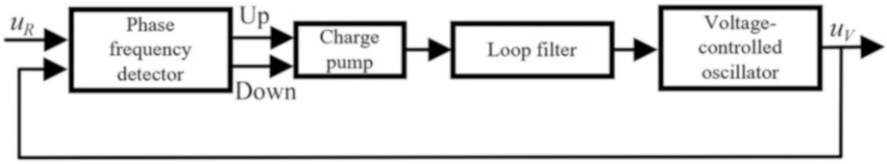

Fig. 26.7 Charge-pump phase-locked loop

Software Phase-Locked Loops

The software phase-locked loop is implemented using software [11]. The parameter design is more flexible and the structural design is simpler. It has better versatility than the other phase-locked loops. The principle of the software phase-locked loop does not differ significantly from that of other phase-locked loops; however, there are differences in the mathematical models and implementation methods. The software phase-locked loop does not have the complex circuit structure of other phase-locked loops but uses microsecond computing time to replace the electronic components in other phase-locked loops. The higher the precision of the software phase-locked loop, the higher the performance, and the more complex the corresponding algorithm instructions.

Its speed and accuracy can be compared with other phase-locked loops, but only if the algorithm instructions can be executed sufficiently fast on the hardware. If the algorithm instructions run slowly on the hardware platform or the hardware platform is not sufficiently powerful, then a more powerful hardware platform needs to be adopted, which will also increase the cost. Therefore, the software phase-locked loop is applicable to systems with low and low-frequency requirements.

Comparison of Analog and Digital Phase-Locked Loops

Phase-locked loops are classified into analog and digital. Table 26.2 compares their performance.

The analog phase-locked loop has a strong tracking ability for signals with sinusoidal characteristics, and its locking time is very short, ensuring a steady-state difference between the output clock and reference clock. The voltage-controlled oscillator limits the center frequency of the analog phase-locked loop to a small range. The performance of the analog phase-locked loop depends on the transistor size. The expected performance is achieved using a complex circuit structure and sacrificing power consumption. The loop-filter capacitance occupies a large area. With the continuous reduction in the process size, the operating-frequency range of the analog phase-locked loop will be significantly reduced.

The digital phase-locked loop has strong scalability, good portability, excellent anti-interference performance, and is easy to integrate in large-scale digital circuits [110]. The actual circuit often works in an imperfect environment, and the analog phase-locked loop circuit is easily affected by external imperfect factors, whereas the digital phase-locked loop circuit effectively overcomes the problems caused by changes in the process, voltage, temperature, etc. [111].

Table 26.2 Comparison between analog and digital phase-locked loops

Performance metric	Analog phase-locked loop	Digital phase-locked loop
Lock time	Longer	Shorter
Lock speed	Faster	Slower
Noise resistance	Weak	Stronger
Circuit complexity	Higher	Lower
Portability	Poor	Better
Area	Larger	Smaller
Power dissipation	Same	Same
Jitter performance	Better	Related to control word
Compatibility	Digital circuit needs to be considered	No need to consider in digital circuit

Other Classifications

Other classifications are based on analog and digital phase-locked loops.

Phase-Locked Loops with Different Frequency-Division Coefficients

According to the different frequency-division coefficients of the frequency divider, phase-locked loops can be divided into integer frequency-division and fractional frequency-division.

When the phase-locked loop is unlocked, the frequency and phase detector compares the reference signal F_{ref} and the divided signal F_{out} and outputs the phase-error signal between them. After feedback, the loop can lock the reference and feedback signal phases. Therefore, the reference-signal frequency must be equal to the frequency of the signal output after frequency division; thus, there is a locking relationship between the output frequency of the voltage-controlled oscillator and N times the input reference frequency, as shown in Eq. (26.1):

$$F_{\text{out}} = N \times F_{\text{ref}}. \tag{26.1}$$

Figure 26.8 shows an integer frequency-division phase-locked loop. The entire loop has a simple structure and good noise performance. The disadvantage of this method is that the frequency resolution of the integer phase-locked loop is low. When the circuit has high accuracy requirements, it cannot meet the design requirements.

Because N is an integer, the minimum step length of the phase-locked loop is equal to the frequency F_{ref} of the reference signal. Therefore, to obtain a lower step length, the input reference frequency must be reduced; however, this will increase the value of the frequency divider and increase the in-band noise accordingly. Consequently, the overall performance of the phase-locked loop is reduced.

To improve the in-band noise of the integer frequency-division phase-locked loop, the value of the frequency divider can be reduced. However, when the output frequency is the same, the input reference frequency must increase; that is, the frequency and phase detector must have a higher phase-discrimination capability.

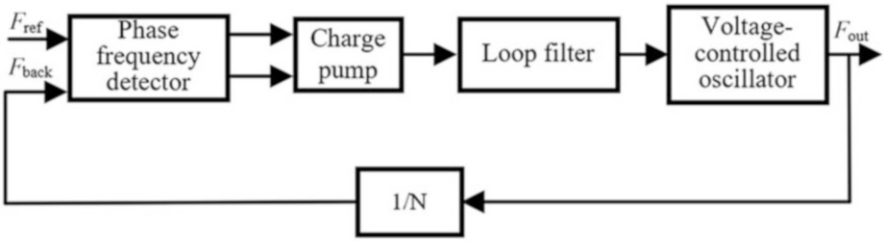

Fig. 26.8 Structure block diagram of an integer frequency-division phase-locked loop [112]

Therefore, when the output frequency requires a higher accuracy, the fractional frequency-division phase-locked loop is generally selected. As shown in Fig. 26.9, the fractional-frequency phase-locked loop [112] is generally constructed based on the charge-pump phase-locked loop structure.

The PLL in Fig. 26.9 consists of a frequency and phase-frequency detector (PFD), charge pump (CP), loop filter (LPF), voltage-controlled oscillator (VCO), and a two-mode frequency divider controlled by a delta–sigma modulator. The delta–sigma modulator consists of a delta modulator and an integrator that acts as a summation. With this structure, it is possible to obtain a higher frequency resolution and push low-frequency noise into high-frequency noise to shape or modulate the noise [113].

In a fractional-frequency phase-locked loop, the delta–sigma modulator quantization error can be removed by a low-pass filter, and the influence of the quantization error on the output phase noise can be reduced to a negligible degree by reducing the bandwidth of the phase-locked loop.

Phase-Locked Loops of Different Types and Numbers

Phase-locked loops are divided into different types according to the number of integrators in the loop, that is, according to the number of zeros. Many important properties of phase-locked loops are related to their type number. Because the voltage-controlled oscillator performs an integral operation, the phase-locked loop is of at least one type. In contrast, Class-II phase-locked loops are widely used, whereas Class-III phase-locked loops are occasionally used, owing to their complex structure.

Narrowband and Broadband Phase-Locked Loops

Bandwidth is the most basic property of a phase-locked loop. Depending on the bandwidth, they can be divided into narrowband and broadband. However, their applications are different.

The narrow band and automatic-tracking characteristics of narrowband phase-locked loops make them widely used in receivers. In the receiver, the frequency or phase contains both the input-signal information and additive noise. The phase-locked receiver correctly reconstructs the original signal to eliminate as much additive noise as possible. When the narrowband phase-locked loop inputs a signal with a stable frequency, the local oscillator can track it with less information. The phase-locked loop in this application can be regarded as a device for filtering noise

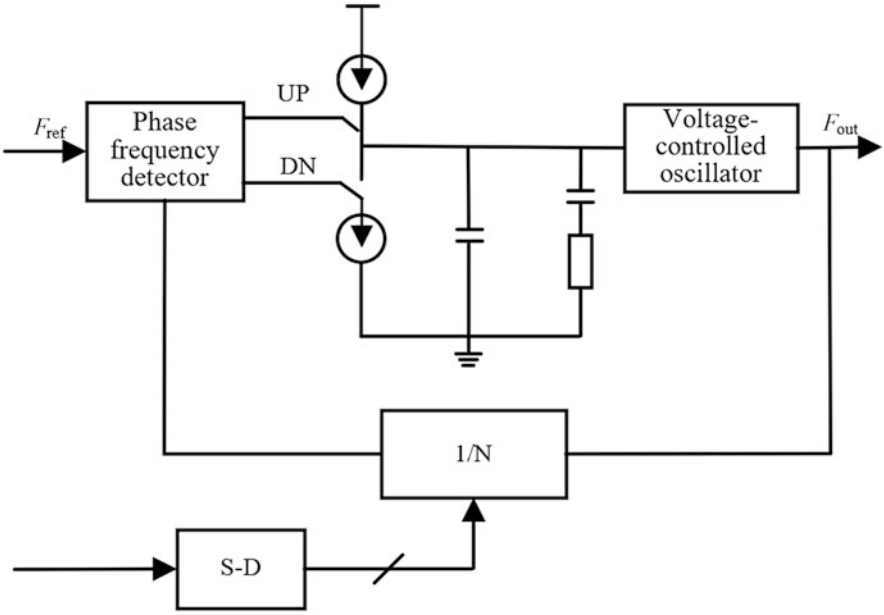

Fig. 26.9 Traditional fractional frequency-division phase-locked loop [112]

[114]. The narrowband phase-locked loop is primarily used for carrier synchronization and reducing the clock jitter of digital circuits. The input signal can be tracked when the bandwidth of a broadband phase-locked loop is sufficiently wide.

In a frequency-modulation system, the voltage of the frequency-modulation signal directly controls the modulation signal output by the voltage-controlled oscillator. In practice, to obtain high-quality modulated signals, open-loop phase-locked loop frequency modulators, closed-loop phase-locked loop frequency modulators, and two-point modulators are typically used to effectively suppress the impact of the nonlinearity of the voltage-controlled oscillator.

Figure 26.10 shows the structure diagram of a closed-loop phase-locked loop frequency modulator. In this structure, the transfer function from the loop-filter noise to the output-phase noise is consistent with the transfer function from the modulated signal to the output. Figure 26.11 shows the structure diagram of phase-locked loop signal demodulation, where the control voltage is the demodulated output signal.

Parameters of Electronic Phase-Locked Loops

Following are the parameters of electronic phase-locked loops.

1. Frequency tuning range: This refers to the range between the minimum and maximum output frequencies of the phase-locked loop, that is, the size of the

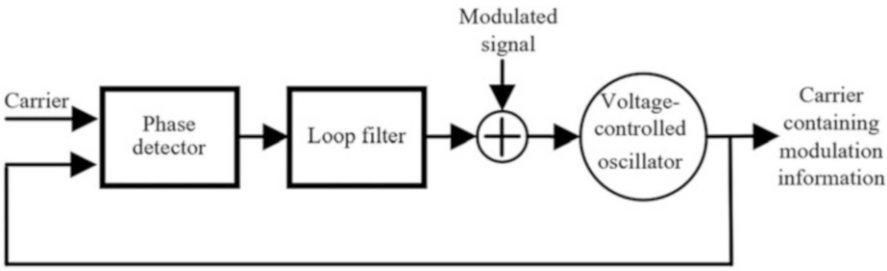

Fig. 26.10 Closed-loop phase-locked loop frequency modulator [115]

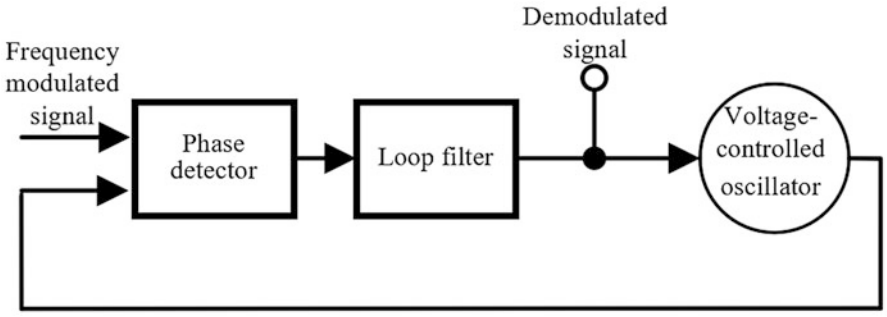

Fig. 26.11 Signal demodulation using a phase-locked loop

output frequency. Generally, the best tuning range of the output frequency and the appropriate frequency band are selected according to the communication standard and specific situation.

2. Frequency resolution: This refers to the minimum frequency interval of the signal output by the phase-locked loop.
3. Frequency conversion time: The time required for the phase-locked loop to change from any frequency to another frequency must meet this requirement for the communication system to work in different frequency bands.
4. Phase noise and spurious components: If phase noise is taken as the measurement of the output frequency, it is ideal for the PLL to output a single frequency point pulse in the frequency domain. However, in practical applications, owing to noise and various non-ideal effects, the output signal contains other frequency components that are generally called spurious.
5. Lock time: When the phase-locked loop is in a stable operation state, it is said to have entered the lock state. The requirements for the length of the lock time differ in different wireless communication systems. The loop bandwidth significantly affects the phase lock time [74]. When the loop bandwidth is less than one-tenth of the reference-clock signal frequency, the loop stability is good.

Applications of Electric Phase-Locked Loops

In a pulse-position modulation (PPM) and demodulation optical wireless communication system, the receiver-information detection part of the optical wireless communication system must have a strict time-synchronization relationship with the superframe to ensure that the communication system can normally demodulate the information in the PPM frame.

Figure 26.12 shows the structure of an optical wireless communication receiver. At the receiver end, after the monopolar narrow pulse signal is output by the avalanche photodetector (APD), it reaches the preprocessing part, and the high-frequency noise in the signal is removed through the low-pass filter. Finally, the received signal is sent by the splitter to the PPM detection demodulator, slot-synchronization unit, and frame-synchronization unit for corresponding processing.

The time-slot synchronization unit of an optical wireless communication receiver is shown in Fig. 26.13. It primarily uses a digital phase-locked loop to extract the signal of the time-slot clock. First, the interference noise with lower amplitudes of the input narrow pulse signal is filtered in the amplitude comparator. Then, the signal is processed by the width comparator for noise reduction. The pulse signal is transmitted to the pulse stretcher, so that the duty cycle of the signal is adjusted to 50%. The corresponding level signal is output, then sampled by the analog-to-digital converter (A/D), and finally sent to the digital phase-locked loop. The clock signal is

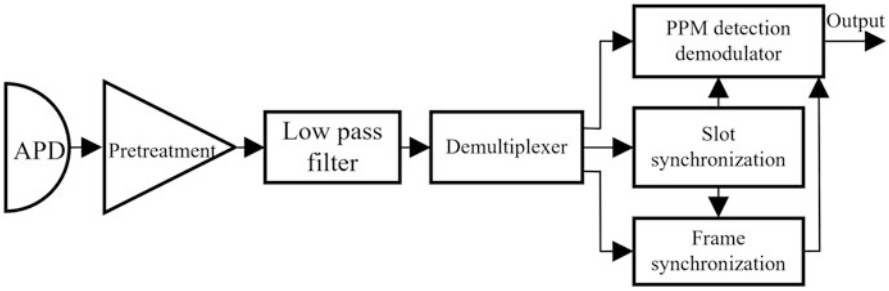

Fig. 26.12 Block diagram of an optical wireless communication receiver [116, 117]

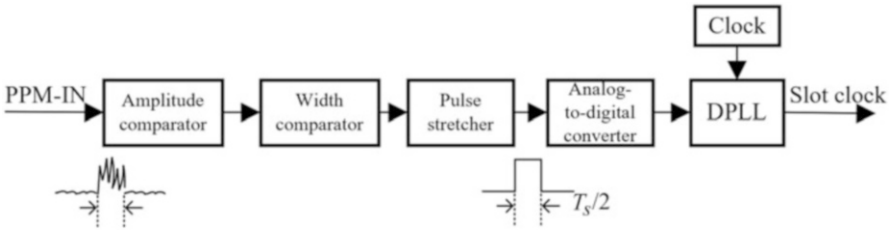

Fig. 26.13 Time-slot synchronizer [116, 117]

used to extract the synchronous-slot clock and ensure slot synchronization in optical wireless communication.

Electric phase-locked loop technology also plays an important role in radio and television, measuring instruments and meters, remote control, national defense technology, electronic countermeasures, digital signal processing, mechanical processing, and other fields.

Optical Phase-Locked Loops in Optical Communication

Basic Structure of an Optical Phase-Locked Loop

The optical phase-locked loop is essentially the same as the traditional electric phase-locked loop. It is also a closed-loop locking circuit for the frequency and phase. In particular, an optical phase-locked loop is a control system that acts in the optical frequency range.

The structural difference between the two is that the phase-detection function of the optical phase-locked loop is completed through the optical hybrid and the front-end circuit. It uses a tunable laser to replace the voltage-controlled oscillator in the electric phase-locked loop, and adds a photoelectric detection circuit after the optical hybrid. It converts the differential frequency signal output by the optical hybrid into an electrical signal so that the loop-filter circuit can perform the corresponding processing [96]. Therefore, in the theoretical analysis, the optical and electric phase-locked loops are the same.

Figure 26.14 shows the basic circuit structure of the optical phase-locked loop. It is composed of four units: an optical hybrid, photoelectric detection circuit, loop filter, and tunable laser.

Following is the working principle of the structure shown in Fig. 26.14. First, in the optical hybrid, the input signal light and the local oscillator light are mixed coherently. Then, the mixed light is converted into the corresponding electrical signal through the photoelectric detection circuit, filtered, and integrated into the loop filter. This generates a signal in the tunable laser, which is used to control the optical frequency output by the local oscillator laser. Then, the output signal of the local oscillator laser is fed back to the optical hybrid. This is repeated to achieve a closed-loop control. During this process, the output frequency of the local oscillator laser is constantly close to the input-signal frequency.

Optical Hybrids

The function of the optical hybrid is to couple the input signal light and local oscillator light, according to a certain phase relationship to produce the mixing light. Optical hybrids are mainly divided into 90° optical hybrids and 180° optical hybrids. Their equivalent phase model is shown in Fig. 26.15.

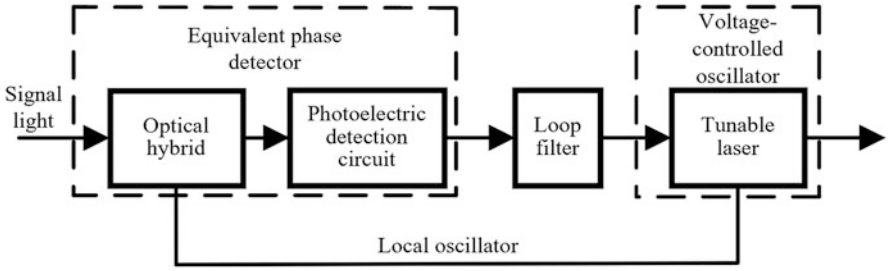

Fig. 26.14 Basic structure of an optical phase-locked loop

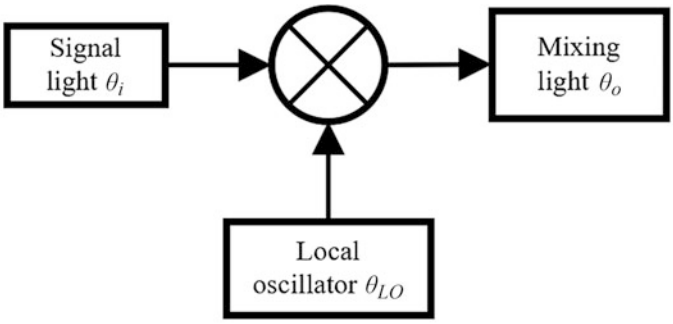

Fig. 26.15 Equivalent phase model of an optical hybrid (θ represents the phase)

In Fig. 26.15, setting the signal light as $u_i = U_i \sin(\omega_i t + \theta_i)$ and the local oscillator as $u_{LO} = U_{LO} \sin(\omega_{LO} t + \theta_{LO})$, the mixing light can be expressed as

$$u_o = K_d \sin(\theta_o), \tag{26.2}$$

where $\theta_o = \theta_i - \theta_{LO}$, $K_d = \frac{1}{2} K_m U_i U_{LO}$, and K_d is the maximum output of the optical hybrid's equivalent phase detector.

Photoelectric Detection Circuit

The photoelectric detector converts the optical phase-error signal output by the optical hybrid to the corresponding electrical signal. Generally, a balanced detector is used because it can better suppress the laser noise. Figure 26.16 shows the structure of the balanced detector. A balanced detector means that the two photoelectric detectors have the same performance, as far as possible. After subtraction, the signal is doubled, the noise is eliminated, the direct-current component disappears, and the signal-to-noise ratio is greatly improved.

The photoelectric-detection circuit is fabricated using the photoelectric effect of certain substances in the semiconductor material under light radiation. Electrons in the semiconductor material are excited by photons to form a current. The other type of detector uses matter to induce a photothermal effect under light irradiation. The photon energy acts on the lattice and causes the temperature to rise and enhances the vibration, which changes the characteristics of matter and forms a current.

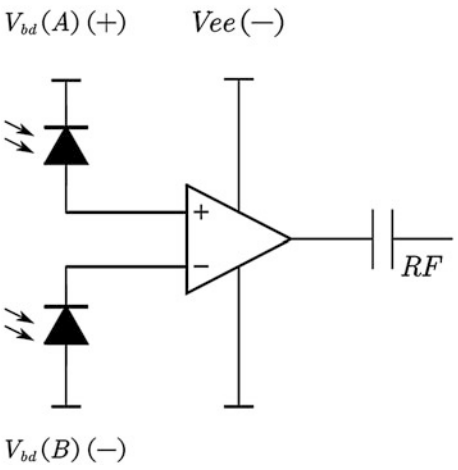

Fig. 26.16 Balanced detector structure

Loop Filter

While filtering the high-frequency components and noise in the signal, the loop filter can also affect the loop stability, acquisition time, loop-acquisition bandwidth, and tracking time by changing its parameters.

The working principle is to use an integral circuit to convert the photodetector output into the corresponding error-feedback voltage. While effectively adjusting the loop gain and compensating the loop-phase margin, the low-pass filter circuit further reduces the loop noise.

The key to designing an optical phase-locked loop is the open-loop transfer function. The transfer function of the phase-detector unit and the tunable laser in the optical phase-locked loop is determined by the characteristics of the device itself, and the design space is small. Therefore, the loop filter is the key to designing an optical phase-locked loop, and is equivalent to the control algorithm in a general control system.

In the Laplace-transform domain of the basic phase-locked loop, $\theta_i(s)$ is the input signal. $\theta_o(s)$ is the output signal of the voltage-controlled oscillator. When the loop is in the locked state, the equivalent phase-detector output voltage of the optical hybrid is shown in Fig. 26.17:

$$V_d = K_d(\theta_i - \theta_o). \tag{26.3}$$

We set the phase error $\theta_e(s)$ as

$$\theta_e = \theta_i - \theta_o. \tag{26.4}$$

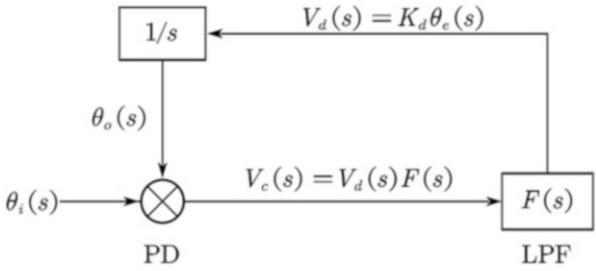

Fig. 26.17 Basic block diagram of a phase-locked loop

We assume that V_c is the control voltage used to control the frequency of the voltage-controlled oscillator, expressed as

$$V_c(s) = V_d(s)F(s). \tag{26.5}$$

The input control voltage of the voltage-controlled oscillator is $V_c(t)$. The frequency offset is K_oV_c. Subsequently, the output signal of the voltage-controlled oscillator is transformed into

$$\theta_o(s) = \frac{K_oV_c(s)}{s}. \tag{26.6}$$

The open-loop transfer function of the phase-locked loop is

$$G(s) = \frac{\theta_o(s)}{\theta_e(s)} = \frac{K_dK_oF(s)}{s}. \tag{26.7}$$

The closed-loop transfer function is

$$H(s) = \frac{\theta_o(s)}{\theta_i(s)} = \frac{G(s)}{1+G(s)} = \frac{K_dK_oF(s)}{s+K_dK_oF(s)}. \tag{26.8}$$

The error transfer function is

$$E(s) = \frac{\theta_e(s)}{\theta_i(s)} = \frac{1}{1+G(s)} = 1 - H(s) = \frac{s}{s+K_dK_oF(s)}, \tag{26.9}$$

where $s = j\omega$. $F(s)$ is the transfer function of the loop filter; it is determined by the specific structure of the filter. From the above expression, we can see that the system transfer function performs low-pass filtering on the input signal and the error transfer function performs high-pass filtering on the input signal.

Tunable Laser

The linewidth, noise intensity, tunable range, and other parameters of the tunable laser directly affect the optical phase-locked loop, which can be regarded as a linear voltage-frequency conversion device. The instantaneous angular frequency is expressed as follows:

$$\omega_{LO}(t) = \omega_o + K_l V_c(t), \tag{26.10}$$

where ω_o is the initial angular frequency, $V_c(t)$ is the input control voltage of the tunable laser, and K_l is the gain coefficient of the tunable laser ($rad \cdot Hz/V$).

Equation (26.10) is expressed as a Laplace transfer operator in the form of

$$K_{LO}(s) = \frac{k_l}{s}. \tag{26.11}$$

Classification of Optical Phase-Locked Loops

Initially, the optical phase-locked loop was developed based on the electric phase-locked loop. With the emergence of coherent communication technology, optical phase-locked technology has developed rapidly and various optical phase-locked loops have emerged. The following is a comparative analysis of the composition principle and working performance of optical phase-locked loops.

Balanced Optical Phase-Locked Loop

Figure 26.18 shows the balanced phase-locked loop. Its structure is simple and easy to implement, and is the basis of other optical phase-locked loops. It is composed of a 180° optical hybrid, a balance detector, a loop filter, and a local oscillator laser. It has a symmetrical structure. The local oscillator and signal light are coherently mixed by a 180° optical hybrid to generate two optical signals with a phase difference of 180°. The optical signal is converted into an electrical signal using a photoelectric balance detector.

The direct-current component of the electrical signal is filtered by a trans-resistance amplifier, and the electrical signal containing the phase error of the two light beams is filtered and corrected by a loop filter to generate a signal to control the local oscillator laser. When the system is in a closed-loop state, the frequencies of the local oscillator light and signal light will be close to each other, and the phases of the local oscillator light and signal light are synchronized.

The balanced phase-locked loop must have residual carriers perpendicular to the local oscillator light so that it can use the current signal generated by the phase shift to control the output of the local oscillator laser and lock the phase. In addition, owing to the presence of residual carriers, the loop can output baseband signals only after secondary demodulation. The balanced phase-locked loop can transmit analog signals and process digital signals. Using a 180° optical hybrid can minimize the loss from power consumption. The laser linewidth is related to the communication rate, whereas the relationship between the maximum linewidth of the balanced phase-locked loop laser and the system-transmission rate is $\Delta\nu \leq 5.8 \times 10^{-6} R_b$ [118], where R_b is the bit rate in bit/s, when the bit-error rate is 10^{-10} and the power loss is 1 dB.

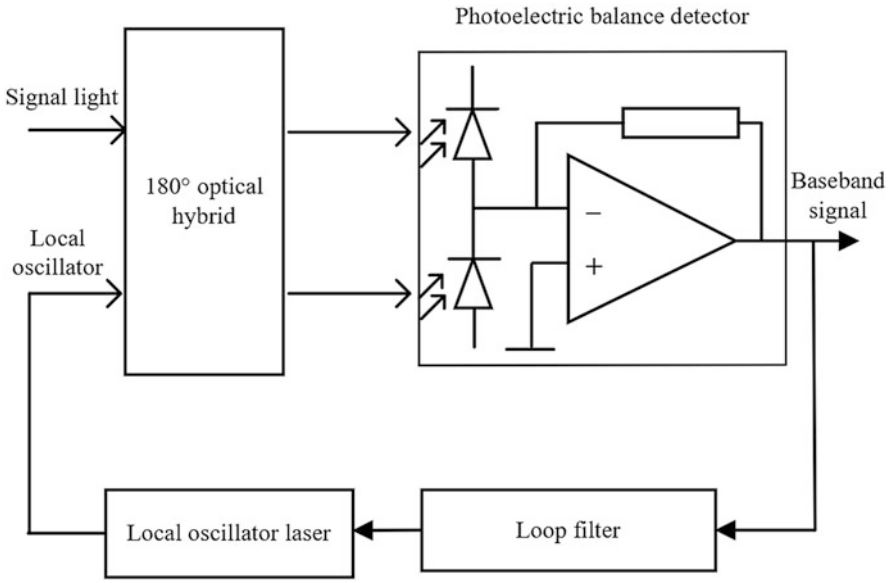

Fig. 26.18 Balanced optical phase-locked loop [118]

Costas Optical Phase-Locked Loop

The Costas loop uses a 90° optical hybrid, whose structure is shown in Fig. 26.26. In the 90° optical hybrid, the local light and signal light are coherently mixed, and then four optical signals with a phase difference of 90° are generated. After conversion by the photoelectric balanced detection circuit, the four optical signals are divided into two signal channels, namely, the in-phase and quadrature channels. These two channels carry modulation information with a phase difference of 90°. The signals from these two channels are multiplied to eliminate modulated signals.

In this process, a phase-error signal of the local oscillator and signal light with twice the frequency are generated, and the signal is processed by the loop filter to obtain a voltage signal, which controls the output of the local oscillator laser. The frequencies of the local oscillator light and the signal light continue to approach each other, and the intermediate-frequency signal continues to decrease until the frequency phases of the local oscillator light and the signal light are equal; that is, the voltage in the loop is zero, so that the loop is locked. At this time, the output of the same branch is the baseband signal (Fig. 26.19).

Because the Costas loop uses a 90° optical hybrid with a complex structure, it does not need to transmit residual carriers, nor does it have the problem of crosstalk between the phase-locked signal and data. An alternating-current coupling element is used in the loop, which effectively suppresses the noise interference generated by the laser; therefore, the Costas loop has high reception sensitivity.

Compared to the balanced phase-locked loop, the structure of the 90° optical hybrid is much more complex than that of the 180° optical hybrid, and its

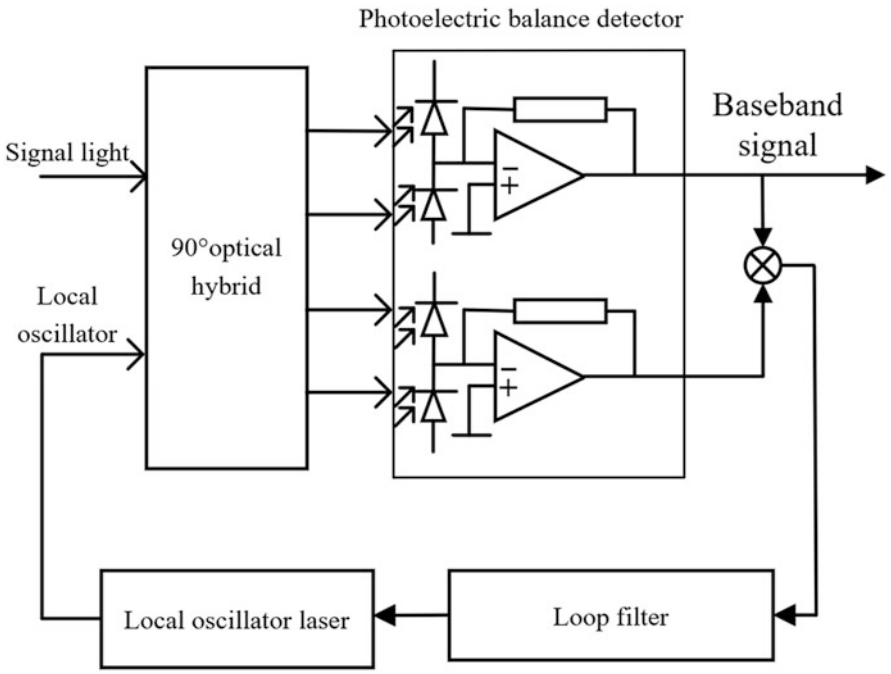

Fig. 26.19 Costas optical phase-locked loop [65]

implementation is more difficult. The Costas loop can process both analog and digital signals, and its laser-linewidth requirements are relatively low. The relationship between the maximum linewidth of the laser and the system transmission rate is $\Delta v \leq 5.02 \times 10^{-4} R_b$ [65], where R_b is the bit rate in bit/s, when the bit-error rate is 10^{-10} and the power loss is 1 dB.

Decision-Driven Optical Phase-Locked Loop

A decision-driven optical phase-locked loop is an optical phase-locked loop that suppresses the carrier wave. The structure is shown in Fig. 26.23. The circuit includes a 90° optical hybrid, a photodetector, a loop filter, a delayer, a threshold comparator, and a local oscillator (LO) laser. Comparing the decision-driven optical phase-locked loop with the Costas optical phase-locked loop, it can be found that the two have considerable structural similarity. Only the data-decision circuit unit is added to the in-phase channel of the decision-driven phase-locked loop; it is composed of a low-pass filter circuit and a threshold comparator.

A one-bit delay circuit is added to the quadrature channel, which can compensate for the problem in which the two-channel signals are not synchronized because of the data decision. Although a one-bit delay circuit is added, it is still difficult to ensure that the quadrature branch and in-phase branch are synchronized in time, which affects the signal modulation (Fig. 26.20).

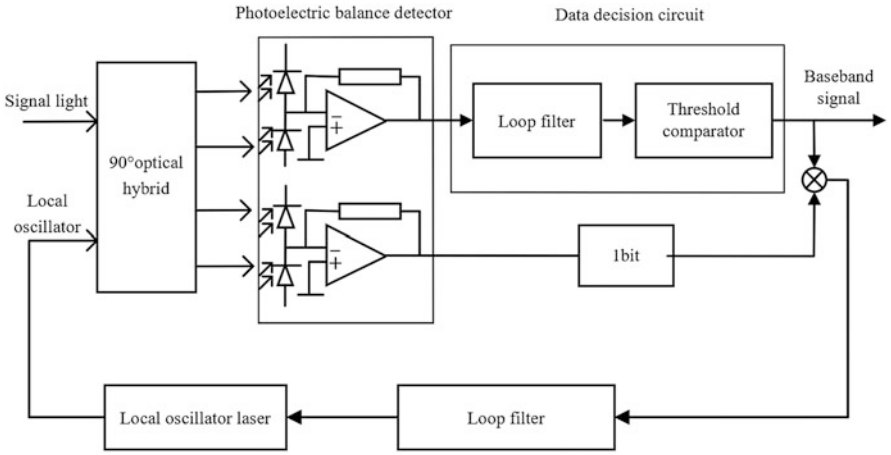

Fig. 26.20 Decision-driven optical phase-locked loop [23]

Compared with the Costas loop, the phase error of the decision-driven optical phase-locked loop is smaller; however, it can only process digital signals. It has higher requirements for the laser linewidth than the Costas loop. The relationship between the maximum linewidth of the laser and the system transmission rate is $\Delta v \leq 4.5 \times 10^{-4} R_b$ [23]. R_b is the bit rate in bit/s, when the bit-error rate is 10^{-10} and the power loss is 1 dB.

SyncBit Optical Phase-Locked Loop

The SyncBit optical phase-locked loop has the advantages of a balanced phase-locked loop and a Costas phase-locked loop. Its structure is simple. The circuit is shown in Fig. 26.24. It involves adding a signal amplifier, data holding, and phase modulation to the balanced phase-locked loop circuit structure. The phase-locked loop uses a 180° optical hybrid to optically mix the signal. It inputs the obtained optical signal to the photoelectric balance detector, and then sends it to the phase-locked circuit after a photoelectric conversion.

In most cases, the phase-locked loop is in an open state and its output signal is used for data demodulation. In this case, the loop can be regarded as an in-phase channel in the Costas phase-locked loop. During data transmissions, the loop is closed and the phase is locked. The output end of the LO laser uses the phase modulator to adjust the phase of the LO light, so that the initial phase of the light wave increases by 90°. This achieves the goal of a 90° phase difference between the optical phase of the output signal of the photoelectric balance detector and the phase of the previous moment. At this time, the loop can be regarded as an orthogonal channel in Costas-loop phase locking.

The phase-error information is obtained by multiplying the electrical signals of the two channels. Then, the loop completes the phase-locking, uses the signal

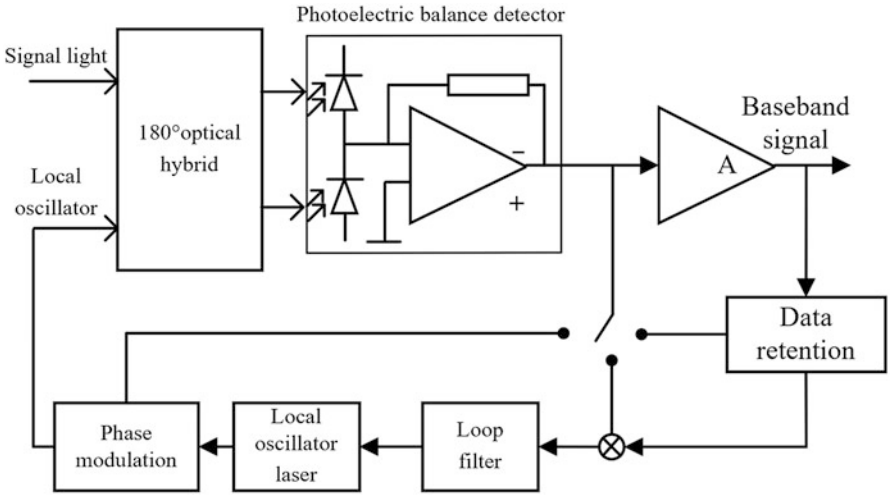

Fig. 26.21 SyncBit optical phase-locked loop [119]

amplifier to amplify and filter, and restores the output of the photoelectric balance detector by the baseband signal (Fig. 26.21).

The advantage of the SyncBit optical phase-locked loop is that the signal input to the 180° optical hybrid is coherently mixed in a time-sharing manner to achieve the effect of 90° optical mixing. The work of the Costas optical phase-locked loop can be completed using a branch, reducing the complexity of the system.

The disadvantage is that the signal-to-noise ratio is reduced and bandwidth will be lost because the phase-locked loop needs to perform special coding processing on the data, which generates a large amount of redundant information. If the communication bandwidth is increased to solve this problem, the noise will increase. If the same bandwidth is used, the transmission rate will be reduced, and the system's requirements for communication bandwidth will be increased.

The relationship between the maximum linewidth of the laser and the system's transmission code rate is $\Delta\nu \leq 3.1 \times 10^{-4} R_b$ [119]. R_b is the bit rate in bit/s, when the bit-error rate is 10^{-10} and the power loss is 1 dB.

Dither Optical Phase-Locked Loop

The structure of the dither optical phase-locked loop is relatively complex; however, it is applicable to a variety of modulation modes. Its structure is shown in Fig. 26.22, including a 180° optical hybrid, balance detector, radio-frequency amplifier, detector, bandpass filter, loop filter, 90° phase shifter, oscillation source, and local oscillator laser.

The circuit uses a 180° optical hybrid to optically mix the signal light and the local oscillator light, converts the photoelectric signal of the mixed light through the balance detector, and simultaneously outputs the electrical signal. The radio frequency amplifier and the detector in the loop of the dither optical phase-locked

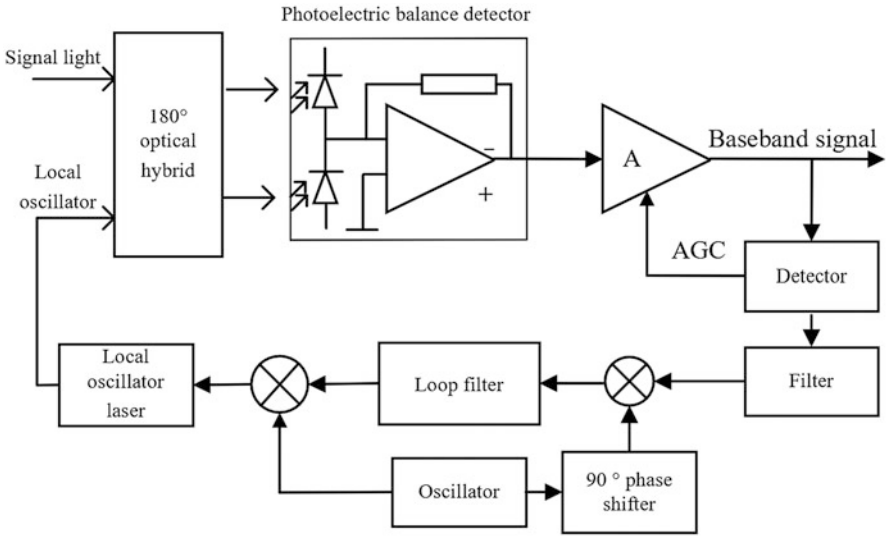

Fig. 26.22 Block diagram of a dither phase-locked loop [43]

loop are combined into an automatic gain control module, which adjusts the electrical signal output from the previous stage and outputs the adjusted electrical signal to the phase lock branch.

The dither optical phase-locked loop is an oscillation source that generates a disturbance in front of the local oscillator laser circuit. After the oscillation source is turned on, the generated disturbance signal is added to the phase of the local oscillator laser. When the loop is unlocked, a frequency signal containing the phase error is detected at the end of the loop, where the signal amplitude represents the magnitude of the phase error. The filtered signal can be used as a control signal to adjust the local oscillator laser and lock the loop.

Compared with the balanced phase-locked loop, the dither optical phase-locked loop can process both analog and digital signals without transmitting the residual carrier. However, additional oscillation signals and corresponding signal processing must be carried out, which reduces the average amplitude of the input signal, resulting in increased loop power consumption. The relationship between the maximum linewidth of the laser and the system transmission rate is $\Delta v \leq 2.6 \times 10^{-4} R_b$ [43]. R_b is the bit rate in bit/s, when the bit-error rate is 10^{-10} and the power loss is 1 dB.

Subcarrier Optical Phase-Locked Loop

The local oscillator laser plays an important role in the negative feedback circuit. Usually, the phase of a local oscillator laser is adjusted by changing the injection current of the laser using a piezoelectric transducer (PZT). However, the response time of the piezoelectric converter limits the laser tuning bandwidth. The key component of the subcarrier optical phase-locked loop (SC-OPLL) circuit structure is the optical voltage-controlled oscillator (OVCO). Figure 26.23 shows a schematic

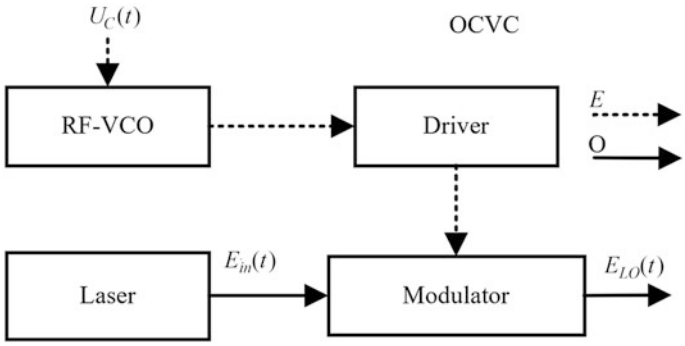

Fig. 26.23 Schematic diagram of an optical voltage-controlled oscillator

diagram. It is composed of a radio-frequency voltage-controlled oscillator (RF-VCO), driver, external modulator, and laser.

The subcarrier optical phase-locked loop does not directly control the tunable laser but modulates the intensity of the local oscillator laser through an optical voltage-controlled oscillator. The nonlinearity of the modulator generates subcarriers. The phase change caused by these subcarriers is caused by a change in their control voltage.

The advantage of the optical voltage-controlled oscillator is that it can change the optical phase of the subcarrier, based on the radio-frequency voltage-controlled oscillator. It does not need to directly modulate the laser at a high-speed frequency.

The subcarrier optical phase-locked loop is shown in Fig. 26.24. The optical phase-locked loop has the advantages of a wide range and fast frequency tuning, and the pseudo-amplitude modulation caused by the frequency change of the tunable laser can also be avoided. The relationship between the maximum linewidth of the laser and the system transmission rate is $\Delta v \leq 5.8 \times 10^{-6} R_b$ [93]. R_b is the bit rate in bit/s, when the bit-error rate is 10^{-10} and the power loss is 1 dB.

Parameters of the Optical Phase-Locked Loop

Following are the parameters of the optical phase-locked loop.

1. Residual phase error: This refers to the phase-error variance between the input and output. Its function is to measure the ability of the optical phase-locked loop system to track the signal light, that is, the phase shift generated when the local oscillator follows the signal light.
2. Tracking performance: In the locked state, the output light phase can stably track the input light phase and the error between the two is small. When the input light phase changes, the output light automatically tracks it within a certain range. The length of the tracking time and size of the steady-state error are both parameters used to evaluate the tracking performance of the system.

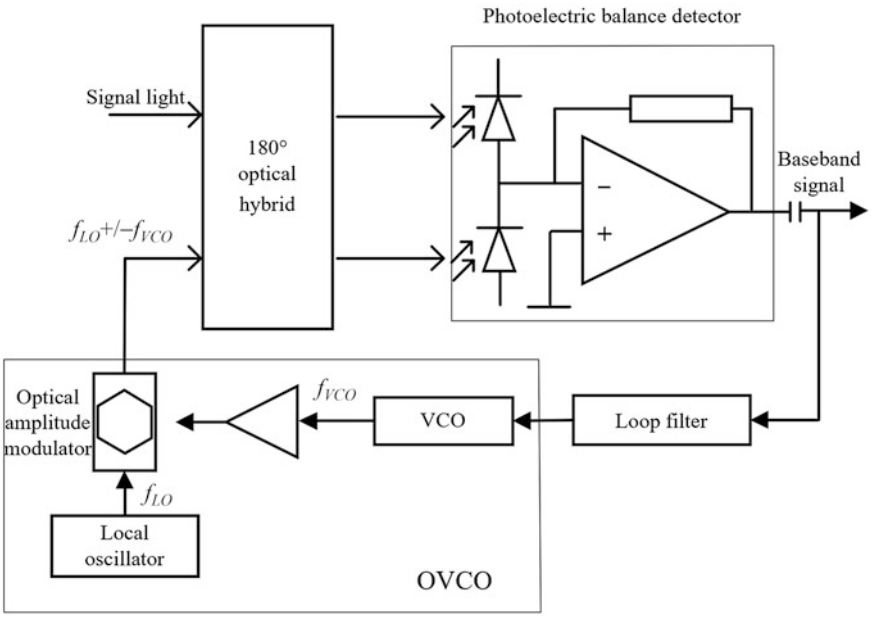

Fig. 26.24 Subcarrier optical phase-locked loop [45]

3. Loop bandwidth: The loop bandwidth refers to the −3-dB bandwidth of the closed-loop transfer function of the optical phase-locked loop, which is the maximum bandwidth at which the local oscillator laser can track the phase of the signal laser. Beyond this range, the local oscillator laser cannot automatically track the signal light. The greater the loop bandwidth, the better the system dynamics.
4. Lock time: This refers to the time required to recover the phase error to 1% when the input light exhibits a step jump. Thus, the locking time should be as short as possible.
5. Laser linewidth: This refers to the full half-peak width of the laser spectrum. This is because the laser is affected by elements of the external environment, such as excited atoms, phase noise, spontaneous ion emission, and temperature jitter. The lower the linewidth, the higher the spectral purity, the better the monochromatic performance of the laser, and the stronger the coherence.

Performance Comparison of Various Optical Phase-Locked Loops

To achieve high-performance coherent-optical communication, it is necessary to comprehensively consider the characteristics of various types of optical phase-locked loops, including the requirements for laser linewidth, types of transmission

Table 26.3 Comparison of performance parameters of various optical phase-locked loops

Type of OPLL	Balanced loop	Costas loop	Decision-driven loop	SyncBit loop	Dither loop	Subcarrier loop
Residual carrier	Yes	No	No	No	No	Yes
90° optical hybrid	No	Yes	Yes	No	No	No
AC coupling link	Not allowed	Allowed	Allowed	Allowed	Allowed	Not allowed
Transparent link	Yes	Yes	No	No	Yes	Yes
Laser linewidth	$\leq 5.8 \times 10^{-6}$	$\leq 5.02 \times 10^{-4}$	$\leq 4.5 \times 10^{-4}$	$\leq 3.1 \times 10^{-4}$	$\leq 2.6 \times 10^{-4}$	$\leq 5.8 \times 10^{-6}$
Data type	Analog, digital	Analog, digital	Digital	Digital	Analog, digital	Analog, digital
Phase-locked power adjustable	No	No	No	No	Yes	No
Characteristic	Laser phase noise tolerance is weak	Laser phase noise tolerance is weak	Only digital signals can be transmitted	Data preprocessing is required	Constant envelope modulation is required	OVCO scheme

signals, and other characteristics. Table 26.3 summarizes the main parameters and compares the performance of various types of optical phase-locked loops.

By comparing several different optical phase-locked structures and analyzing the table and the previous section, it can be seen that the structure of the balanced phase-locked loop is the simplest, and it does not require a 90° optical hybrid. If the energy loss is considered, the power of the 90° optical hybrid is 3 dB lower than that of the 180° hybrid in theory. The SyncBit optical phase-locked loop must preprocess the transmitted data signal, thus introducing additional bits and resulting in reduced spectral efficiency.

The phase-error variance of the decision-driven phase-locked loop is low. A dither phase-locked loop requires constant envelope modulation and a high laser linewidth. The Costas loop has excellent stability and strong capacity to accommodate laser phase noise, with the best comprehensive performance and wide application. The maximum allowable linewidth of the optical phase-locked loop is related to the communication rate of the system, that is, the higher the communication rate, the narrower the laser linewidth.

The Costas loop has the lowest laser-linewidth requirement. The subcarrier optical phase-locked loop can be seen as adding an optical voltage-controlled oscillator to the balanced optical phase-locked loop; therefore, the requirements for the laser linewidth of the subcarrier optical phase-locked loop are also higher.

Optical Phase-Locked Loops in Optical Wireless Coherent Communication

Optical Phase-Locked Loop for Coherent Optical Communication

To meet the requirements of a wider transmission bandwidth, longer transmission distance, and higher sensitivity of the optical communication system, optical coherent modulation technology is introduced into free-space optical communication to form coherent optical communication technology, which has a greater channel capacity and better frequency selectivity.

Figure 26.25 shows a schematic diagram of a optical wireless coherent communication system; its basic principle is the communication modulation part at the transmitter. The frequency and phase of the optical carrier to be transmitted are modulated according to the signal to be transmitted. After reaching the receiving end through an atmospheric transmission, the signal light and the local oscillator light are mixed in the optical hybrid to generate the differential frequency signal carrying the transmission information. The intermediate-frequency signal is obtained through a photoelectric detector, and the baseband signal can be directly obtained by zero-difference coherent detection.

However, owing to the complexity of the space environment, the frequency fluctuation of the signal light and the local oscillator light will negatively affect the performance of the coherent optical communication system, thus, reducing its advantages. Coherent optical communication based on an optical phase-locked loop can effectively capture the frequency of the signal light and maintain stable tracking. Its main application is to meet high requirements for sensitivity and communication speed; however, it cannot use an optical relay. Areas with high requirements for system power consumption and complexity include high-speed optical transmission networks and inter-satellite optical communication systems.

In a coherent optical communication system, an optical phase-locked loop is used to track the optical phase of the receiver, which to a certain extent, ensures a strict match between the signal light and the local oscillator light when mixing, to ensure coherent signal demodulation.

Figure 26.26 shows a schematic diagram of the optical phase-locked loop used in the optical wireless coherent detection process. Homodyne coherent detection has

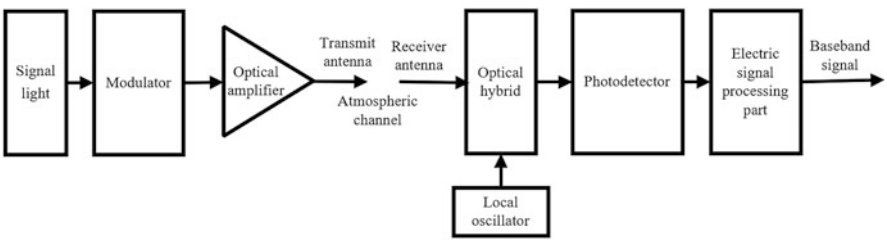

Fig. 26.25 Optical wireless coherent communication system

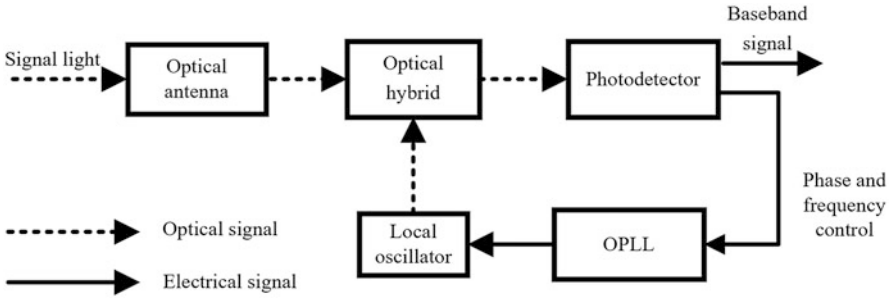

Fig. 26.26 Optical phase-locked loop in a coherent optical communication system

the advantage of directly obtaining the baseband signal [117]. An optical phase-locked loop is crucial for coherent optical communication systems.

Optical phase-locked loop technology receives and demodulates signals coherently in the optical domain and directly recovers the data signals. When the natural frequency difference between the input signal light and the local oscillator light is within a certain range, the optical phase-locked loop can ensure that the difference between the phases of the local oscillator optical signal and the input optical signal is always maintained in a fixed and limited range. This process, controlled by an optical phase-locked loop, is called the capture process.

If the phase difference between the final input optical signal and the local oscillator optical signal is stable, it is called the synchronization state or phase-locked state. In contrast, when the phase difference increases with time, it enters the lock-out state.

The working principle of homodyne coherent detection is shown in Fig. 26.26. The signal light and local oscillator light received by the receiving antenna are first sent into the optical hybrid for coherent mixing. Then, the optical-detection circuit is used to convert the obtained intermediate-frequency signal into the corresponding electrical signal, and then the phase-difference information is fed back to the optical phase-locked loop. This realizes the fast frequency tuning, optical-phase synchronization, and signal demodulation of the local oscillator.

Typical Applications of Optical Phase-Locked Loops

A homodyne coherent detection system based on an optical phase-locked loop has a strong anti-interference ability and a longer transmission distance, and is compatible with DPSK, QPSK, and other modulation formats. With the continuous research on homodyne coherent detection based on optical phase-locked loops, various countries have carried out space optical-communication plans and achieved certain results.

Table 26.4 lists the typical applications of optical phase-locked loops in optical wireless coherent communication. The LEO–LEO inter-satellite communication between the US NFIRE satellite and German TerraSAR-X was the first inter-satellite

Table 26.4 Typical applications of optical phase-locked loops in optical wireless coherent communication

coherent laser communication experiment in the world, which is of great significance for the coherent communication of wireless light.

It is predicted that with the demand for continuous communication development toward high capacity, ultra-long distances, and high speed, zero-difference coherent optical communication technology based on optical phase-locked loops is still the ideal choice for countries to realize space optical transmissions.

In addition, optical phase-locked loops play an important role in optical-frequency modulation, continuous-wave measurement, high-stability time-delay simulation for earth gravity-field measurement, large dynamic optical-fiber transmission links, and precision measurements, such as spectral analysis and other fields.

Summary

Both electric phase-locked loops and optical phase-locked loops have the advantages of a stable output-signal frequency, synchronous tracking, high-speed real-time reception, anti-interference, and noise-suppression performance and have important research value. With the development of optoelectronic technology and the continuous improvement of device technology, electric phase-locked loops and optical phase-locked loops have broad application prospects in many emerging research fields. To improve the practical application of phase-locked loop technology, its performance can be further improved and optimized, as summarized below.

1. Further study the relationship between the mixing efficiency and phase-locked loop error, loop bandwidth, and communication error rate to comprehensively improve the comprehensive performance of the phase-locked loop.
2. Improve the frequency-discrimination acquisition circuit. Optimize the acquisition algorithm. Improve the accuracy of the frequency-difference control in the phase-locked loop. Reduce the acquisition time of the loop frequency to quickly lock the phase-locked loop and increase the acquisition range of the loop frequency [98].
3. Expand the automatic loop-gain adjustment function of the optical phase-locked loop. Further, improve the system robustness, control accuracy, and system-communication performance [95].
4. Optimize the parameters and circuit design of the loop filter to enable the optical phase-locked loop to achieve high-precision performance. Improve the locking ability of weak light and more accurately eliminate the self-excited oscillation signal in the circuit [92].
5. Optimize the loop delay in the system and increase the loop bandwidth to ensure that the phase-locked loop can effectively suppress broadband phase noise while ensuring a certain phase margin.
6. Optimize the temperature-control system of the local oscillator and the signal light. Improve the temperature-control accuracy. Stabilize the temperature of the laser resonator and reduce the frequency drift [98].
7. Develop a fully integrated optical phase-locked loop to reduce loop delay. Further, improve the noise performance and dynamic characteristics of the optical phase-locked loop and reduce the volume and weight of the entire system [77].

Abstract

Deformable mirror is the key device to realize wavefront correction in adaptive-optics system, and its performance directly determines the wavefront-distortion correction ability of the system. This chapter summarizes the research progress of deformable mirrors at home and abroad. Taking several typical deformable mirrors as examples, the classification, modeling, and main performance indicators of deformable mirrors are introduced. Mirrors, thin film deformable mirrors, dual-piezoelectric deformable mirrors, micro-electromechanical systems (MEMS), deformable mirrors, and voice-coil deformable mirrors are introduced in detail. The correction accuracy of different control algorithms for wavefront distortion is analyzed, and the work done by Xi'an University of Technology in this field is also introduced. Finally, the future technological breakthroughs and improvement directions in this field are pointed out.

Introduction

A deformable mirror is a key device for correcting wavefronts in adaptive-optics systems, and its performance directly determines the wavefront-distortion correction ability of the system. This chapter reviews the research progress on deformable mirrors at home and abroad.

Taking several typical deformable mirrors as examples, their classification, modeling, and main performance indicators are introduced. Moreover, different types of deformable mirrors are discussed, such as separation actuator, spliced, thin film, dual piezoelectric, micro-electromechanical system (MEMS), and voice coil. Finally, the technical breakthroughs and directions for future improvement in this field are presented.

Deformable mirrors (DMs) are widely used in various optical systems to correct wavefront distortions. They correct the distorted wavefront by changing the optical path of the light-wave transmission. They offer the advantages of large travel and good linearity. Many types of deformable mirrors exist, and they each have different characteristics, such as different hysteresis, response times, and deformations. To improve the correction accuracy, it is necessary to control the deformable mirror using a control algorithm. Therefore, research on deformable mirror control algorithms has become a key task in adaptive optics.

Foreign Research Progress

In 1953, Babcock proposed the concept of adaptive optics. Its main idea was to place a "corrector" on the pupil surface, and change the surface shape of the corrector through real-time control of the optical wavefront to compensate for distortion caused by atmospheric disturbances. The corrector mentioned by Babcock in his groundbreaking discussion was called an "eidophor." Its working principle involved applying a thin oil film to the surface of a mirror, and applying a control voltage to the oil film. Under the effect of electrostatic forces, the oil film thickness changed with the spatial distribution of the charge, thus affecting the optical path of the incident light [1].

In 1976, Yellin et al. designed and fabricated a thin-film deformable mirror by comprehensively considering the frequency response and driving signal. A thin-film deformable mirror mainly adopts an ultrathin electrostatic film with a thickness of 0.5–1 μm. Because of the advantages of thin films, such as low voltage and zero hysteresis, thin-film deformable mirrors are the best choice for image compensation systems, both physically and in engineering, and have been widely used in the space field [2].

In 1979, Kokorowsky and Schwartz et al. proposed a dual-piezoelectric deformable mirror. It was composed of two piezoelectric-ceramic sheets bonded together with opposite polarization directions. Using the transverse–converse piezoelectric effect of piezoelectric materials, a voltage was applied to the sheet. One sheet

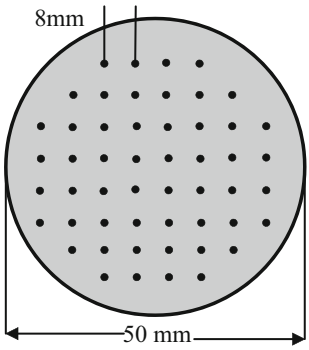

Fig. 27.1 Arrangement of deformation mirror actuators [6]

expanded and the other sheet shrunk in the direction perpendicular to the polarization, which deformed the surface shape of the deformable mirror [3, 4].

In 1982, Freeman et al. developed a phase-correction device that used a deformable mirror with a refrigeration system. The actuator arrangement is shown in Fig. 27.1. The deformable mirror had 52 control units. They used an 8 × 8 square array layout. The distance between adjacent actuators was 8 mm and the effective luminous aperture was 50 mm. A single actuator consisted of 99 piezoelectric chip stacks with a 15% coupling coefficient [5].

In the early 1990s, Hulburd et al. developed a spliced deformable mirror and real-time atmospheric compensation system. Each submirror of the spliced deformable mirror had three actuators made of piezoelectric-ceramic materials [7].

In 1994, Takami et al. designed a thin-film deformable mirror for the adaptive-optical system of the Subaru Telescope in Japan. The thin film of the deformable mirror was a 2-μm-thick nitrocellulose material. The diameter of the deformable mirror was 50.8 mm, the effective luminous aperture was 25 mm, and the surface shape had a 0.03λ root-mean-square (RMS) error. The electrode actuator was a 5 × 5 square array and the distance between adjacent actuators was 4 mm [8].

In 1997, Oppenheimer et al. developed a deformable mirror. The number of actuator control units was 349, and the mirror surface was 2-mm-thick silver plating. After flattening, the surface shape was better than 19-nm RMS [9].

In 1997, Bifano et al. developed a continuous-surface deformable mirror using micromachining technology. The deformable mirror had nine actuators with a 2-μm spacing. A performance test showed that the influence range of the adjacent actuators was 5–10% [10].

In 1998, Lowrey et al. tested the performance of three deformable mirrors with 349, 577, and 941 elements. The actuator spacing of the three deformable mirrors was 7 mm. The effective luminous aperture of the 349-element deformable mirror was 148 mm. After flattening, the surface error was 20-nm RMS. The diameter of the 577-unit deformable mirror was 182 mm, and the effective luminous aperture was 190 mm. After flattening, the surface error was 19-nm RMS.

The 941-unit deformable mirror had 941 actuators in a 35 × 35 square-array arrangement. The working voltage was ±30 V, the bias voltage was 70 V, the

maximum travel was ±2 μm, and the effective luminous aperture of the deformable mirror was 288 mm [11]. The 941-element deformable mirror was applied to the adaptive-optical system of a SOR3.5 telescope to compensate for the phase interference in the atmosphere [12].

In 2000, Paterson et al. developed a low-cost adaptive-optical system using a 37-element thin-film deformable mirror. The film was made of silicon nitride with a 500- to 700-nm thickness. The effective aperture of the film-deformable mirror was 15 mm, distance between adjacent actuators was 1.75 mm, and maximum deformation was 1000 nm [13]. Thin-film deformable mirrors can measure and correct human-eye aberrations in real time and are widely used in human-eye adaptive-optics technology [14].

To satisfy the requirements of space-coronal observation telescopes and planetary high-resolution imaging telescopes [15], Ealey et al. developed a deformable mirror with a high-density actuator array in 2004. This deformable-mirror technology was based on a modular actuator array and could be expanded to thousands of actuator elements. The number of actuator control units was 1946. They were arranged in a 42 × 42 square array, and the spacing between adjacent actuators was 1 mm [16].

In 2005, Sinquin et al. developed a 188-electrode deformable mirror for the Subaru Telescope and successfully applied it to the adaptive-optics system, enabling it to reach the diffraction limit [18]. The performance of the deformable mirror was tested and is described in detail in [17].

In 2008, Sinquin et al. developed an actuator module for a high-density deformable mirror with the support of the European Southern Observatory. It had a 50 × 50 square array with a 1-mm distance between adjacent actuators. They predicted that with the development of technology, high-density deformable mirrors could greatly increase, with 30,000 actuator control units, a 200-mm maximum effective luminous aperture, and 3-μm travel [18].

In 2008, Comelissen et al. developed a 4096-unit MEMS deformable mirror to correct higher-order wavefront aberrations. The effective aperture size of the deformable mirror was 27.2 mm, and the actuators were in a 64 × 64 square arrangement with a 400-μm actuator spacing. The working bandwidth was 2.5 kHz, and the travel could reach 4 μm [18].

In 2010, Dekany et al. developed a 4356-element deformable mirror for a Palomar 5.1-m telescope, enabling the ultraprecision near-infrared observation of exoplanets [19].

In 2012, Verpoort et al. developed a new single-pressure deformable mirror for real-time intracavity phase control of high-power continuous lasers and introduced its dynamic characteristics, influence function, and other characteristics. The effective aperture of the deformable mirror was 9 mm. In the low-order aberration mode, it produced several micrometers of travel [20].

In 2016, Kuiper et al. designed a 61-element electromagnetic deformable mirror. Its diameter was 200 mm, the actuator coupling efficiency was 24%, and the distance between adjacent actuators was 22 mm. Deformable mirrors are used in various applications in terrestrial astronomy and space fields [21]. Two years later, Kuiper et al. studied an actuator based on the variable reluctance principle, developed a

deformable mirror using this technology, and tested its performance. The surface diameter of the deformable mirror was 160 mm, with 57 actuator control units [22].

Domestic Research Progress

In 1995, Jiang et al. developed a system to correct wavefront distortion under different turbulence intensities. A separation-actuator continuous-surface deformable mirror was used to correct higher-order aberrations in the system. It had 55 deformable-mirror actuator control units. The effective luminous aperture was 100 mm, the deformation was ±1.5 μm, nonlinear hysteresis was less than ±4%, and resonant frequency was greater than 2 kHz [23].

In 1998, Jiang et al. also developed a 61-unit adaptive-optical system and docked it with a tracking and pointing system, realizing the first atmospheric-transmission compensation experiment in China. The effective aperture of the deformable mirror was 120 mm, the maximum deformation was ±3 μm [a lot], the nonlinear hysteresis was less than 5%, the resonant frequency was greater than 2 kHz, and the interconnection value was 8–12% [24].

In 1998, Ling et al. developed a discrete piezoelectric deformable mirror with 61 actuation units and applied it to an adaptive-optical system. They successfully completed the docking between acquisition, pointing, and tracking (APT) and AO systems, and improved the APT tracking accuracy [25].

In 2006, Xiang et al. developed a new deformable mirror with a transparent electrode using MEMS technology and tested its performance. A schematic diagram is shown in Fig. 27.2. The deformable mirror could perform bidirectional deformations. When a certain driving voltage was applied, the maximum deformation range of the deformable mirror reached 19 μm [26].

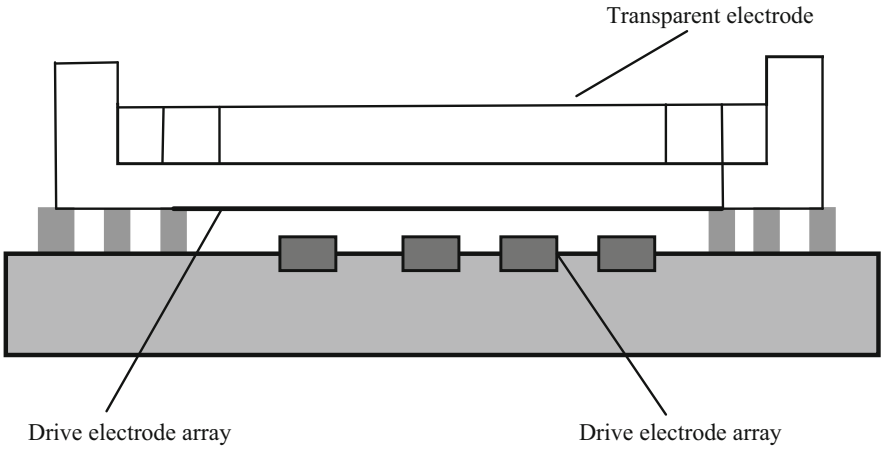

Fig. 27.2 Schematic diagram of a deformable mirror with transparent electrodes [26]

In 2008, Zhou et al. developed a 20-element dual-piezoelectric deformable mirror, and tested and analyzed the performance. The results showed that the dual-piezoelectric deformable mirror was suitable for low-order aberration corrections [27].

In 2010, Wei et al. developed a 127-element deformable mirror and applied it to a 1.8-m astronomical telescope to achieve high-resolution star imaging [28].

In 2012, Lin et al. initially developed the DM21-1 deformable mirror. The effective luminous aperture of the deformable mirror was 50 mm. The actuator was composed of a piezoelectric-ceramic material. It had 21 actuator control units, arranged in a 5 × 5 square array. The distance between adjacent actuators was 9 mm. Figure 27.3 shows the actuator arrangement of the deformable mirror [29].

In 2013, Lin et al. developed a 97-element piezoelectric deformable mirror. The effective luminous aperture of the deformable mirror was 70 mm, the actuators were arranged in an 11 × 11 square array, the distance between adjacent actuators was 6.5 mm, and the intersection value was 4.8% [30].

In the same year, Lin et al. developed a deformable mirror that separated the continuous surface of the actuator. The effective luminous aperture was 90 mm, and the number of actuator control units was 137, arranged in a 13 × 13 square array. The distance between adjacent actuators was 7 mm, the interconnection value was 22–26%, and the maximum deformation was ±2.5 μm. The nonlinear hysteresis was less than 5%, the total resonant frequency was greater than 12 kHz, and the surface shape was better than $\lambda/50(\lambda = 632.8$ nm) RMS after active flattening [31].

To ensure the normal use of adaptive-optics systems at low temperatures and correct higher-order aberrations, You et al. developed a 913-element continuous-surface deformable mirror in 2019 and tested and analyzed its main performance indicators. The results showed that the maximum deformation of a single actuator of the deformable mirror was ±3.5 μm. The interaction value of adjacent actuators was 9.3% [32].

In 2022, Du et al. studied the submirror assembly of a spliced deformable mirror and developed an integrated design to ensure the surface accuracy and stability of the

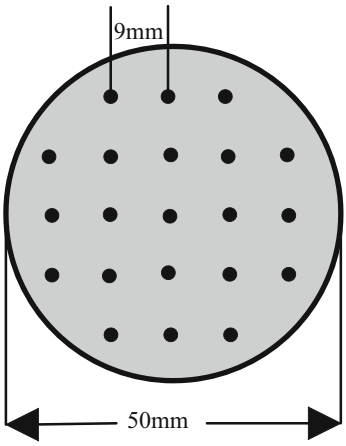

Fig. 27.3 Actuator arrangement of a 21-unit deformable mirror [29]

primary mirror. The spliced deformable mirror was composed of three hexagonal Zerodur submirrors. After integrating the design, the total mass of the submirror was 1.74 kg, and the surface shape of the submirror was better than 0.019λ RMS. It met the design requirements and provided a new idea for the integrated design of space mirrors [33].

Deformable Mirrors

A deformable mirror compensates for wavefront aberrations in a light wave by changing the light wave's optical-path difference. It contains many units. Each independent unit has its own actuator. When a driving voltage is applied to the actuator, the surface shape of the deformable mirror changes. Deformable mirrors play an important role in adaptive-optics systems. Therefore, the study of deformable mirrors affects the development of the entire system.

Classification of Deformable Mirrors

Deformable mirrors are widely used in the adaptive-optics field. One method classifies deformable mirrors according to their surface shape, and the other classifies them according to their driving mode. In this chapter, two classification bases are introduced in detail. The deformable mirrors used in adaptive-optics applications by Ke Xizheng et al. of Xi'an University of Technology are introduced.

Divided by Surface Shape

Depending on their surface shape, deformable mirrors can be divided into two types: discrete surface (whose surface structure is shown in Fig. 27.4) and continuous surface (whose surface structure is shown in Fig. 27.5) [34].

Most early deformable mirrors were discrete-surface deformable mirrors composed of several independent submirrors. Each independent mirror modified a wavefront by controlling the translational or tilting motion of the actuator of each independent submirror. This type of deformable mirror is easy to control and assemble; however, its surface is discrete and large. Gaps between adjacent mirror

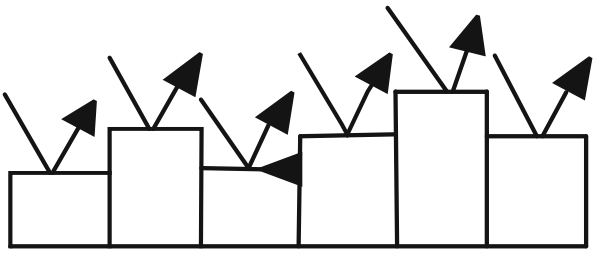

Fig. 27.4 Surface structure of a discrete-surface deformable mirror [35]

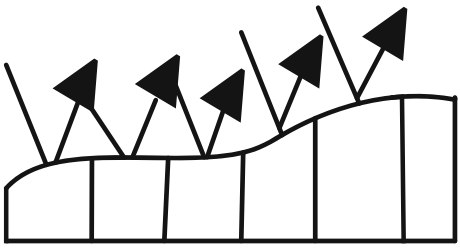

Fig. 27.5 Surface structure of a continuous-surface deformable mirror [35]

surfaces lead to a loss of light energy and affect the correction accuracy of the deformable mirror.

A continuous-surface deformable mirror (CSDM) moves the surface of the deformable mirror through different driving modes to change its shape. This type of deformable mirror has a continuous surface without gaps; therefore, no light is lost and the phase is continuous. Consequently, continuous-surface deformable mirrors have a higher correction accuracy than discrete-surface deformable mirrors [35].

Divided by Driving Mode

According to their driving mode, deformable mirrors can be divided into piezoelectric, electromagnetic, and electrostrictive [36]. The piezoelectric deformable mirror has a hysteresis; therefore, a specific control algorithm must be used to eliminate the hysteresis to ensure the correction accuracy; however, this increases the complexity of the correction algorithm and reduces the real-time performance of the system [34].

The electromagnetic deformable mirror is mainly composed of a coil and a magnet. When the coil is energized, the interaction force between the coil and magnet causes the mirror surface to move up and down, changing its shape. Electromagnetic deformable mirrors have large travel and wide correction ranges, and are widely used in optical communication systems [35].

An electrostrictive deformable mirror is also called a lead–magnesium–niobate (PMN)-deformable mirror. The actuator is made of electrostrictive materials (Pb (Mg, Nb,) O_3 (PMN)). The main difference between piezoelectric deformable mirrors and electromagnetic deformable mirrors lies in the different materials used to make actuators.

Ke Xizheng et al. at Xi'an University of Technology have been successful in adaptive-optics applications. The deformable mirror used in this application was the DM69, which is a continuous deformable mirror driven by electromagnetism. The DM69 is controlled by applying a control voltage to the 69 actuators in the deformable mirror. The effective luminous aperture is 10.5 mm, the weight is 0.45 kg, the distance between adjacent actuators is 1.5 mm, and the maximum correction amount of the tilt wavefront peak–valley (PV) is 60 μm. The working temperature is −10–35 °C, and the nonlinear error is less than 3%. A structural diagram of the DM69 deformable mirror is shown in Fig. 27.6. Figure 27.7 shows the layout and sequencing diagram of the DM69 deformable-mirror actuator.

Typical Deformable Mirrors

As key wavefront-correction components, deformable mirrors have been studied for many years, and researchers have summarized their rich experience. The following are typical deformable mirrors, according to their structure and working principle.

Separation-Actuator Continuous-Surface Deformable Mirror

The structure of a continuous-surface deformable mirror with separate actuators is shown in Fig. 27.8. From bottom to top, the deformable mirror is composed of three parts: the base, actuator, and specular surface (mirror). The reflector adopts a continuous thin lens, and the surface shape of the thin lens changes with the actuator displacement. When the actuator moves, the base does not deform, but the thin mirror connected to the actuator deforms accordingly. This requires the mirror to be much more flexible than the base; thus, the base should be made of very hard metal materials. The design difficulty of the deformable mirror mainly lies in selecting the actuator materials.

The actuator materials for separating the actuator continuous-surface deformable mirrors are generally piezoelectric materials (Pb (Zr, Ti,) O_3) or electrostrictive materials (Pb (Mg, Nb,) O_3). The actuators are made of these two materials; the former is called PZT, and the latter is called PMN [6]. When a driving voltage is applied to a deformable mirror, the displacement of the voltage-driven actuator changes, resulting in a deformation of the surface shape of the deformable mirror, which is similar to a Gaussian function [37]. In addition, the surface shapes of

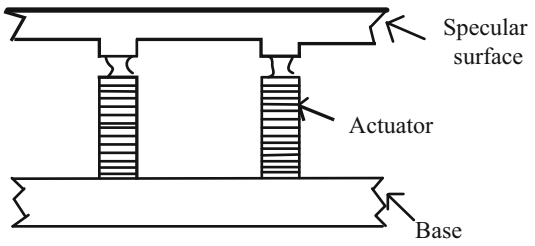

Fig. 27.8 Structure of continuous-surface deformable mirror for a separation actuator

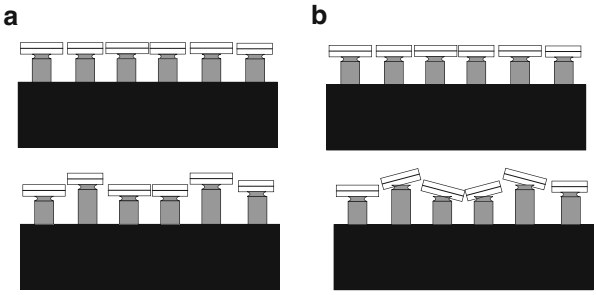

Fig. 27.9 Spliced deformable mirror. (**a**) Piston only; (**b**) piston and tip/tilt

mirrors on adjacent actuators also deform, and the deformation is generally 10–30% of the maximum deformation of deformable mirrors.

Spliced Deformable Mirror

The basic structure of the spliced deformable mirror is shown in Fig. 27.9. It can be observed from the figure that the mirror surface is separated into several small submirrors. One or three actuators are arranged under each submirror to adjust the mirror surface. If only one actuator is under the subreflector, the subreflector will move a piston along the beam-propagation direction to adjust the mirror surface. If three actuators are under the submirror, the submirror not only moves a piston along the beam-propagation direction, but also makes a 2D tip/tilt adjustment to change the surface shape of the deformable mirror.

A gap exists between each submirror of the deformable mirror, which reduces the utilization rate of the light energy received by the deformable-mirror surface and increases the difficulty of adjusting the mirror surface. To ensure a continuous wavefront structure, the phases between adjacent submirrors must be the same; therefore, this deformable mirror is rarely used in practical system applications.

Thin-Film Deformable Mirror

The thin-film deformable mirror is supported by multiple actuators, and the mirror surface is a continuous silicon-nitride mirror. Its structure is shown in Fig. 27.10a, and its deformation principle is shown in Fig. 27.10b. The film is very flexible; thus, only a small force is needed to change its surface shape. Generally, the actuator is made of an electrostrictive material, and a fixed support is required around the film to

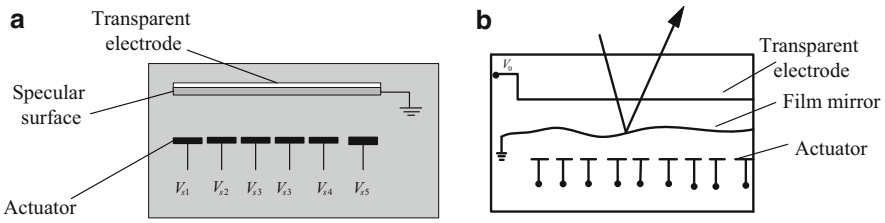

Fig. 27.10 (**a**) Structure diagram and (**b**) deformation schematic diagram of a thin-film deformable mirror

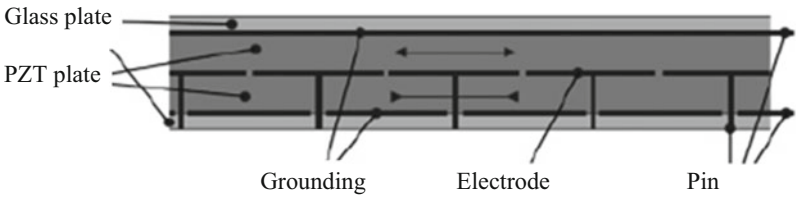

Fig. 27.11 Cross-section diagram of a dual-piezoelectric deformable mirror

provide tension for it to form a plane. The static deformation of the thin-film deformable mirror is [2]:

$$\nabla^2 z = \frac{-p(r)}{T_m}, \tag{27.1}$$

where $p(r)$ is the pressure on the film (unit: Nm^{-1}), and T_m is the linear tension of the film (unit: Nm^{-1}).

Dual-Piezoelectric Deformable Mirror

The dual-piezoelectric deformable mirror is composed of two piezoelectric-ceramic plates, two common electrodes (as shown in Fig. 27.11), one control electrode, and two thin glass plates. The cross-section of the deformable mirror is shown in Fig. 27.11. One common electrode is located above one piezoelectric-ceramic sheet, and the other is located below the other piezoelectric-ceramic sheet. The control electrode is located between the two piezoelectric-ceramic sheets. Two thin optical glass sheets are used as reflectors to connect the surfaces of the piezoelectric-ceramic sheets.

The basic principle of the deformable mirror is to apply a voltage to the control electrode using the transverse–converse piezoelectric effect of piezoelectric-ceramic materials. One of the piezoelectric-ceramic plates expands laterally, while the other shrinks laterally, resulting in a deformation of the thin lens connected to its surface. The deformation of a thin mirror can be expressed as [6]:

$$\nabla^4 r(x,y) = -A\nabla^2 V(x,y), \tag{27.2}$$

where $V(x, y)$ is the voltage on the piezoelectric-ceramic sheet, and A is a constant related to the sheet material properties.

MEMS Deformable Mirror

The micro-electromechanical system (MEMS) deformable mirror is a type of microdevice made of a silicon wafer using a thin-film process. The three manufacturing steps are depositing the film, patterning the film with a mask, and etching the film through the mask. These steps are repeated until a complete multilayer structure is generated. Finally, the silicon device is fabricated using wet etching. Figure 27.12 shows a discrete deformable mirror prepared using MEMS technology [38].

Voice-Coil Deformable Mirror

The bottom layer of the voice-coil deformable mirror, provided by the official website of the French ALPAO adaptive-optics product manufacturer, is composed of an independent coil, and the upper layer is composed of a covered thin mirror. The coil and thin mirror are connected using a magnet with a connecting rod. When the coil is energized, the magnet above the coil moves up and down under the reaction force of the ampere force, driving the connecting rod to move the thin mirror on top of it, causing the surface of the thin mirror to deform.

A voice-coil deformable mirror converts electrical energy (voltage) into kinetic energy (displacement). According to the static theory, the relationship between the voltage U and displacement x is [39]:

$$x = \frac{k_s U}{RK}, \tag{27.3}$$

where k_s denotes the motor-force constant, R is the coil resistance, and K is the structural stiffness matrix.

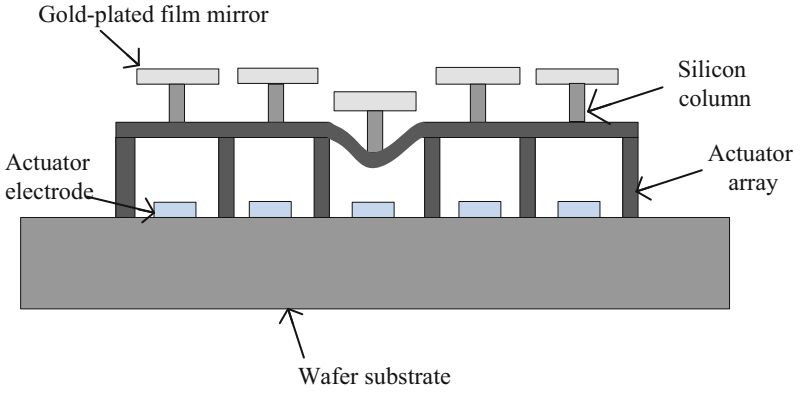

Fig. 27.12 MEMS discrete-surface deformable mirror

Performance Index of Deformable Mirrors

The main performance metrics of a deformable mirror, in addition to its luminous aperture and surface accuracy, are as follows:

1. Linearity: This mainly depends on the actuator material. The better the linearity of a deformable mirror, the higher its control accuracy.
2. Number of control units: This is the number of deformable-mirror actuators. It is usually determined by an adaptive-optical system according to the correction requirements and is proportional to the correctable spatial frequency.
3. Response time: When a control voltage is applied to the actuator of a deformable mirror, the time from the beginning to the end of the deformation of the surface shape is called the response time. The shorter the response time, the better the performance of the deformable mirror.
4. Resonant frequency: This is the lowest frequency before the deformable mirror reaches the resonant point. It is generally required to be ten times higher than the operating frequency of the deformable mirror.
5. Stability: The actuator of a deformable mirror must have sufficient strength, as well as static and dynamic stability. Taking discrete deformable mirrors as an example, static stability means that the deformable mirrors can maintain the same surface shape when working in different environments, whereas dynamic stability means that the surface can be restored to its original shape when the deformable mirrors stop working [40].

Model of a Deformable Mirror

We consider the relationship between the shape function $\varphi(x, y)$ of the deformable mirror, influence function $f_k(x, y)$ of the kth actuator, and control-voltage signal V_k of the kth actuator:

$$\varphi(x,y) = \sum_{k=1}^{n} V_k \cdot f_k(x,y), \tag{27.4}$$

where n represents the number of actuators. f is the influence function of the deformable mirror, which is usually regarded as a Gaussian function [37]:

$$f(x,y) = \exp\left[\mathrm{In}\omega\left(\sqrt{(x-x_i)^2 + (y-y_i)^2}/d\right)^{\alpha}\right], \tag{27.5}$$

where α is the exponent of the Gaussian function; d is the distance between actuators; x_i is the abscissa of the ith actuator; and y_i is the ordinate of the ith actuator; that is, (x_i, y_i) is the coordinate of the ith actuator. N is the number of actuator control units and ω is the coupling coefficient.

Deformable-Mirror Control Algorithms

A deformable mirror is one of many wavefront correctors. It can compensate for wavefront aberrations of a light wave by changing its optical path and correcting the wavefront aberration. We not only improved the structure and manufacturing process of deformable mirrors through technical innovation but also improved the correction accuracy of the deformable mirror by optimizing its control algorithm.

This section introduces a control algorithm, decoupling control algorithm, and sparse-sampling control algorithm based on the Prandtl–Ishlinskii (PI) hysteresis model and summarizes the application of deformable-mirror control algorithms in adaptive optics studied by Xi'an University of Technology.

Control Algorithm Based on the PI Hysteresis Model

The actuator of the piezoelectric deformable mirror, driven by the control voltage, cannot keep up with the change in the applied voltage and has hysteresis characteristics. Yang [41] proposed a control algorithm to eliminate the hysteresis characteristics and obtain the actual voltage, after the actuator eliminated the hysteresis. The basic principle of the algorithm is to describe the hysteresis characteristics of the piezoelectric deformable mirror using a mathematical model of the PI hysteresis, and then use its inverse model to eliminate the hysteresis characteristics of the piezoelectric deformable mirror.

The surface-shape information of a piezoelectric deformable mirror is expressed using a Zernike polynomial, as follows:

$$\varphi(x,y) = \sum_{j=1}^{m} a_j Z_j(x,y), \tag{27.6}$$

where a_j is the coefficient of the jth term of the Zernike polynomial and m is the number of terms in the Zernike polynomial. The influence function $f_i(x, y)$ of the ith actuator is expressed as a Zernike polynomial, as follows:

$$f_i(x,y) = \sum_{k=1}^{M} b_{ki} Z_k(x,y), \tag{27.7}$$

where b_{ki} denotes the coefficient of the ith actuator at $Z_k(x, y)$. Equation (27.6) can also be expressed as

$$\begin{aligned} \varphi(x,y) &= \sum_{i=1}^{N} v_i f_i(x,y) \\ &= \sum_{i=1}^{N} v_i \left[\sum_{k=1}^{M} b_{ki} Z_k(x,y) \right] \\ &= \sum_{k=1}^{M} \left(\sum_{i=1}^{N} v_i b_{ki} \right) Z_k(x,y). \end{aligned} \tag{27.8}$$

The Zernike polynomial coefficients of the influence functions of n piezoelectric actuators are stored in matrix B, which is called the response matrix. The relationship between the piezoelectric-actuator control-voltage vector $\boldsymbol{v}$ and deformable-mirror surface-shape vector $\boldsymbol{a}$ is obtained as follows:

$$\boldsymbol{a} = \boldsymbol{B}\boldsymbol{v}, \begin{bmatrix} a_1 \\ a_2 \\ \vdots \\ a_m \end{bmatrix} = \begin{bmatrix} b_{11} & b_{12} & \cdots & b_{1n} \\ b_{21} & b_{22} & \cdots & b_{2n} \\ \vdots & \vdots & \ddots & \vdots \\ b_{m1} & b_{m2} & \cdots & b_{mn} \end{bmatrix} \begin{bmatrix} v_1 \\ v_2 \\ \vdots \\ v_n \end{bmatrix}, \tag{27.9}$$

where n is the number of actuators and v_n is the driving voltage of the nth actuator. The deformation of each actuator is calculated using this formula. The mathematical model of a PI hysteresis is expressed as [41]

$$\begin{aligned} y(t) &= \boldsymbol{w}^{\mathrm{T}} \boldsymbol{H}_r[v(t), \boldsymbol{y}_0] \\ &= \sum_{i=0}^{n} w_i \cdot \max\{v(t) - r_i, \min[v(t) + r_i, y_i(t - T)]\}, \end{aligned} \tag{27.10}$$

where $w^T = [w_0, w_1, \ldots, w_n]$ is the weight vector, $\boldsymbol{H}_r$ represents a hysteresis operator with threshold r, $r = [r_0, r_1, \ldots, r_n]^T$ is the threshold vector, and $0 = r_0 < r_1 < \ldots < r_n < r_{\max}$ is the maximum input value. $n + 1$ is the number of operators used, v is the input (voltage) of the hysteresis operator, y_0 is the initial value of the output (deformation) of the hysteresis operator, T is the sampling period, and $y_i(t - T)$ is the output of the ith operator the moment before.

Because the PI hysteresis model and its inverse model are symmetric with respect to $y = x$, and their product is the unit matrix E, the expression of the output drive voltage (also the actual voltage after eliminating the hysteresis), with the deformation as the input of the PI-hysteresis inverse model, is

$$\begin{aligned} v(t) &= w'^{T} \boldsymbol{H}_{r'}[y(t), v_0] \\ &= \sum_{i=0}^{n} w'_i \cdot \max\{y(t) - r'_i, \min[y(t) + r'_i, v_i(t - T)]\}, \end{aligned} \tag{27.11}$$

where $w'^T = \left[w'_0, w'_1, \ldots, w'_n\right]$ is the weight vector of the inverse model, $r' = \left[r'_0, r'_1, \ldots, r'_n\right]^T$ is the threshold vector of the inverse model, $\boldsymbol{H}_{r'}$ represents a hysteresis operator with a threshold of r', and $v_i(t - T)$ is the output of the previous moment of the ith operator.

Decoupling Control Algorithm

When an actuator of a deformable mirror operates, the mirror connected to the actuator position deforms, and the mirrors connected to the adjacent actuators also deform to some extent, which causes a coupling between the actuators. When multiple deformable mirrors work synchronously, owing to the different spatial-

distribution characteristics of the deformable mirrors, a coupling effect occurs between the deformable mirrors. This may cause their correction quantities to offset each other and waste their correction range.

Coupling affects the correction effect of the deformable mirror and the system stability. To suppress this coupling, many scholars have proposed decoupling control algorithms to improve the correction accuracy of deformable mirrors.

Decoupling Control Algorithm of a Single Deformable Mirror

Zernike polynomials can only describe slowly changing wavefronts. Because the influence function of the deformable-mirror actuator changes rapidly with space in the local position, the influence function of the actuator cannot be expressed using Zernike polynomials. The accuracy of the deformable mirror is limited when determining the control quantity or driving voltage.

Because Zernike polynomials have difficulty expressing wavefront information completely and accurately, Liu et al. [42] proposed to directly use the wavefront-aberration plane to obtain the driving voltage of the deformable mirror. That is, they decouple the wavefront from the driving voltage through a direct-wavefront response matrix.

The surface shape of a specified area is expressed by Eqs. (27.4) and (27.5) as [42]

$$S = \sum_{i=1}^{n} v_i \times R_i, \tag{27.12}$$

where

$$S = \begin{bmatrix} s_{11}\ s_{12} \ldots s_{1e} \\ s_{21}\ s_{22} \ldots s_{2e} \\ \ldots\ \ \ldots\ \ \ldots\ldots \\ s_{h1}\ s_{h2} \ldots s_{he} \end{bmatrix}; R_i = \begin{bmatrix} r_{i_{11}}\ r_{i_{12}} \ldots r_{i_{1e}} \\ r_{i_{21}}\ r_{i_{22}} \ldots r_{i_{2e}} \\ \ldots\ \ \ldots\ \ \ldots\ldots \\ r_{i_{h1}}\ r_{i_{h2}} \ldots r_{i_{he}} \end{bmatrix},$$

where i represents the ith actuator, S represents the matrix of the specified area, and s_{11}, s_{12}, …, s_{he} are elements in matrix S, that is, the value of each element corresponding to the sampling point. h is the number of horizontal samples in the specified area, e is the number of vertical samples in the specified area, and the total number of samples is $h \times e$. R_i is also a matrix, where $r_{i_{11}}$, $r_{i_{12}}$, …, $r_{i_{he}}$ are the elements in matrix R_i, and each element corresponds to the value of the sampling point of the ith actuator in the specified area under the unit voltage.

The surface shape in the specified area can also be expressed by a Zernike expression

$$\Phi = \sum_{j=1}^{m} a_j \times Z_j, \tag{27.13}$$

where Φ is a matrix composed of the sampling points of the wavefront shape in the specified area, Z_j is a matrix composed of the values of Zernike polynomials in the specified size area, and a_j is the coefficient of the jth term of the Zernike polynomials.

According to the wavefront-compensation principle of deformable mirrors,

$$\Phi + S = 0, \tag{27.14}$$

where S is a zero matrix with the same dimensions. From Eqs. (27.12) and (27.14), we obtain

$$\Phi = -\sum_{i=1}^{m} v_i \times R_i. \tag{27.15}$$

Because the wavefront information can also be expressed by Zernike polynomials,

$$\sum_{j=1}^{m} a_j \times Z_j = -\sum_{i=1}^{m} v_i \times R_i. \tag{27.16}$$

It can be seen from Eq. (27.16) that no matter how many Zernike terms there are, the driving voltage of the deformable mirror can be calculated.

Decoupling Control Algorithm of Dual-Deformable Mirrors

Dual-deformable mirrors are used in the system to correct the wavefront distortion and improve the correction accuracy. The first type is a deformable mirror with a high coupling coefficient and low spatial resolution, commonly called a low-order deformable mirror, which is used to compensate for large-scale and low-order aberrations in wavefront distortion. The second type is a deformable mirror with a low coupling coefficient and high spatial resolution, usually called a high-order deformable mirror, which is used to compensate for small and high-order aberrations in wavefront distortion.

The residual-wavefront slope g is reconstructed using a Zernike polynomial, and the expression is [43]

$$g = Za, \tag{27.17}$$

where Z is the wavefront reconstruction matrix composed of Zernike polynomials and a is the coefficient of the Zernike polynomials. According to Eq. (27.19), the coefficient expression of the Zernike polynomial is

$$a = Z^{+}g \tag{27.18}$$

$$g = g_w + g_t, \tag{27.19}$$

where Z^+ is the generalized inverse matrix of Z, g_w is the uncompensated wavefront aberration of the lower-order deformable mirror, and g_t is the uncompensated wavefront aberration of the higher-order deformable mirror.

According to the space-compensation capability of the low-order deformable mirror, some low-order mode coefficients in coefficient a of the Zernike polynomial are selected as low-order aberrations and assigned to the low-order deformable mirror. The expression is

$$a_w = I_w a = I_w Z^+ g, \tag{27.20}$$

where I_w is the diagonal matrix used to select low-order aberrations. They are usually assigned to uncompensated mode aberrations of low-order deformable mirrors by setting the diagonal elements to 0 or 1, such as $I_w = \mathrm{diag}(1, 1, 1, 1, 1, 0, 0\ldots)$.

Because the low-order deformable mirror is responsible for compensating the low-order Zernike mode component in the wavefront aberration, the cumulative voltage v_w of the low-order deformable mirror is

$$v_w = R_w^+ Z a_w = R_w^+ Z I_w Z^+ g, \tag{27.21}$$

where R_w^+ is the pseudo-inverse matrix of the slope response of a low-order deformable mirror.

Using a typical proportional–integral (PI) controller, the driving voltage V_w of a low-order deformable mirror is

$$V_w(k+1) = k_p{}^* V_w(k) + k_i{}^* v_w, \tag{27.22}$$

where k_p and k_i are the control parameters of the PI controller, representing the proportional and integral coefficients of the current controller, respectively. Moreover, the wavefront-distortion slope g_t of a high-order deformable mirror is expressed as

$$g_t = g - g_w = (I - Z I_w Z^+) g, \tag{27.23}$$

where I denotes the identity matrix. The cumulative voltage v_t and driving voltage V_t of the high-order deformable mirror are as follows:

$$v_t = R_t^+ g_t = R_t^+ (I - Z I_w Z^+) g \tag{27.24}$$

$$V_t(k+1) = k_p{}^* V_t(k) + k_i{}^* v_t, \tag{27.25}$$

where R_t is the slope-response matrix of the high-order deformable mirror.

Because deformable mirrors have fitting errors for Zernike modes of different orders, coupling will occur when high-order and low-order deformable mirrors work simultaneously. To suppress the coupling between the two deformable mirrors, according to the correlation between the influence function of each actuator of the higher-order deformable mirror and the Zernike mode assigned to the lower-order

deformable mirror, a coupling-suppression matrix R_m of the higher-order deformable mirror was constructed. The suppression matrix is expressed as follows:

$$R_m(i,j) = k\frac{\iint V_i(x,y)Z_j(x,y)ds}{\iint Z_j(x,y)Z_j(x,y)ds}, \tag{27.26}$$

where V_i (x, y) is the influence function of the ith actuator of the high-order deformable mirror, $Z_j(x, y)$ is the surface function of the jth-order Zernike mode, and k is the coupling-suppression factor used to adjust the coupling-suppression degree of the high-order deformable mirror.

If the high-order deformable mirror is not coupled to the low-order deformable mirror, the total drive voltage satisfies the following formula:

$$0 = R_m V_t. \tag{27.27}$$

To eliminate the coupling component between the high-order and low-order deformable mirrors, we reset the driving voltage V_t of the high-order deformable mirror according to Eq. (27.27). The process is as shown in Eqs. (27.28) and (27.29):

$$\begin{bmatrix} I \\ R_m \end{bmatrix} V_t' \approx \begin{bmatrix} V_t \\ 0 \end{bmatrix} \tag{27.28}$$

$$V_t' = \begin{bmatrix} I \\ R_m \end{bmatrix}^+ \begin{bmatrix} V_t \\ 0 \end{bmatrix} = C \begin{bmatrix} V_t \\ 0 \end{bmatrix}. \tag{27.29}$$

In Eq. (27.29), C is the reset matrix and V_t' is the control voltage of the high-order deformable mirror; that is, there is no voltage component coupled with the low-order deformable mirror in V_t'.

Laplace-Eigenfunction Decoupling Control Algorithm

Because the first-order partial derivative of the Zernike polynomial is not orthogonal, the influence function of the higher-order deformable-mirror actuator must be accurately measured or fitted before constructing its coupling-suppression matrix. Some large-aperture telescope systems require numerous deformable mirrors with actuating elements. The large number of actuating elements makes it difficult to measure the influence function of each actuator. Therefore, a Laplace-eigenfunction decoupling control algorithm is introduced.

By solving the Laplace eigenfunctions in different pupil regions under different homogeneous Neumann boundary conditions, a wavefront-reconstruction matrix is constructed using the eigenfunctions, and the driving voltage of the higher-order deformable mirror is calculated. Because the first-order partial derivative of the eigenfunction is orthogonal, it is not necessary to measure the influence function of the higher-order deformable-mirror actuator when constructing the coupling-suppression matrix of the higher-order deformable mirror [44].

Under the homogeneous Neumann boundary condition, the first-order partial derivative of the Laplace eigenfunction $\nabla W(r)$ is orthogonal [43]:

$$\begin{aligned}\int_{\sigma} \nabla W_i(r) \nabla W_j(r) d\sigma &= -\int_{\sigma} \nabla W_j(r) \nabla^2 W_i(r) d\sigma \\ &= \gamma_i^2 \int_{\sigma} W_j(r) W_i(r) d\sigma \\ &= \gamma_i^2 c_i \delta_{ij} \\ &= \begin{cases} \gamma_i^2 c_i & i = j \\ 0 & i \neq j \end{cases},\end{aligned} \tag{27.30}$$

where c is the pupil boundary, σ is the pupil area, $W(r)$ is the eigenfunction, $\nabla W(r)$ is the first-order partial derivative of the eigenfunction, and γ^2 is the eigenvalue corresponding to the eigenfunction $W(r)$.

The eigenfunction is used to construct the wavefront-reconstruction matrix E instead of the Zernike wavefront-reconstruction matrix Z in section "Decoupling Control Algorithm of Dual-Deformable Mirrors." Taking the multistage corrector as an example, E can be expressed as follows:

$$E = \begin{Bmatrix} \frac{1}{A_1}\int_{P_1} \frac{\partial W_1(r)}{\partial x} d\sigma & \frac{1}{A_1}\int_{P_1} \frac{\partial W_2(r)}{\partial x} d\sigma & \cdots & \frac{1}{A_1}\int_{P_1} \frac{\partial W_{m_e}(r)}{\partial x} d\sigma \\ \frac{1}{A_2}\int_{P_2} \frac{\partial W_1(r)}{\partial x} d\sigma & \frac{1}{A_2}\int_{P_2} \frac{\partial W_2(r)}{\partial x} d\sigma & \cdots & \frac{1}{A_2}\int_{P_2} \frac{\partial W_{m_e}(r)}{\partial x} d\sigma \\ \vdots & \vdots & & \vdots \\ \frac{1}{A_N}\int_{P_N} \frac{\partial W_1(r)}{\partial x} d\sigma & \frac{1}{A_N}\int_{P_N} \frac{\partial W_1(r)}{\partial x} d\sigma & \cdots & \frac{1}{A_N}\int_{P_N} \frac{\partial W_{m_e}(r)}{\partial x} d\sigma \\ \frac{1}{A_1}\int_{P_1} \frac{\partial W_1(r)}{\partial y} d\sigma & \frac{1}{A_1}\int_{P_1} \frac{\partial W_2(r)}{\partial y} d\sigma & \cdots & \frac{1}{A_1}\int_{P_1} \frac{\partial W_{m_e}(r)}{\partial y} d\sigma \\ \frac{1}{A_2}\int_{P_2} \frac{\partial W_1(r)}{\partial y} d\sigma & \frac{1}{A_2}\int_{P_2} \frac{\partial W_2(r)}{\partial y} d\sigma & \cdots & \frac{1}{A_2}\int_{P_2} \frac{\partial W_{m_e}(r)}{\partial y} d\sigma \\ \vdots & \vdots & & \vdots \\ \frac{1}{A_N}\int_{P_N} \frac{\partial W_1(r)}{\partial y} d\sigma & \frac{1}{A_N}\int_{P_N} \frac{\partial W_1(r)}{\partial y} d\sigma & \cdots & \frac{1}{A_N}\int_{P_N} \frac{\partial W_{m_e}(r)}{\partial y} d\sigma \end{Bmatrix},$$

where A_k is the area of the kth effective aperture of the Hartmann sensor, p_k is the kth effective aperture of the Hartmann sensor, $k = 1, 2, \ldots, N$, and $\frac{\partial W_i(r)}{\partial x}$ and $\frac{\partial W_i(r)}{\partial y}$ represent the first-order partial derivatives of the ith eigenfunction in the x and y directions, respectively. m_e is the order of the eigenfunction and N is the number of effective apertures in the Hartmann sensor.

It can be seen from Eq. (27.30) that the first-order partial derivative of the eigenfunction is orthogonal. Eq. (27.31) is written in discrete form, as follows:

$$\sum_{k=1}^{N}\left(\frac{\partial W_i(x,y)_k}{\partial x}\frac{\partial W_j(x,y)_k}{\partial x}+\frac{\partial W_i(x,y)_k}{\partial y}\frac{\partial W_j(x,y)_k}{\partial y}\right)=0, \quad i\neq j, \tag{27.31}$$

where $\frac{\partial W_i(x,y)_k}{\partial x}$ represents the first partial derivative of the eigenfunction in the x direction at the kth sampling point, also known as the slope, and $\frac{\partial W_i(x,y)_k}{\partial y}$ represents the first partial derivative of the eigenfunction at the kth sampling point in the y direction, namely the slope.

For Eq. (27.31), when the sampling rate of the Hartmann sensor is high, the average slope on the subaperture is closer to the slope at the discrete sampling points, namely

$$\lim_{A_k\to 0}\frac{1}{A_k}\int_{p_k}\frac{\partial W_i(r)}{\partial x}d\sigma=\frac{\partial W_i(x,y)_k}{\partial x} \tag{27.32}$$

$$\lim_{A_k\to 0}\frac{1}{A_k}\int_{p_k}\frac{\partial W_i(r)}{\partial y}d\sigma=\frac{\partial W_i(x,y)_k}{\partial y}. \tag{27.33}$$

Equations (27.32) and (27.33) indicate that the column vector of the wavefront-reconstruction matrix E corresponding to the eigenfunction is orthogonal when the sampling frequency of the Hartmann sensor subaperture is high. Therefore, Eq. (27.26) can also be written as

$$R_m(i,j)=k\frac{\sum_{r=1}^{2N}R_t(r,i)E(r,j)}{\sum_{r=1}^{2N}E(r,j)E(r,j)}, \tag{27.34}$$

where $R_t(r, i)$ represents the element corresponding to position (r, i) in the slope-response matrix of the high-order deformable mirror, and $E(r, j)$ represents the element corresponding to position (r, j) in the eigenfunction.

The new matrix R_m is obtained by substituting Eq. (27.34) into Eqs. (27.28) and (27.29), and the reset matrix of the higher-order deformable mirrors based on the Laplace-eigenmode driving voltage is obtained; that is, the coupling component between the higher-order and lower-order deformable mirrors is eliminated.

Sparse-Sampling Control Algorithm

To accurately control the high-order and low-order coefficients of deformable-mirror shape expressions, Cheng et al. [45] proposed a sparse-sampling control algorithm to control a deformable mirror.

A deformable mirror typically consists of multiple actuators and a reflector. When the actuator applies the driving voltage, the surface shape of the deformable mirror changes accordingly. The driving voltage of each actuator is arranged to form the control-parameter vector S, which is [45]

$$S = [s_1\ s_2 \ldots s_i \ldots s_n]^T, \tag{27.35}$$

where n is the number of actuators, i is the number of the ith actuator (i.e., the actuator), s_i is the driving voltage of the ith actuator, and $s_i \in [-1, 1]$.

After the control-parameter vector S is applied, the surface shape of the deformable mirror is represented by the sum of Zernike polynomials, as follows:

$$z(x, y) = \sum_{1}^{K=m} c_K Z_K(x, y). \tag{27.36}$$

The formula is a Zernike polynomial and c_k is the coefficient of the polynomial. The value of m is related to the fitting accuracy and the solution complexity of the surface shape. The relationship between the two should be comprehensively considered and an appropriate value should be selected.

Because Eq. (27.36) is a definite expression, its coefficient component vector is used to describe the surface-shape information of the deformable mirror. The coefficient vector of the Zernike polynomial is defined as the surface-shape feature vector c, which is expressed as

$$c = [c_1\ c_2 \ldots c_K \ldots c_m]^T. \tag{27.37}$$

Assuming that the deformation of the deformable mirror is within the linear-variation range, and considering the linear mechanical model of the deformable mirror, the relationship between the control-parameter vector of the deformable mirror and the surface-shape feature vector is as follows:

$$c = Gs, \tag{27.38}$$

where G is the response matrix of the deformable mirror.

In the iterative control process of the deformable mirror, the feature vector of the current surface shape is represented by c_N and the feature vector of the target surface shape is represented by c_d, where N is the number of iterations. The mirror-shape correction is expressed as follows:

$$\Delta c_N = c_d - c_N. \tag{27.39}$$

From Eqs. (27.35), (27.38), and (27.39), it can be seen that the relationship between the change of the deformable-mirror surface shape and the change of the control parameters is as follows:

$$\Delta c_N = G\Delta s_N. \tag{27.40}$$

Because the response matrix G of the deformable mirror is irreversible and the number of columns is greater than the number of rows, the solution of Eq. (27.41) is essentially the solution of the underdetermined equations. Therefore, the sparse-control parameter φ can be obtained by establishing the sparse matrix θ_N obtained from the discrete cosine transform. The control-parameter variable Δs_N is sparsely sampled using the orthogonal matching-pursuit method, and is expressed as follows:

$$\Delta c_N = G\varphi\theta_N. \tag{27.41}$$

After completing the sparse solution of the control parameters, the sparse matrix of Eq. (27.41) is used to recover the changes of the actual control parameters φ, and the correction of the control parameter Δs_N is obtained. The expression is

$$\Delta s_N = \varphi\theta_N. \tag{27.42}$$

In summary, the iterative relationship between the control parameters of the deformable mirror is

$$s_{N+1} = s_N + \varphi\theta_N. \tag{27.43}$$

The mapping relationship of Eq. (27.38) can be written as

$$\Delta c = G\Delta s, \tag{27.44}$$

where Δs is the vector that controls the change in the parameters and Δc is the vector that changes the shape of the deformable mirror.

The zero-state surface shape c_{-1} is defined as the average surface shape of the deformable mirror before loading the control parameter; the parameter is defined as the zero-state control parameter s_{-1}. To reduce the repeated influence of hysteresis on the surface-shape data and improve the surface-shape accuracy, the following methods were used to obtain sample data.

At the beginning of the experiment, the deformable mirror was loaded with control parameter s_{-1}. Second, the control-parameter vector s_t, satisfying a random Gaussian distribution, was loaded, where t is the serial number of the surface-shape information collection. Using an interferometer, the surface-shape feature vector c_t of more than 70% of the effective area of the deformable mirror was measured, and the change of the control parameter Δs_t and the change of the surface-shape feature vector Δc_t were obtained. The expressions are

$$\Delta c_t = c_t - c_{-1} \qquad \Delta s_t = s_t - c_{-1}. \tag{27.45}$$

The sample data were collected, and the control parameter-change sample set $\Delta s'$ and surface-shape feature-vector change sample set $\Delta c'$ were established. The expressions are

$$\begin{aligned} \Delta s' &= [\Delta s_1\ \Delta s_2 \ldots \Delta s_R] \\ \Delta c' &= [\Delta c_1\ \Delta c_2 \ldots \Delta c_R], \end{aligned} \tag{27.46}$$

where R is the upper limit of t.

Using the sample set, the expression is

$$\min\left\{ \left(\|\Delta c' - G\Delta s'\|_F \right)^2 \right\}. \tag{27.47}$$

where $\|.\|_F$ is the F norm. The least squares method was used to solve Eq. (27.47), and the response matrix G was obtained as

$$G = \Delta c \left[\Delta s^T \left(\Delta s \Delta s^T \right)^{-1} \right]. \tag{27.48}$$

After Eq. (27.48) was substituted into Eq. (27.44), both sides of the equation were multiplied by the pseudo-inverse matrix G^+ of the response matrix, and the correction value of the control parameters was obtained as follows:

$$\Delta s_N = \left[\Delta c \left(\Delta s^T \left(\Delta s \Delta s^T \right)^{-1} \right) \right]^+ \Delta c_N. \tag{27.49}$$

During the experiment, the optimization objective in the experiment process was generally set to minimize the relative change of the deformable-mirror surface shape, and the initial value of the iteration was set as the median of the control parameters. At this time, the deformable mirror was in the middle state, under the given control parameters, and the eigenvector of the surface shape was defined as the initial value eigenvector c_0. The two groups of control parameters used in the experiment were $s_i \in [-1, 1]$; thus, the initial value of the iteration was the zero vector.

Application of Deformable-Mirror Control Algorithms in Adaptive-Optics Systems

In recent years, Ke Xizheng et al. at Xi'an University of Technology have devoted themselves to studying deformable-mirror control algorithms and applying them to adaptive-optics systems.

In 2018, Wu [46] investigated the stochastic parallel gradient-descent (SPGD) algorithm, studied wavefront-distortion correction using this algorithm, and analyzed the influence of different parameter values in the SPGD algorithm on the correction effect, and numerically simulated different parameter values.

The simulation results showed that when the disturbance amplitude $\delta u = 0.006$, the SPGD algorithm based on the variable-gain coefficient effectively corrected the

wavefront distortion. The SPGD algorithm also well corrected the wavefront distortion under different turbulence intensities. In addition to verifying the algorithm through numerical simulations, experiments were also conducted to correct the wavefront distortion at 600 m, 1300 m, and 10.2 km in an external field. This verified that the algorithm had a good wavefront-distortion correction ability.

In 2019, Han [47] used the SPGD algorithm to control a deformable mirror to correct optical-wavefront distortions. The simulation results showed that the performance-evaluation function's Strehl ratio improved from 0.15–0.87, and the beam distortion was improved. A deformable mirror was used as the wavefront corrector of the system and a wavefront-free adaptive system was built for the experiment. The experimental results showed that the deformable mirror had a good correction effect, and after the correction, the shape and brightness of the light spot were improved.

In 2020, Zhang [35] studied the proportional–integral–differential (PID) algorithm, and then analyzed and simulated the influence of the input universe of different control voltages and the input universe of the first derivative of different control voltages on the algorithm's correction results. The simulation results showed that the input universe of the control voltage should be reasonably selected, according to the actual wavefront situation, and that the actual input universe should be smaller than the set input universe to ensure the correction accuracy of the deformable mirror.

To verify the influence of the algorithm parameters on the correction results, an outfield experiment was conducted. The experimental results were consistent with the simulation results, proving the correctness of the dual fuzzy PID algorithm.

In 2020, Li [48] deduced the eigenmode of a deformable mirror, studied the correction principle of the eigenmode deformable-mirror method, established a mathematical model of the 69-element continuous-surface deformable mirror, and deduced its eigenmode. The wavefront distortion was corrected, based on the eigenmode method, and a numerical simulation was performed.

The simulation results showed that the stability of the system could be improved by improving the atmospheric environment. To study the performance of the model in a practical application system, wavefront distortions under different turbulence intensities were corrected, and an indoor experimental system was established.

The results showed that the model method could effectively correct wavefront distortions caused by atmospheric turbulence. An outdoor experimental system was established to conduct the experiment. The experimental results showed that the deformable-mirror eigenmode method effectively corrected the wavefront distortion caused by external-field dynamic turbulence.

In 2021, Cheng [49] studied a residual-distortion correction algorithm based on a PID algorithm. This algorithm mainly eliminated the residual part of the distortion variables, except for period expansion, and was used to simulate wavefront correction with large distortions, which improved the system performance. To verify the algorithm, an experimental system was built to analyze and correct the algorithm for an indoor static distorted wavefront, and 1.2-km, 10-km, and 100-km dynamic distorted wavefronts in the field, proving the correctness of the algorithm.

Summary

The wavefront corrector is an important wavefront-correction component in adaptive-optics systems, and its performance directly determines the correction level of the system. Several typical deformable mirrors were introduced, applied, and verified in practice and achieved good results.

However, owing to the different characteristics and manufacturing processes of deformable mirrors, the most suitable systems should be comprehensively considered when designing systems. Moreover, the constant improvement of application requirements and the emergence of high-integration technology require continuous innovation of technology and theory, as well as gradual improvements and enhancements of deformable-mirror control algorithms to improve the correction accuracy and communication performance of adaptive-optical systems [6].

China has made great breakthroughs in the research fields of deformable mirrors and their control algorithms. The main research units are the Institute of Optoelectronics Technology, Chinese Academy of Sciences, Changchun Institute of Optics and Mechanics, Chinese Academy of Sciences, and Xi'an University of Technology. Over the years, significant progress has been made in the research on deformable-mirror systems and element technology. However, many aspects remain to be studied in the future.

1. New structures and new fabrication processes should be studied to find new ways to improve deformable-mirror performance.
2. Actuator materials should be improved and actuator arrays with smaller spacing and higher density should be developed to meet the needs of larger telescopes.
3. The coating range of MEMS deformable mirrors should be studied to obtain good deformable-mirror shape quality [8].
4. The quantitative relationship between the number of actuators and number of sampling points for the decoupling control algorithm of a single deformable mirror should be studied to improve the algorithm solution accuracy [42].
5. Control algorithms for deformable mirrors should be optimized, simpler and more efficient control algorithms should be sought, and the deformable-mirror correction level and system stability should be improved.
6. The working bandwidth of dual deformable-mirror adaptive-optical systems should be improved to obtain a better aberration-compensation effect [43].

Abstract

Liquid-crystal spatial light modulators control the optical path of light waves by modulating the refractive index. They play an important role in adaptive optics as phase-correction devices. This chapter expounds on the domestic and foreign development and research status of liquid-crystal spatial light modulators and light-beam modulation. The principles of optical-amplitude and phase modulation of liquid-crystal spatial light modulators are introduced, and their future applications are proposed.

Introduction

Liquid-crystal spatial light modulators achieve control of the light path by modulation of the refractive index. As an important phase-correction device, it plays an important role in adaptive optics. This chapter describes the foreign development status of liquid-crystal spatial light modulator and the current status of foreign research on beam modulation of liquid-crystal spatial light modulator, introduces the realization principle of optical amplitude and phase modulation of liquid-crystal spatial light modulator, and looks forward to the future application of liquid-crystal spatial light modulator.

Liquid-Crystal Spatial Light Modulators

Liquid Crystal and Spatial Light Modulators

As condensed matter, the characteristics and structure of a liquid crystal are between those of solid crystals and isotropic liquids; it is an ordered fluid. In terms of macroscopic physical properties, it not only has the fluidity and viscosity of a liquid, but also the anisotropy of a crystal. Similar to crystals, it can produce birefringence, Bragg reflection, diffraction, and optical-rotation effects, and can also produce thermo-optical, electro-optical, or magneto-optical effects under the action of external fields.

An optical wavefront propagating through atmosphere will be distorted by atmospheric turbulence. An adaptive-optics system is an important method for suppressing the influence of atmospheric turbulence. The wavefront corrector is a key device in an adaptive-optics system, and its main function is to correct the distortion aberration measured by the wavefront sensor [1].

When light is incident on a liquid crystal, the liquid-crystal molecules have two refractive indices, which are parallel and perpendicular to the optical axis. This is called the birefringence characteristic. According to the anisotropy characteristics of liquid-crystal molecules, the refractive index of the light beam differs in all directions when the liquid-crystal molecules propagate.

When a light beam propagates in liquid-crystal molecules, two types of light waves are often formed: ordinary and extraordinary. The refractive indices of the two are n_o and n_e, respectively. The transmission rate differs between the two, resulting in significantly different refractive-index characteristics, which is called birefringence [2, 3].

A liquid-crystal spatial light modulator can modulate the wavefront phase; it has no mechanical inertia, extremely low power consumption, an extremely low energy-absorption rate, and a high system resolution. In its liquid-crystal molecule unit, the

voltage can be programmed to control the liquid-crystal molecules. Therefore, it has unique advantages for wavefront correction [4–6].

Spatial light modulators can adjust the light beam and load information in one- or two-dimensional optical data fields, and can effectively utilize the inherent speed, parallelism, and interconnection capabilities of light to modulate the light wave. Spatial light modulators contain many independent units, which are spatially arranged in one- or two-dimensional arrays. Each unit can be independently controlled by optical or electrical signals, using various physical effects, such as the Pockels, Kerr, acousto-optic, magneto-optic, semiconductor self-electro-optic, and photorefractive effects. The units change their own optical properties to modulate the light waves incident on them.

These individual small units are often referred to as the "pixels" of a spatial light modulator. The signal that controls the pixel is called the "write light." The input light wave that illuminates the entire device and is modulated is called the "read out light." The light wave emitted after passing through the spatial light modulator is called the "output light." Visually speaking, a spatial light modulator can be regarded as a transparent sheet whose transmittance or other optical-parameter distribution can be quickly adjusted as needed. The write signal contains information that controls the individual pixels of the modulator. The process of passing this information separately to the corresponding pixel positions is called "addressing."

A liquid-crystal spatial light modulator uses the liquid-crystal layer as the light-modulation material, which adopts the mixed field-effect working mode of a nematic liquid crystal. By applying different electric fields to each region of the crystal layer, the arrangement direction and position of the liquid-crystal molecules can be changed. This changes their optical properties, making them transparent or opaque, and modulates the optical signals.

Spatial light modulators are composed of cells controlled by many integrated circuits, and use electrical signals to control the 1 or 0 state of each cell. Liquid crystals are used as the modulation medium to form low-power, low-voltage spatial light modulator light-addressable liquid-crystal light valves. (They are typically called spatial light modulators when used for light operations and light valves when used in displays.) Electrically addressable thin-film transistors drive the liquid-crystal displays (TFT-LCDs).

The amount of phase correction by the liquid-crystal spatial light modulator is usually determined by the refractive index of the liquid-crystal material and the thickness of the liquid-crystal layer. In an actual operation, the liquid-crystal spatial light modulator corrects the front of the wave by changing the refractive index. The phase-modulation amount is approximately 1 mm, and this value is determined according to the thickness of the liquid-crystal layer constituting the modulator.

The lack of sufficient phase modulation limits the use of liquid-crystal spatial light modulators. By increasing the thickness of the liquid-crystal layer and improving the performance of the liquid-crystal material, the modulation amount with the refractive-index difference is improved. Although these changes increase the response time of the liquid-crystal spatial light modulator, the phase-modulation amount of the corrector can be greatly improved by adding an intrinsic phase-modulation amount of one wavelength to the liquid crystal through phasogram technology.

When an adaptive-optics system works in the visible-light band, the atmospheric coherence length is significantly reduced because of the shorter wavelength in the visible-light band. This places higher requirements on an adaptive-optics system composed of deformable mirrors.

Compared with a traditional deformable-mirror adaptive-optics system, the advantages of the liquid-crystal spatial light modulator, in correcting the wavefront in an adaptive-optics system, are as follows: The pixel density of the liquid-crystal spatial light modulator is high, and it is easy to achieve the order of millions of pixels, plus small pixels. Combined with the phase-hologram technology of binary optics, correction amounts on the order of more than 10 μ can be reached, which is better than the correction amount of deformable mirrors. In addition, the liquid-crystal spatial light modulator is stable, the device technology is excellent, and its cost performance is better than that of a deformable mirror.

Unfortunately, the liquid-crystal spatial light modulator has shortcomings in engineering applications, mainly reflected in its low energy utilization and slow response speed. The main reasons for the low energy-utilization rate are the polarization dependence of the liquid-crystal corrector and the dispersion effect of the liquid-crystal material. The liquid-crystal adaptive-optics system can only work on polarized light; thus, it can only correct the wavefront after it has been filtered by a polarizer, which results in energy loss. The dispersion effect of the liquid-crystal materials also restricts the energy-utilization rate.

The wavelength of the incident rays affects the refractive index of the material. This phenomenon makes it impossible to consistently correct distortions over a wide wavelength range for devices that change the refractive index to adjust the wavefront. In addition, the liquid-crystal corrector is a binary-diffraction correction device, and its diffraction-dispersion effect further restricts the working-band range of the system. These two factors reduce the spectral width of the system working band to approximately 10–30 nm and the optical-energy loss is serious.

The response speed of the liquid-crystal spatial light modulator also affects the working performance of the system. When dual-frequency liquid crystals are used to shorten the response time of the liquid-crystal spatial light modulator, the response time is on the order of sub-milliseconds. However, when driving a dual-frequency liquid crystal, a large external voltage must be connected, so this method is not widely used. Nematic liquid-crystal materials are used in liquid-crystal spatial light modulators. Reducing the thickness of the liquid-crystal layer shortens the response time, which reduces the impact of the response speed on the working performance to a certain extent.

Research Progress

Foreign Research Progress

In 1975, Meyer et al. discovered ferroelectric liquid-crystal materials with many novel electro-optical properties. Clark et al. proposed a surface-stable liquid-crystal mode and applied ferroelectric liquid crystals to the display field [7].

At the end of the twentieth century, the United States began a program code-named "Steered Agile Beams" to study liquid-crystal optical correctors. Major institutions in the United States also began to study liquid-crystal optical correctors [8, 9].

In 1989, Raytheon Corporation of the United States launched the first liquid-crystal optical phased array. In 1996, a reflective liquid-crystal phased array with 5000 independent electrodes and a $2 \times 2\text{-cm}^2$ device aperture size was launched. The Stokes–MacCulbrough measurement technique was used for measuring 10.6-μm beams of light. It was found that the device performance of the phased array was affected by the thermal effect, and $\pm 5^\circ$ field-of-view scanning was achieved [10].

In 2002, Rockwell Scientific Corporation of the United States developed a reflective liquid-crystal phased array with 512 independent electrodes. The array-element size was 10 μm and the optical aperture was $5 \times 5\ \text{mm}^2$. In 2005, a transmissive liquid-crystal optical phased array with a dual-frequency liquid-crystal material was proposed, with four independently addressable $1 \times 4\ \text{cm}^2$ areas. They were arranged in a linear array to produce a continuous $4 \times 4\ \text{cm}^2$ clear aperture with 8-μm pixel spacing. Experiments confirmed that under incident rays with a 1.55-μm wavelength, the field-of-view deflection angle was 2.5°, and the diffraction efficiency reached more than 60% [11].

In Reference [12], an optical phased array of $1 \times 12{,}288$ pixels was proposed. In this design, the pixel pitch was reduced from 1.8 μm to 1.6 μm. The backplane voltage increased from 5 V to 13 V and the effective light aperture increased from $7.4 \times 6.0\ \text{mm}^2$ to $21.66 \times 21.66\ \text{mm}^2$. Under the new liquid-crystal construction, when calibrated with the new automatic-correction program, the scanning angle of the optical phased array was more than doubled, and the response time was 5–30 ms. Operating wavelengths ranged from 635 nm to 1.55 μm [12].

In Reference [13], a linear-array spatial light modulator with a linear pixel-array geometry was proposed. The time distribution of femtosecond light pulses was controlled by a computer, and the pixel width was 1000 mm. The existing version handled beams of light with wavelengths ranging from 450 to 2000 nm. Experiments showed that the array had more than 700 deflection-quantization angles and a response time of less than 200 μs [13].

Reference [14] proposed a two-dimensional liquid-crystal spatial light modulator with an effective light-passing aperture of $15.36 \times 8.64\ \text{mm}^2$. It had a unit element size of 8 μm, operating-wavelength range of 420–1700 nm, diffraction efficiency of 93%, and response time of 5.6 ms [14].

In 2022, Meadowlark Corporation of the United States launched a pure-phase liquid-crystal spatial light modulator with a high liquid-crystal response speed (2 kHz at 532 nm), high light-utilization efficiency (98%), high fill factor (97.2%), and high resolution (1024×1024). A silicon-based liquid-crystal spatial light modulator was specially designed for pure-phase applications and combined analog data addressing with a high refresh rate. This combination provided users with the fastest response time and high phase stability.

Domestic Research Progress

In 1994, Huang et al. proposed a new type of liquid-crystal light-valve (LCLV) projection system based on amorphous silicon (a-Si). The system had a short

response time, wide input spectrum, and simple manufacturing process. Experiments showed that the display ratio of the system was 1.5 × 1.2 m^2, the illuminance was 190 lx, the response time was less than 1 ms, and the resolution was above 20 lp/mm [15].

In 1995, Han manufactured an nc-Si–H/a-Si–H liquid-crystal light valve with a heterogeneous structure. The liquid-crystal light valve used multiple absorption layers. The multilayer absorption layer had a high absorption capacity in the visible and near-infrared ranges, ensuring the high sensitivity of the liquid-crystal light valve [16].

In 2002, Zhao et al. modulated the intensity distribution of spatial light beams through a liquid-crystal spatial light modulator, and obtained a light beam with an output near-field modulation of 1.5: 1. Auxiliary features were added to the liquid-crystal spatial light modulator to adjust the optical path and rotate the light spot. A thin-film transistor liquid-crystal light valve was used, which was an electrically addressable transmission-type working mode. After perfecting the system, it was applied to a high-power laser device [17].

In 2005, Ding et al. introduced a new method of light-beam shaping using a liquid-crystal light valve, studied the incident phase-modulation and spatial transmission characteristics of the shaped light beam, and experimentally concluded that the light valve had an excellent shaping effect [19].

In Reference [18], a liquid-crystal phased array with 1920 × 1080 independent phased-array elements was proposed. The phased array had a diffraction efficiency of 60%, 60-Hz frame rate, and 8-μm array unit element size [18].

In 2008, Zhang et al. developed a liquid-crystal spatial light modulator with 2014 independent phase-control units. The array size was 10 μm, and the thickness of the liquid-crystal cell was 5.8 μm. The working voltage was provided to the liquid-crystal cell through a field-programmable gate array, with more than 60 deflection angles. The maximum deflection angle was 2.0014° [19].

In 2012, Huang et al. developed an optically addressable liquid-crystal spatial light modulator. The experiment tested its performance under continuous light with a 1053-nm wavelength, and showed that it had a maximum transmittance of 85% [20]. In 2016, Huang et al. reported the latest progress in the development of liquid-crystal spatial light modulators and conducted preshielding experiments on high-power laser systems [21].

In 2020, Wang et al. developed a liquid-crystal optical phased array with a large aperture. This liquid-crystal phased array achieved a light-beam deflection of 0–3°, with a diffraction efficiency of more than 80%, a pointing error of less than 90 μrad, and a circuit refresh rate of 150 kHz [22] (Fig. 28.1).

In 2019, Li [23] developed a transmissive liquid-crystal spatial light modulator, which had a unit liquid-crystal layer thickness of 1.5 μm, a diffraction efficiency of 35%, and deflected light beams from 0° to 11° with a resolution of 877 lp/mm.

At the end of 2020, Zhongke MSI realized an autonomous core device through the independent design of a liquid-crystal light-valve device. In 2022, Zhongke MSI launched two self-designed spatial light modulators, namely, 2k-color amplitude-type and 2k-color phase-type spatial light modulators. The technical parameters of the products are listed in Table 28.1.

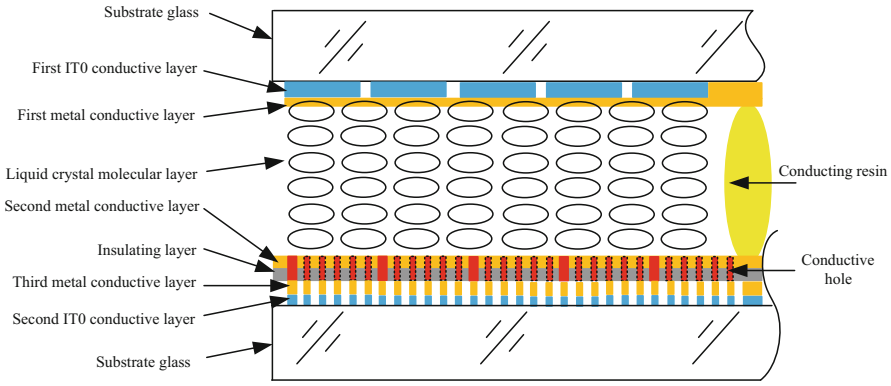

Fig. 28.1 Large-aperture liquid-crystal optical phased-array structure diagram [22]

Table 28.1 Technical parameters of the space light modulator independently designed by Zhongke MSI

Model number	FSLM-2K39-A02	FSLM-2K39-P02
Modulation type	Amplitude type	Phase type
Display type	Monochrome display, synchronous support for color display	
Gray-release grade	256	
Resolution	1920 × 1080	
Pixel size	4.5 μm	
Effective area	8.64 × 4.85 mm^2	
Fill factor	> 91%	
Contrast ratio	≥ 600: 1	–
Phase-modulation range	–	2π (max 3.8π)
Optical utilization	75% ±5%	
Refresh frequency	Monochrome 200 Hz	Color 60 Hz
Spectral range	420–650 nm	
Data interface	Mini DP	
Power supply	DC 5 V, 2 A	

LC-SLM Basic Working Principle

Electronically Controlled Birefringence Properties of Liquid Crystals

In existing research, liquid-crystal spatial light modulators (LC-SLMs) can be divided into two types: twisted nematic spatial light modulators (TN-SLM) and parallel-arrangement nematic spatial light modulators (PA-SLM).

The biggest feature of the TN-SLM is that it has a twisting effect; that is, when a beam of light passes through the liquid-crystal cell, the polarization direction of the light beam is affected by the change in the optical-axis direction of the liquid-crystal

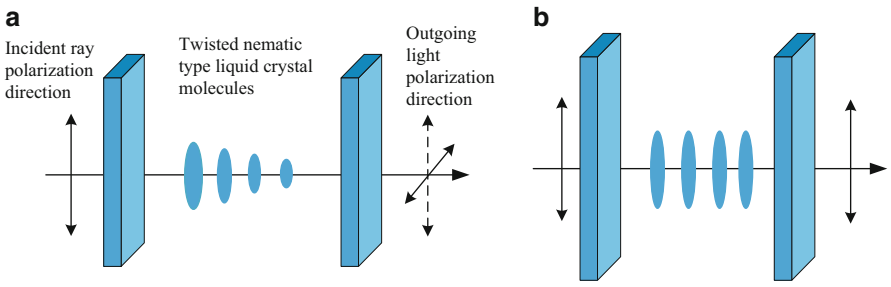

Fig. 28.2 Working principle of a TN-SLM. (**a**) Driving voltage equal to 0; (**b**) driving voltage not equal to 0

cell. As shown in Fig. 28.2, when the left and right surfaces of the liquid-crystal cell are anchored, the liquid-crystal molecules close to them are arranged in a preset direction. The difference between the liquid-crystal molecules on the two sides is $\pi/2$ [24]. The liquid-crystal layer of the twisted nematic spatial light modulator can be regarded as a multilayer stack containing microtwisted uniaxial crystals [25].

Figure 28.2 shows the modulation schematic diagram of a TN-SLM, in which Fig. 28.2a represents the arrangement of liquid-crystal molecules when no external electric field is applied. It appears to be helical at this time. In the absence of an applied voltage, the liquid-crystal layer appears to be weakly twisted. If the optical-axis direction and polarization direction of the incident ray are the same, a change in the former will lead to a change in the latter. The two are closely correlated, and the polarization direction of the outgoing light remains the same as that of the optical axis.

At this time, it can be considered that the phase difference between the o-light and e-light is fixed, and its expression is as follows:

$$\phi = \frac{\pi d(n_e - n_o)}{\lambda}, \tag{28.1}$$

where d represents the thickness of the liquid-crystal layer and λ is the wavelength of the modulated light wave.

As shown in Fig. 28.2b, the presence of an electric field has a significant effect on the liquid-crystal molecules, resulting in changes in the birefringence of the liquid crystal. This phenomenon occurs because the degree of electric-field influence on each position of the liquid-crystal cell is different. The surface is basically unaffected, whereas the interior, especially the middle part, is more susceptible. Therefore, when the voltage is higher, the number of molecules arranged in the direction of the electric field increases significantly, reducing the distortion effect to a certain extent.

In addition, when the rotation angle q changes, n_e will change accordingly; however, it does not affect the size of n_o. The phase difference ϕ between the ordinary and extraordinary light will also change according to the change in the rotation angle. At this point, the equivalent refractive index of extraordinary light $n_e(\theta)$ can be expressed as follows:

$$\frac{1}{{n_e}^2(\theta)} = \frac{\cos^2\theta}{{n_e}^2} + \frac{\sin^2\theta}{{n_o}^2}. \tag{28.2}$$

In the formula, the size of $n_e(\theta)$ is related to the characteristics of the liquid crystal. When the TN-SLM modulates the phase, the amount of modulation is directly related to the applied voltage. In the phase-modulation process, the amplitude is modulated to a certain extent; therefore, to modulate the amplitude, a polarizer should be added to the system.

Figure 28.3 shows the nematic liquid-crystal spatial light modulator arranged in parallel, and the liquid-crystal molecules arranged in parallel. The liquid-crystal molecules at the junction of the electrode surface are always fixed and maintain a vertical relationship with the electrode surface, which does not twist with the change in the applied electric field [26].

Figure 28.3a shows that when there is no electric-field force, the liquid-crystal molecules do not have a twisting effect, and the molecules are parallel to each other and to the liquid-crystal cell. Figure 28.3b shows that when an electric field is applied, the liquid-crystal molecules rotate such that the optical-axis direction of the molecules is perpendicular to the direction of the applied electric field. This is because the liquid-crystal molecules have an elastic force, and under the action of the electric-field force and molecular-elastic force, the liquid-crystal molecules rotate [27, 28].

When a voltage V_r is applied to the PA-SLM, the rotation angle of the liquid-crystal molecules θ can be described by the magnitude of the voltage as [24]

$$\theta = \begin{cases} 0 & , V_{rms} < V_c \\ \dfrac{\pi}{2} - 2\tan^{-1}\left\{\exp\left[-\left(\dfrac{V_r - V_c}{V_o}\right)\right]\right\}, & V_{rms} \geq V_c \end{cases}, \tag{28.3}$$

where V_c and V_o represent the threshold voltage and saturation voltage, respectively. It can be seen from Eq. 28.3 that the rotation conditions of the liquid-crystal molecules are as follows: When $V_r < V_c$, the liquid-crystal molecules deflect, and when $V_r > V_c$, the liquid-crystal molecules do not rotate.

When liquid-crystal molecules are subjected to an electric-field force, the changes in n_e and n_o can be obtained by analyzing the refractive-index ellipsoid, from which

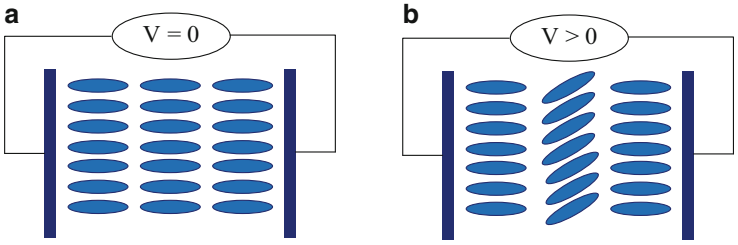

Fig. 28.3 Working principle of a PA-SLM [29]. (**a**) Driving voltage equal to 0; (**b**) driving voltage not equal to 0

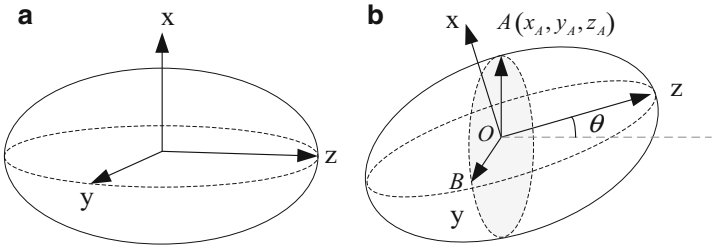

Fig. 28.4 Refractive-index ellipsoid. (**a**) Applied voltage is equal to 0; (**b**) applied voltage is not equal to 0

the liquid-crystal phase-transition principle can be deduced [29]. When there is no external electric-field force, the direction of the long axis changes and the direction and tendency of the electric field maintain a vertical relationship. Influenced by the electric-field force and elastic force of the liquid-crystal molecules, the liquid-crystal molecules begin to rotate. Its angle is expressed as θ, and the result is shown in Fig. 28.4b [23].

In Fig. 28.4, the long axis of the liquid-crystal molecule, O_z, selects a point on the ellipsoid, A (coordinates (x_A, y_A, z_A)); the origin of the ellipse is O; then, the expression is obtained as

$$\frac{x_A^2}{n_1^2} + \frac{z_A^2}{n_2^2} = 1. \tag{28.4}$$

In the formula, $x_A = OA \cos\theta$, $z_A = OA \sin\theta$, $OA = n_e$, the intersection of the cross section of points O and A and the y-axis is represented by B, and the value of OB is n_o. The short and long semi-axes of the ellipse are n_1 and n_2. Therefore, if the liquid-crystal molecules rotate, the relationship between n_e and n_o is as follows:

$$\begin{cases} \dfrac{1}{n_e^2(\theta)} = \dfrac{\cos^2\theta}{n_1^2} + \dfrac{\sin^2\theta}{n_2^2} \\ n_0 = n_1 \end{cases}. \tag{28.5}$$

Combined with the information in Fig. 28.4, it can be seen that the rotation process of the liquid-crystal molecules has certain particularities. When the incident ray is parallel to the surface, the phase-modulation process can be completed, owing to the change in the OA length. For incident rays that remain perpendicular to the surface, the OB length is fixed; therefore, the relationship between the polarization direction and the surface is also fixed and will not change. Therefore, it can be concluded that the direction of the polarization-state component affects the modulation effect.

If the incident ray is perpendicular to the surface, there is no modulation effect; however, when it is parallel, there is a modulation effect. During the phase-modulation experiment, it was necessary to ensure that there were no polarization

components in other directions, so that the liquid-crystal spatial light modulator could work in a pure phase state without affecting the intensity. A polarizer or half-wave plate was added to the experimental optical path.

It can be seen from the above analysis that when the polarization direction is parallel to the optical-axis direction, the polarization direction is fixed. At this time, only the phase of the outgoing light changes, and pure phase modulation can be performed. When the molecular optical axis is not parallel to the polarization direction, the polarization direction and the phase of the outgoing light change.

Directional Distribution of Liquid Crystals

The pointing vector of liquid-crystal molecules is used to characterize the direction vector of the overall liquid crystal. The pointing average of the long sides of the molecules is a statistical average of the local part. The pointing vector of liquid-crystal molecules can be analyzed using the Cartesian coordinate system, as shown in the figure, where φ is the azimuth angle and $\theta = \theta(z)$ is the inclination angle [25].

As shown in Fig. 28.5, the unit vector can be expressed as

$$\vec{n} = (\cos\theta\cos\varphi,\ \cos\theta\sin\varphi,\ \sin\theta). \tag{28.6}$$

According to the elastic-deformation theory of the liquid-crystal continuum, the Gibbs free energy in a liquid-crystal cell is composed of splay, twist, and bend deformations [30]:

$$W_g = \int_0^d f_g dz = \frac{1}{2}\int_0^d \left\{ K_S\left(\nabla\cdot\vec{n}\right)^2 + K_T\left(\vec{n}\cdot\nabla\vec{n}\right)^2 + K_B\left(\vec{n}\times\nabla\times\vec{n}\right) - \vec{D}\cdot\vec{E}\right\} dz, \tag{28.7}$$

where K_S is the S coefficient, K_T is the T coefficient, K_B is the B coefficient, and ε is the dielectric tensor that constitutes the liquid-crystal cell material. The electric-field strength is expressed in $\vec{E}$ and the electrical displacement $\vec{D} = \varepsilon\vec{E}$. The free-energy density can be expressed as follows:

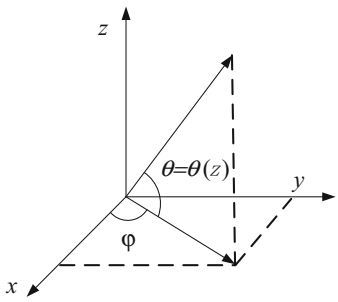

Fig. 28.5 Schematic diagram of the vector distribution of liquid-crystal molecules

$$f_g = \frac{1}{2}\left[f(\theta)\left(\frac{d\theta}{dz}\right)^2\right] - \frac{1}{2}\left(\frac{dU}{dz}\right)^2\left(\varepsilon_{\parallel}\cos^2\theta + \varepsilon_{\perp}\sin^2\theta\right), \tag{28.8}$$

where $\varepsilon_{\parallel}$ and $\varepsilon_{\perp}$ respectively denote parallel and perpendicular to the direction vector:

$$f(\theta) = K_S\cos^2\theta + K_B\sin^2\theta$$

$$g(\theta) = \left(K_T\cos^2\theta + K_B\sin^2\theta\right)\cos^2\theta.$$

By calculating the partial differential of $f(g)$ with respect to the inclination angle θ, azimuth angle φ, and potential U, the following equations can be deduced:

$$\begin{aligned}
&\frac{\partial f_g}{\partial\theta} - \frac{d}{dz}\left[\frac{\partial f_g}{\partial\left(\frac{d\theta}{dz}\right)}\right] = 0\\
&\frac{\partial f_g}{\partial\varphi} - \frac{d}{dz}\left[\frac{\partial f_g}{\partial\left(\frac{d\varphi}{dz}\right)}\right] = 0\\
&\frac{\partial f_g}{\partial U} - \frac{d}{dz}\left[\frac{\partial f_g}{\partial\left(\frac{dU}{dz}\right)}\right] = 0.
\end{aligned} \tag{28.9}$$

By solving the differential equation of Eq. 28.9 and substituting the boundary conditions, the vector distribution can be obtained.

Reasons for and Experiments with the Phase Calibration of Liquid-Crystal Spatial Light Modulators

Liquid-crystal material is used in the phase modulation of spatial light modulators; however, it is limited by the liquid-crystal material, resulting in several problems in the spatial light modulator that cannot be ignored.

1. Owing to the different photoelectric characteristics of the individual liquid-crystal pixels in the liquid-crystal spatial light modulator, there is a small deviation in the light-modulation process, resulting in an uneven phase modulation in the entire space. This inhomogeneity is related to the surface-protection glass of the spatial light modulator and the curvature of the baseplate of the address-selection circuit. The curvature of the backplate of the address-selection circuit is the result of the different polishing rates of the nonmetallic and metal regions of the backplate

during the polishing process, resulting in an initial phase difference of the liquid-crystal spatial light modulator [31, 32].
2. In the control software of the liquid-crystal spatial light modulator, the initial optimal phase is affected by external factors, which leads to the need to compensate for the initial deviation, thereby increasing the error [33, 34].
3. The dispersion effect of liquid-crystal molecules [35] causes the device to have a 2π phase modulation for a single set wavelength [36].

Therefore, before actual use, it is necessary to calibrate the liquid-crystal spatial light modulator to achieve a better correction effect [37]. At present, under different-wavelength light beams, the phase-calibration methods of liquid-crystal spatial light modulators include interferometry and diffraction methods [38, 39]. Interferometry mainly includes double-slit interference, Mach–Zehnder interference [40, 41], and Twyman–Green interference [42, 43]. Interferometry primarily uses the relative displacement of the fringes for phase calibration. The two beams of light pass through a long path before interference. Under the interference of external factors, the optical-path difference is affected, and unstable fringes are collected [44]. The following two interferometric methods are introduced.

Double-Slit Interference

Double-slit interferometry is shown in Fig. 28.6. The specific implementation process is as follows: When the light beam is punched into two sets of double slits, it generates two sets of interference fringes, and the distance between these is reasonably fixed. Relative movement will occur and, using this relative-movement amount, the relationship between the phase-modulation amount of the liquid-crystal spatial light modulator and the added gray release can be calculated.

This method requires a reference group, and the only phase modulation obtained by this method is the phase information on the phase seam; thus, the phase-modulation characteristics of the liquid-crystal spatial light regulator cannot be derived [45].

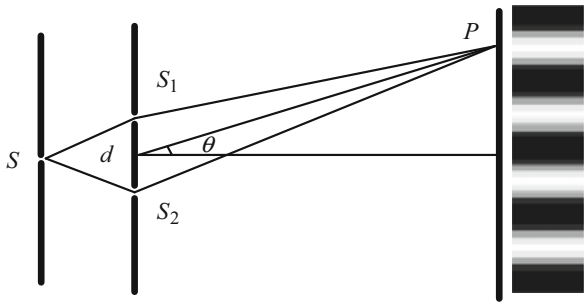

Fig. 28.6 Schematic diagram of double-slit interference

Twyman–Green Interference (Fig. 28.7)

The specific implementation process of Twyman–Green interferometry is as follows: A beam-splitting prism is used to split the incident ray. After the beam is split, one of the light beams is reflected by a mirror, and the other beam is reflected by a liquid-crystal spatial light modulator. When the two beams are reflected back, a splitting prism is used to interfere with them, and a charge-coupled device (CCD) is used to record the interference fringes.

During the experiment, it was necessary to load the gray-release images of each order on the LC-SLM so that the interference fringes obtained by the CCD camera could be relatively displaced. The relationship between the gray-release value and phase delay can be determined according to the size of the Orvin shift [46, 47]. Through numerical calculations and experimental calibration, it was concluded that this interferometry was a good calibration of the phase of the reflective liquid-crystal spatial light regulator. Mach–Zehnder and shear interferometry were used for the phase measurement and calibration of the transmissive liquid-crystal spatial light regulator [48–51].

Turbulence-Simulation Principle of a Liquid-Crystal Spatial Light Modulator

The atmospheric refractive index is affected by atmospheric turbulence [52]; therefore, when a beam of light travels in the atmosphere, it undergoes phase distortion, light-intensity flickering, light-spot drift, and other effects. The commonly used methods for simulating atmospheric turbulence cannot accurately simulate the phase, spatial, or temporal characteristics of atmospheric turbulence. Therefore, it

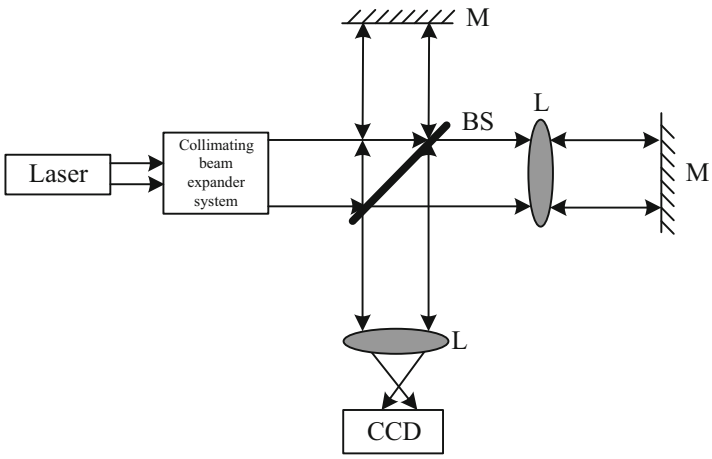

Fig. 28.7 Schematic diagram of Twyman–Green interference

is necessary to use suitable devices to simulate atmospheric turbulence in a laboratory under natural conditions. Thus, not only can the influence of atmospheric turbulence on light waves be studied, but the stability and reliability of the adaptive-optical system can be verified, as well as studying the physical properties of atmospheric turbulence [53].

According to the frozen-turbulence hypothesis [54], it can be concluded that as a beam propagates in atmospheric turbulence, random phase screens can be used to simulate the distortion effect. Therefore, related studies can be conducted using numerical simulations. Commonly used methods can be divided into two categories: indirect simulations in the frequency domain and direct simulations in the spatial domain. Their specific methods differ.

For the former, the power-spectrum inversion method (also known as the Fourier-transform method) is mainly used, and for the latter, the Zernike polynomial method is used. In addition, there are fractal methods [55] and covariance-function methods [56]. The simulation of the atmospheric-transport turbulence effect is mainly divided into two stages: a numerical simulation of the turbulence description and a physical representation of the hardware-in-the-loop simulation.

The specific process of the hardware-in-the-loop simulation is as follows: Through the liquid-crystal spatial light modulator, the phase of the laser wavefront is modulated, and the random energy distribution of the laser in time and space is simulated. Subsequently, the randomly generated phase data sequence is processed and injected into the liquid-crystal spatial light modulator, which modulates the laser. The random phase and far-field distribution of the intensity fluctuation of the laser light spot can be obtained.

An electronically addressable liquid-crystal spatial light modulator was used to complete the hardware-in-the-loop simulation of the turbulence. The main idea is to modulate the phase of the outgoing light using a spatial light modulator [57]. The wavefront can be modulated by changing the voltage alignment of the liquid-crystal molecules, when they form a specific equivalent-phase plane inside the liquid-crystal cell [58].

When there is an electric field in the optical-axis direction, the liquid-crystal molecules in the middle of the substrate deflect. At this time, the equivalent refractive index n_{eff} of the liquid-crystal molecules can be obtained. It is related to the angle θ between the long axis and the x-axis of the liquid-crystal molecules, that is, [59]

$$n_{eff} = \frac{n_o n_e}{\sqrt{n_o^2 \cos^2\theta + n_e^2 \sin^2\theta}}. \tag{28.10}$$

After linearly polarized light with wavelength λ passes through the liquid-crystal layer with thickness d, its phase difference $\Delta\varphi$ can be expressed as

$$\Delta\varphi = \frac{2\pi}{\lambda} \int_{-d/2}^{d/2} \left[n_{eff}(\theta) - n_o \right] dz. \tag{28.11}$$

After simulating the turbulence phase change, the light intensity obtained on the detector surface is

$$I_d = I_0 + I_1 \sin \varphi_e, \tag{28.12}$$

where I_0 is the background light, $I_1 = \mathrm{C}\,|E_m{}^2|$ is the modulated light intensity, $\mathrm{C_o}$ is the amplification coefficient, and $|E_m{}^2|$ is the amplitude of the light emitted by the spatial light modulator.

$$E_m = |E_i(x, y, t)| \times \exp j[\phi_i(x, y, t) - \phi_m(x, y, t) - \phi_o(x, y)], \tag{28.13}$$

where φ_i and φ_m are the phases of the input spatial light modulator and the output signal of the spatial light modulator, respectively.

(x, y, t) is used to describe the time-related position parameters on the light-modulation surface of the liquid-crystal spatial light modulator, and φ_o is used to represent the static phase error caused by the system and the external environment of the liquid-crystal spatial light modulator. In the case of an actual turbulence simulation, a voltage phase lookup table of the liquid-crystal spatial light modulator is mainly used, and the electrode voltages of different pixels are controlled by programming to modulate the phase of the wavefront and simulate the turbulence [60].

Wavefront-Distortion Correction Principle of a Liquid-Crystal Spatial Light Modulator

The static wavefront-correction principle of a liquid-crystal spatial light modulator is based on the phase-conjugation principle. The phase-conjugation principle is equivalent to that of a photoelectric-field operator. The characteristic of a phase-conjugation light is that the beam of light is disturbed by uneven media, and the interference when the phase-conjugate light passes through the medium is cancelled. This is because the phase-conjugation principle is widely used to correct the phase distortion of light beams [61].

According to the wavefront-conjugation principle, the complex amplitude of the received wave can be conjugated to compensate for the wavefront distortion experienced by the light wave during transmission. Suppose that the complex-amplitude expression of the received wave is

$$\psi(r, t) = |\psi(r, t)| \exp[i\phi(r, t)], \tag{28.14}$$

where ψ (r, t) and φ (r, t) are used to express the amplitude and phase of the received wave, respectively, $r = \{x, y\}$ is the position vector perpendicular to the direction of light propagation, r is the magnitude, and t is the time. Through the principle of wavefront-conjugate correction, the complex amplitude of the emitted wave can be expressed as

$$A(r, t) = \alpha\psi^*(r, t) = \alpha|\psi(r, t)| \exp[-i\phi(r, t)] = |A(r, t)| \exp[iu(r, t)], \tag{28.15}$$

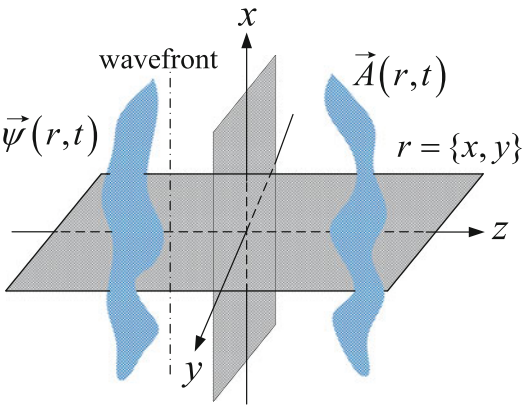

Fig. 28.8 Schematic diagram of wavefront conjugation

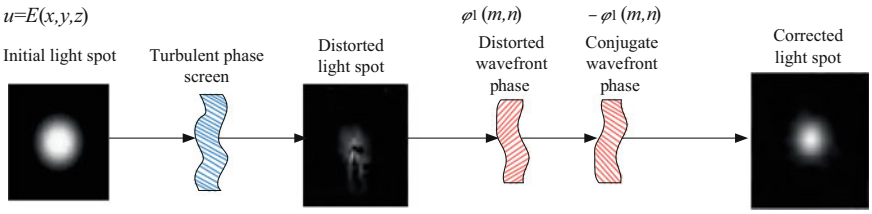

Fig. 28.9 Schematic diagram of static wavefront-conjugate correction

where $|A(r, t)|$ and $u(r, t)$ represent the amplitude and phase after light-wave correction, respectively, and α is the real coefficient. Therefore, the phase conjugate $u(r, t) = -\phi(r, t)$ and amplitude modulation $|A(r, t)| = \alpha|\psi(r, t)|$ constitute the wavefront-conjugate conditions [62]. If the light wave travels along the z-axis, a wavefront-conjugate schematic can be obtained, as shown in Fig. 28.8. A schematic of the experimental setup is shown in Fig. 28.9 [63].

Classification of Liquid-Crystal Spatial Light Modulators

In Fig. 28.10, transmissive-type spatial light modulators are shown in Fig. 28.10a, c, and reflective-type spatial light modulators are shown in Fig. 28.10b, d. Moreover, electrically addressable-type spatial light modulators are shown in Fig. 28.10a, b, and light-addressable-type spatial light modulators are shown in Fig. 28.10c, d.

The photosensitive surface of the spatial light modulator is an important structure in the optical-addressing implementation process. When the two-dimensional light-intensity distribution is projected onto it, each individual pixel of the spatial light modulator will obtain a corresponding optical signal, and through these optical signals, find the address. Similar to optical addressing, electrical-addressing spatial

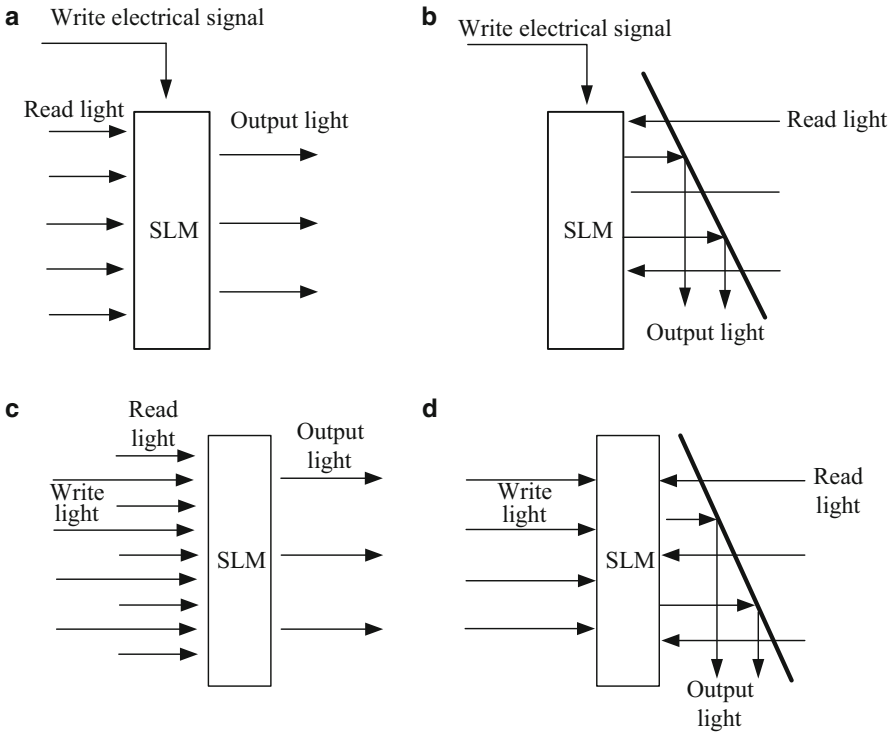

Fig. 28.10 Schematic diagram of four spatial light modulators [62]. (**a**) Electrically addressed transmissive; (**b**) electrically addressed reflective; (**c**) optically addressed transmissive; (**d**) optically addressed reflective

light modulators implement addressing by applying a voltage to each pixel through a circuit [64].

Liquid-crystal spatial light modulators are classified according to the modulation parameters of the light wave. If the amplitude of the light wave is modulated, it is called an amplitude-type spatial light modulator, which primarily modulates the light intensity of incident rays. A phase-type spatial light modulator primarily modulates the wavefront phase of the light wave and is often used to compensate and correct the front of the light wave [65].

Research Status of Optical-Modulation Technology

Foreign Research Progress

In the late twentieth century, McManamon et al. investigated the optical phase-modulation process and concluded that optical-phased arrays had the potential to overcome the limitations of mechanical light-control beams. Lindquist et al. reported

that liquid-crystal phase gratings had a high diffraction efficiency and strong incident-angle dependence. The high anisotropy of the grating demonstrated the properties of blazed gratings, which made the gratings useful for light-beam control and diffraction applications [66, 67].

In 1997, Titus et al. studied the mathematical model of a liquid-crystal cell and used it to construct a diffraction grating. They designed a pure phase grating whose phase distribution was easy to control, and analyzed the change in pointing accuracy [68].

In 2001, Hakamura et al. studied the effect of the overdrive addressing scheme on a liquid-crystal display by applying an initial pulse slightly higher than the rated voltage to the target; it caused the fast director to redirect, depending on the dynamics. The results showed that the overdrive method greatly reduced the liquid-crystal response time and improved the blurred tailing of the image [69].

In 2003, Harris et al. described a simple experimental setup that could be used to measure the steering efficiency of liquid-crystal optical phased arrays. Several optimization methods were discussed to determine the voltage per electrode to optimize the steering efficiency. The experimental results showed that this method could quickly determine the optimal voltage for an ideal far-field diffraction pattern. Compared with the calibration of the open-loop device, the steering efficiency was improved by more than 100% [70].

In 2004, McManamon studied liquid-crystal optical phased arrays through numerical simulations, discussed the effects of the edge electric field, liquid-crystal material properties, and voltage-optimization process on the performance of liquid-crystal optical phased arrays, and discussed the structure of liquid-crystal optical phased arrays. The diffraction angle and diffraction efficiency are related design issues. They proposed a wide-angle design of liquid-crystal optical phased arrays for efficient laser-beam control [71].

In 2004, Barrick et al. proposed an electronically controlled birefringence device that controlled a beam of light using components approximately 2–20 times the wavelength of light inside a liquid crystal. These components were narrow transparent electrodes that formed a sagittal profile along one dimension of the liquid-crystal plate, thereby affecting the phase of the coherent light passing through the device. When dual-frequency liquid-crystal materials were exposed to applied voltages of different frequencies, they exhibited dielectric anisotropy of opposite signs. By using high frequencies to drive liquid-crystal molecules to a state close to their zero-voltage equilibrium conformation, the material improved the switching speed of the device. In the experimental verification, the model for 1550-nm lasers was used; when the beam of light was deflected by 0.86–8.86°, the optimized beam-diffraction efficiency was significantly improved [72].

In 2006, Tholl et al. discovered that a beam of light could be steered by applying a linear phase delay to the aperture of the laser beam. The corresponding wavefront slope determined the steering angle. The combination of a large wavefront slope and large aperture required a large optical-path difference across the aperture, which needed to be achieved by the beam of a light-control device. Based on this, a new pointing-accuracy optimization method was developed [73].

In 2006, Robert et al. developed a programmable circuit for fast-switching liquid-crystal spatial light modulators. It was programmed to improve the speed of nematic liquid-crystal spatial light modulators with a very slow response speed, reducing the modulation phase and the time required. The response time required for the phase to rise from 0 to 2π was shortened from 320 ms to 67 ms, and the response time required for the phase to rise from 2π to 0 was shortened from 420 ms to 8 ms [74].

In 2008, Engstrom et al. found that when using a one-dimensional phase spatial light modulator to control a beam of light, the limited pixel and its quantized phase-modulation value limited the modulation accuracy. Therefore, a method of modulating the phase surface was proposed to calibrate the front of the light wavefront, and the pointing accuracy was optimized by determining the average slope of the wavefront after calibration [75].

In 2011, Kim et al. described and demonstrated a nonmechanical light-beam control device based on passive gratings and liquid-crystal polymers, which achieved a large-angle deflection and had high efficiency. With a nonmechanical light-beam steering range of 80°, for a light beam with a 1064-nm wavelength, there were 32 steering angles, and the angular resolution was 2.6°. The system was efficient at 66–70% throughput, but was limited by reflection and absorption losses caused by the electrode materials [76].

In 2013, Thalhammer et al. proposed two mutually compatible methods for accelerating the dynamic response speed without a loss of diffraction efficiency. One technique involved an overspeed drive, which calculated intermediate modes to expedite the transition to target phase modes. The second method optimized the target pattern to reduce the desired phase change applied to each pixel, which resulted in a dramatic reduction in the change in diffracted-light intensity during the transition. When these methods were applied together, the transition time of the diffracted light field was approximately 1 ms, which was a tenfold improvement over the current methods. Experiments showed that the method was improved in holographic-image projection, light-beam control and switching, and real-time control loops [77].

In 2017, Steven et al. developed a 1550-nm light-beam deflection system with a net aperture of 10 cm that could be steered at a 1° resolution at a 64° × 64° scanning field of view. The light-beam-diffraction efficiency reached more than 80% and maintained the wavefront distortion at $\lambda/10$ root-mean-squared (RMS) [78].

In 2020, Xiao et al. developed a diffraction grating with a large scanning field of view and high diffraction efficiency with a 532-nm wavelength and 400-nm period transmission mode. The angular bandwidth was significantly increased by arranging two inclined grating layers in the same monolithic film. By simulating the optical properties, a diffraction structure with a 48° scanning field of view and diffraction efficiency of 70% was determined [79].

In 2019, He et al. proposed the use of several phase-recovery techniques to directly measure the corresponding wavefront and used the obtained wavefront to correct aberrations caused by spatial inhomogeneity. Using Twyman–Green interferometry, an interferogram-acquisition technique based on SLM wavefront modulation was proposed. In addition, a method for determining the corresponding active

area of the liquid-crystal backplane and the parameters of the two-dimensional projection transformation was proposed to convert the active area into the fitting resolution of the spatial light modulator [80] (Table 28.2).

Domestic Research Status

In 2009, Kong et al. proposed a method for quantitatively calculating the scanning error and found that it was on the order of 10^{-1}, 10^{-2}, and 10^{-3}. They investigated the influence of the manufacturing process of a lidar liquid-crystal phased array element on the scanning accuracy [81, 82].

In 2011, Zou cascaded a multiplex Bragg grating with a liquid-crystal spatial light modulator. The system controlled the light beam to achieve quasi-continuous deflection at 0–11.82°. The cascaded system had a maximum deflection efficiency of approximately 2% for the beam of light [83].

In 2011, Yin built a closed-loop optimization experimental platform and proposed a diffraction-efficiency optimization method based on energy constraints that did not require a probe wavefront phase. The phase-recovery method was used to correct the phase difference between array elements caused by the inhomogeneity of periodic-array elements, which effectively improved the diffraction efficiency of the light beams [84].

In 2012, Zhou et al. developed an optimization algorithm that used the slope-correction accuracy of a single electrode. This method adjusted the gap between the approximate slope and the ideal slope by narrowing the voltage step height and optimized the pointing accuracy [85].

In 2014, Qiao established a lidar system using one-dimensional liquid-crystal optical phased-array scanning, which laid the foundation for an analysis of lidar accuracy. The voltage-quantization noise caused by the side lobes and extension of the laser pulses were analyzed. A scanning-imaging lidar-system platform based on a liquid-crystal optical phased array was established, and steering and ranging accuracy experiments were performed. An iterative phase-compensation method was used to improve the steering accuracy, and the side-lobe suppression method was used to improve the ranging accuracy. The simulation results demonstrated that the proposed method was feasible. When the pointing accuracy $n = 16$, the steering accuracy improved from 0.13 mrad to 0.04 mrad, and the ranging accuracy improved from 0.040 m to 0.021 m [86].

In 2017, Yang et al. built a test system with a silicon-based liquid-crystal spatial light modulator with 1920 × 1080 pixels to realize the intelligent nonmechanical control of light beams. The system divided the incident ray beam into two, three, four, and five beams to separately control each beam [87].

In 2017, Wang et al. proposed a nonmechanical laser-beam control scheme to achieve high-efficiency continuous two-dimensional scanning. The core method was to orthogonally cascade two liquid-crystal optical phased arrays and use them for azimuth and elevation. The steering characteristics of the two-dimensional light beam were verified experimentally. Based on the experimental device, linearly polarized beams with different polarization angles were controlled with high precision. The measured angular deviation was less than 5 μrad, and the beam-deflection efficiency was 84.7% [63] (Table 28.3).

In 2020, Xiao derived the transformation formula of a Gaussian light beam passing through a telescope system to realize the wide-angle deflection of a liquid-

Table 28.3 Research status of key technologies in domestic light modulation

crystal optical phased array [88]. The optical transfer matrix of the telescope was studied and the angular-amplification effect was derived.

In 2019, Li combined a liquid-crystal polarization grating with a liquid-crystal phased array to realize a high-angle, high-precision laser scanning system. Four liquid-crystal polarization gratings were combined to achieve a one-dimensional light-beam deflection with a $\pm 20^\circ$ angle range; the grating vector of the same group of liquid-crystal polarization gratings was rotated 90° to realize a two-dimensional large-angle light-beam deflection. The polarization grating was connected to the liquid-crystal phased array by designing the optical path, and the scanning step size of the grating was filled with the liquid-crystal phased array to achieve a high-precision light-beam deflection [89].

In 2019, Ke et al. used a liquid-crystal spatial light modulator to mount an adaptive-optics system using the conjugate-wavefront method to compensate for

the distortion before the wave and realize static wavefront correction. The Strehl ratio was 0.3795 before correction and 0.8268 after correction [62].

In 2020, based on the establishment of an electrical model of the multilayer physical structure of a liquid-crystal spatial light modulator, Niu et al. proposed a quantitative-calculation model for the mapping relationship between the actual inclination angle and the driving voltage, which accurately controlled the light-beam deflection [90].

In 2022, Chen et al. achieved the real-time continuous modulation of operating wavelengths in anisotropic polymerized cholesteric liquid-crystal (PCLC) films with the help of a microfluidic-based "dip-refill" strategy, with a dynamic range of up to 210 nm [91].

Performance Evaluation of Liquid-Crystal Spatial Light Modulators

Amplitude-Modulation Characteristics

With the twisted nematic liquid-crystal characteristics, a liquid-crystal spatial light modulator can change the polarization state of an incident ray and modulate the light amplitude by selecting a suitable polarizer [92]. Figure 28.11 shows the principle of modulating the amplitude of the twisted liquid crystal. The long-axis distortion angle of the liquid-crystal molecules on the positive and negative surfaces of the liquid-crystal cell is 90°, and the polarizers with the same long-axis direction and polarization direction on the front and rear surfaces of the liquid-crystal cell are placed in the front and rear of the liquid-crystal cell, respectively.

Amplitude modulation controls the polarization direction of the outgoing light by applying different external-field voltages to both ends of the liquid-crystal cell, thereby controlling the light intensity [93].

Phase-Modulation Characteristics

A liquid-crystal spatial light modulator can be regarded as a polarizing device because of its polarization-dependent characteristics. Through a Jones matrix, the light-intensity transmittance of the light beam passing through the polarizer, liquid-crystal spatial light modulator, and polarizer can be measured [94, 95].

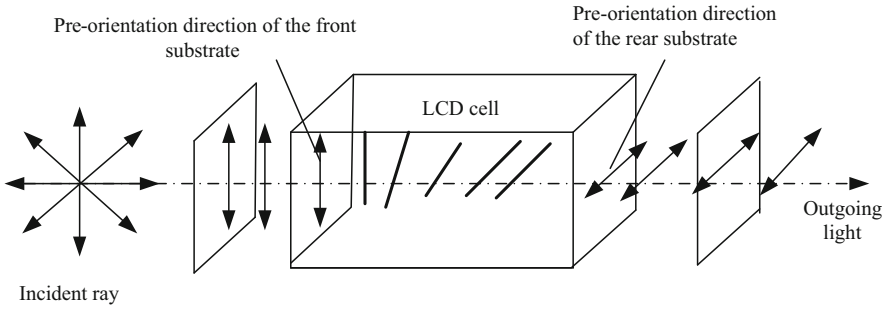

Fig. 28.11 Schematic diagram of liquid-crystal amplitude modulation [93]

Assuming that the incident surface of the liquid-crystal layer is parallel to the x-y plane, the optical axis of the liquid crystal is arranged along the x-axis, and the light propagates along the z-axis. The polarization direction of the polarizer and the x-axis form the angle φ_1, and the polarization direction of the polarizer and the x-axis form angle φ_2.

As shown in Fig. 28.12, the normalized Jones matrix of the incident ray can be expressed as

$$E_{in} = \begin{bmatrix} 0 \\ 1 \end{bmatrix}. \tag{28.16}$$

The polarization direction of the incident ray changes according to the polarizer and its polarization direction, which can be represented by rotating matrix R (φ):

$$R(\varphi) = \begin{bmatrix} \cos\varphi & \sin\varphi \\ -\sin\varphi & \cos\varphi \end{bmatrix}. \tag{28.17}$$

The Jones-matrix vector after the incident ray passes through the polarizer is expressed as

$$E_1 = R(\theta_1)E_{in} = \begin{bmatrix} \cos\theta_1 & \sin\theta_1 \\ -\sin\theta_1 & \cos\theta_1 \end{bmatrix} \begin{bmatrix} 0 \\ 1 \end{bmatrix} = \begin{bmatrix} \sin\theta_1 \\ \cos\theta_1 \end{bmatrix}. \tag{28.18}$$

Because the optical axis of the LC-SLM is parallel to the x-axis, its Jones matrix can be expressed as

$$SLM(\beta) = \begin{bmatrix} 1 & 0 \\ 0 & E^{-i\beta} \end{bmatrix}. \tag{28.19}$$

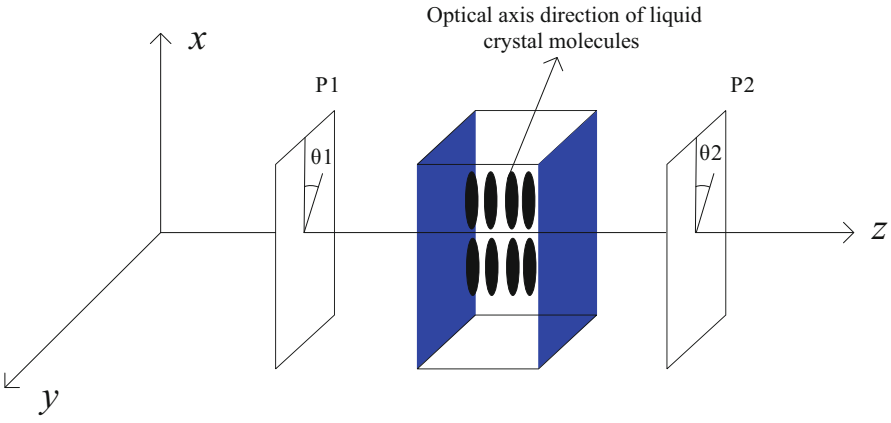

Fig. 28.12 LC-SLM working schematic diagram

The Jones matrix of the analyzer is

$$P = \begin{bmatrix} 0 & 0 \\ 0 & 1 \end{bmatrix}. \tag{28.20}$$

The Jones matrix of the outgoing light after passing the analyzer is

$$E_2 = PR(-\varphi_2) = \begin{bmatrix} 0 & 0 \\ 0 & 1 \end{bmatrix} \begin{bmatrix} \cos\varphi_2 & \sin\varphi_2 \\ \sin\varphi_2 & \cos\varphi_2 \end{bmatrix} = \begin{bmatrix} 0 & 0 \\ \sin\varphi_2 & \cos\varphi_2 \end{bmatrix}. \tag{28.21}$$

From the above derivation, it can be observed that after passing through the polarizer and LC-SLM, the Jones vector of the incident ray can be expressed as

$$\vec{E}_{\text{out}} = PR(-\varphi_2)SLM(\beta)R(\varphi_1)E_{\text{in}}. \tag{28.22}$$

Substituting Eqs. 28.12, 28.13, and 28.15 into the above formula, the complex amplitude of the outgoing light can be obtained as

$$\vec{E}_{\text{out}} = \sin\varphi_1 \sin\varphi_2 + \cos\varphi_1 \cos\kappa_2 e^{-j\beta}. \tag{28.23}$$

Simplifying Eq. 28.17, the light-intensity expression of the outgoing light is

$$I = \frac{1}{4}[\cos(\varphi_1 + \varphi_2) - \cos(\varphi_2 - \varphi_1) + \cos\beta(\cos(\varphi_1 + \varphi_2) - \cos(\varphi_2 - \varphi_1))]^2 + \frac{1}{4}\sin^2\beta[\cos(\varphi_1 + \varphi_2) - \cos(\varphi_2 - \varphi_1)]^2. \tag{28.24}$$

The phase-delay expression of the outgoing light is [96, 97]

$$\delta = \beta + \arctan \frac{\sin\beta[\cos(\varphi_1 + \varphi_2) + \cos(\varphi_2 - \varphi_1)]}{\cos(\varphi_1 + \varphi_2) - \cos(\varphi_2 - \varphi_1) + \cos\beta[\cos(\varphi_1 + \varphi_2) - \cos(\varphi_2 - \varphi_1)]}. \tag{28.25}$$

Application of Liquid-Crystal Spatial Light Modulators to Adaptive Optics

Phase-Screen Simulation of a Liquid-Crystal Spatial Light Modulator

A phase screen is a gray-release value matrix that simulates the phase change of atmospheric turbulence. This matrix is generally obtained from the phase function of the turbulence model that must be loaded. Taking a 256 × 256 LCD screen as an example, the LCD is fitted to a 256 × 256 lattice; then, each gray-release value on

the phase screen represents the phase value of the corresponding point on the lattice. The generated phase-screen matrix must consider the size of the LCD area and its correspondence with the analog phase-screen data [60].

The turbulence-effect simulation system is composed of a phase-type electrically addressable liquid-crystal spatial light modulator to simulate the far-field turbulence effect of laser signals [58]. The light emitted by the laser continuously attenuates the incident laser energy by controlling the relative angle of the polarizer. The wave plate and beam of the light-adjustment system are used to adjust the phase and spot size. By combining the light-beam attenuation, the light-spot size and laser power of the spatial light modulator are within the linear operating range of the system (Fig. 28.13).

The control computer generates a series of phase data as needed and loads these phase data on the liquid-crystal spatial light modulator. The phase-modulated laser is reflected by the mirror on the sampling CCD for recording, and the modulated laser light spot is obtained by simulating the turbulence effect. Temporal and spatial changes in energy distribution are investigated. The settings of the computer are controlled using the voltage of the liquid-crystal spatial light modulator in a lookup table. The relationship between the control voltage and the control pixel phase is used to adjust the spatial phase of the light beam reaching each pixel of the mirror to simulate the turbulence [60].

LC-SLM Coherent Optical Communication Wavefront-Correction Technology

In 2019, Ke Xizheng et al. from Xi'an University of Technology used a liquid-crystal spatial light modulator to correct the optical-signal distortion of a wave transmitted through atmospheric turbulence, thereby improving the performance of

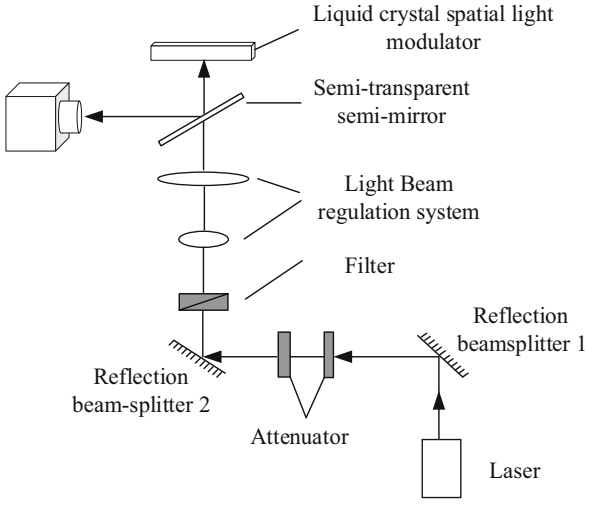

Fig. 28.13 Block diagram of the turbulence-effect simulation system

spatial coherent optical communication. The calibration experiment was divided into static wavefront-correction and field experiments [61].

Static Wavefront-Correction Experiment

The static wavefront-correction experiment adopts the conjugate-wavefront method. As shown in Fig. 28.14, first, the conjugate operation needs to be performed before the 1550-nm distorted wave. Then, the conjugate wavefront is calculated and processed, converted into the required gray-release value, and loaded into the liquid-crystal spatial light modulator to correct the distorted wavefront of the signal light.

The conjugate-wavefront method was used to correct the difference-frequency signal. To reduce the interference of external environmental factors on the difference-frequency signal, a wavefront-correction experiment was conducted at approximately 13 points. The correction results are shown in Fig. 28.15.

It can be seen from the figure that although the amplitude of the corrected difference-frequency signal fluctuates to a certain extent, in general, the amplitude tends to stabilize, and the fluctuation value of the voltage is not large over time; thus, there is not much difference between the amplitudes of the output sine wave. Moreover, the amplitude of the sine wave stabilizes at approximately 46 mV. Compared with the voltage amplitude before correction, the voltage amplitude after correction increased by approximately 1.7 times, and the signal-to-noise ratio after correction increased by nearly three times.

Figure 28.16 shows the output-voltage value of the difference-frequency signal before wavefront correction, where a is the voltage amplitude in the in-phase direction, and b is the voltage amplitude in the quadrature direction (Fig. 28.17).

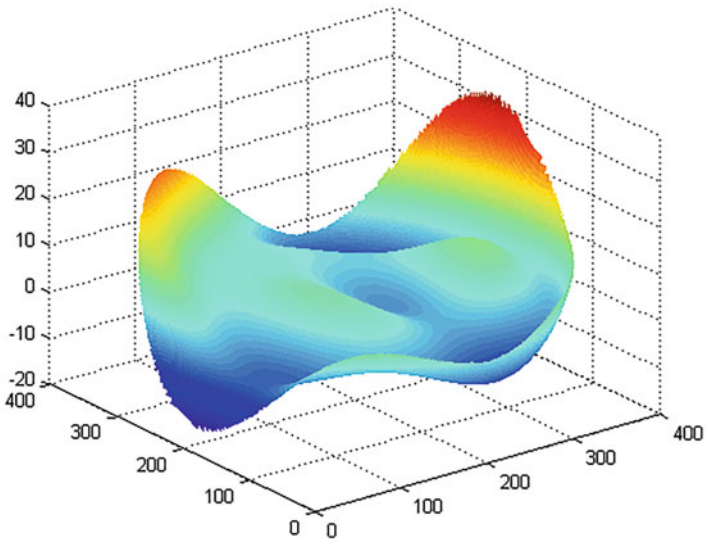

Fig. 28.14 1550-nm light-beam distorted-wave conjugate wavefront

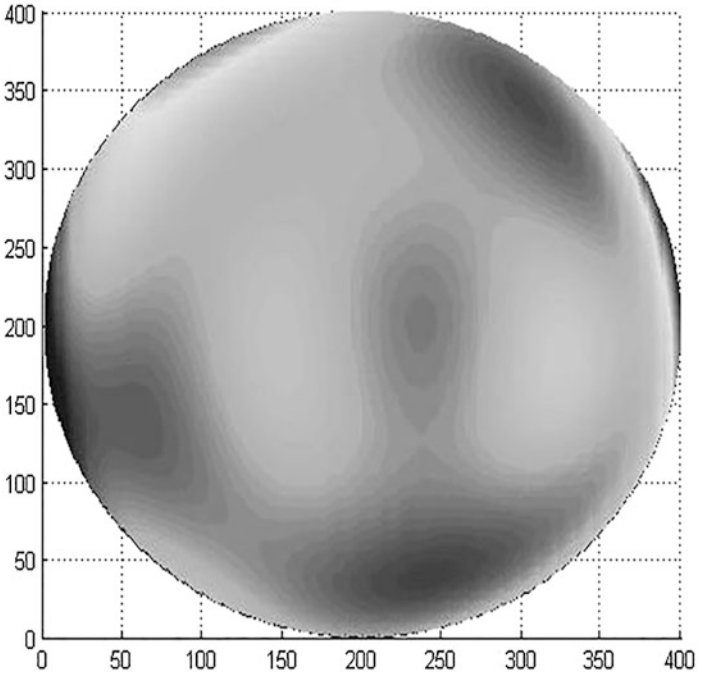

Fig. 28.15 Conjugate-wavefront gray-release diagram

1.3-Km Field Experiment

To further verify the influence of atmospheric turbulence on the signal-light wavefront and heterodyne signal, the laboratory conducted a space optical communication field experiment; the straight-line distance was 1.3 km.

In the experiment, the signal and beacon lights are coupled into the same optical fiber through the coupler and then transmitted by the optical antenna of the transmitting end. The receiving end receives the two beams of light and the sum of the beams of light, while a Shack–Hartmann wavefront sensor measures the beacon light. The wavefront of the beacon light fits the distorted wavefront of the beacon light in real-time.

According to the Zernike polynomial coefficients given in the fitting process, the conjugate wave of the distorted wavefront is obtained by the conjugate method. According to the modulation characteristics of the transmitted liquid-crystal spatial light modulator for the signal and beacon lights, the conjugate wavefront is converted into the gray-release value of the liquid-crystal spatial light modulator. It is then loaded onto the liquid-crystal spatial light modulator to correct the distorted wavefront of the signal light. Figures 28.18, 28.19, 28.20, 28.21, and 28.22 show the results of the field experiment from 12:00 am to 4:00 am on May 7, 2028.

Figure 28.18 shows the amplitude of the difference-frequency signal before and after correction. In the figure, the dotted sine wave represents the difference-

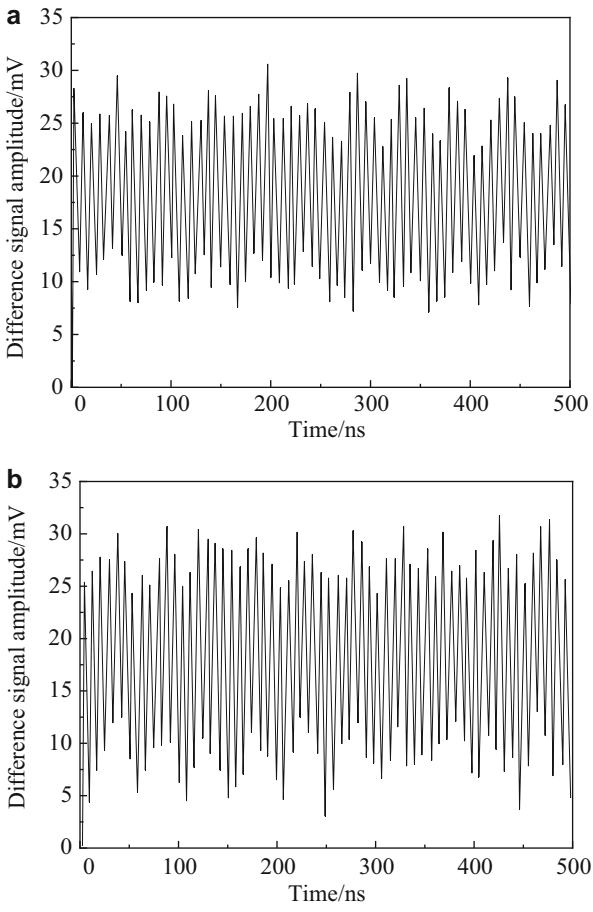

Fig. 28.16 Amplitudes of difference-frequency signal before correction. (**a**) In-phase; (**b**) quadrature [61]

frequency signal in the same phase direction, and the solid sine wave represents the difference-frequency signal in the quadrature direction. It can be observed from the figure that the amplitudes of the two difference-frequency signals output after correction are approximately twice as high as that before correction, and the amplitude of each sine signal tends to be constant.

Figure 28.19 shows the power-spectrum curve of the difference-frequency signal before and after correction. It can be seen from the figure that the main spectral peak of the power spectrum of the difference-frequency signal after correction becomes more acute. The peak value of the power-spectral density of the difference-frequency signal at the main spectral peak increases from 15.7 dB/Hz to 21.3 dB/Hz. The noise of the difference-frequency signal before correction is filtered out, and the system signal-to-noise ratio is improved.

As shown in Fig. 28.20, the amplitude of the difference-frequency signal of the system before correction is too small, and it fluctuates significantly in the adjacent

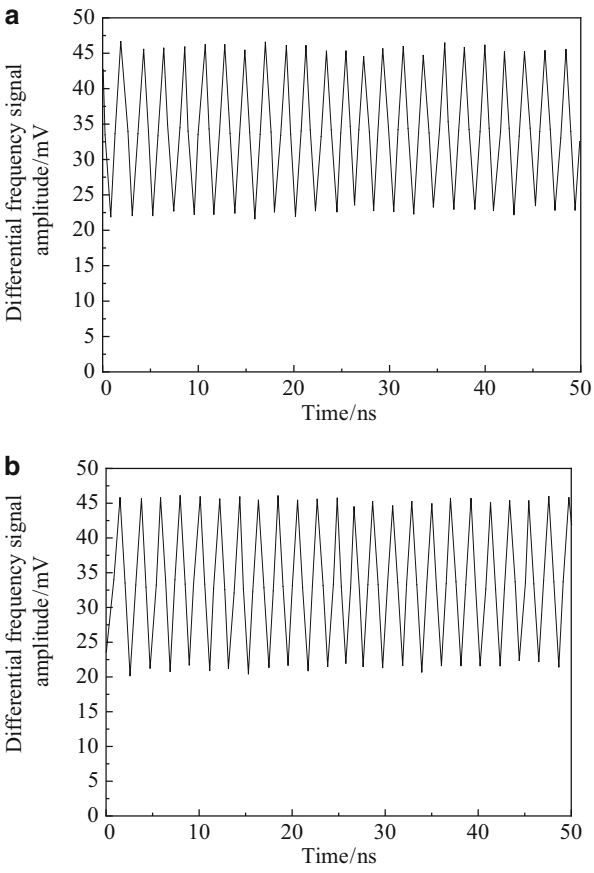

Fig. 28.17 Amplitude of the corrected difference-frequency signal. (**a**) in the same phase direction; (**b**) in the orthogonal direction [61]

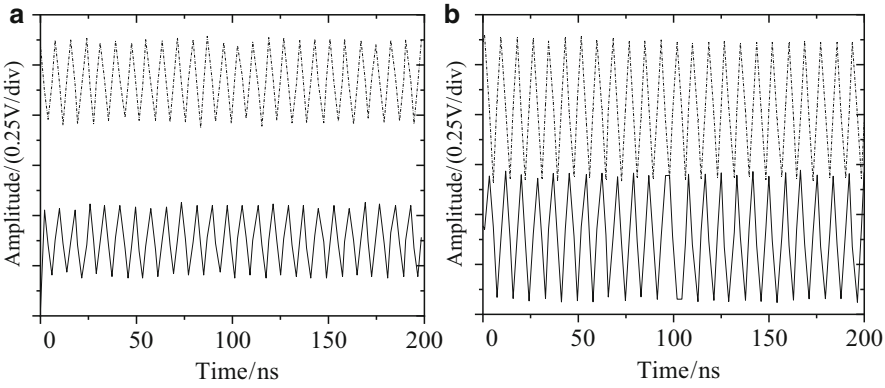

Fig. 28.18 Difference-frequency signal amplitude before and after correction [61]. (**a**) Before correction; (**b**) after correction

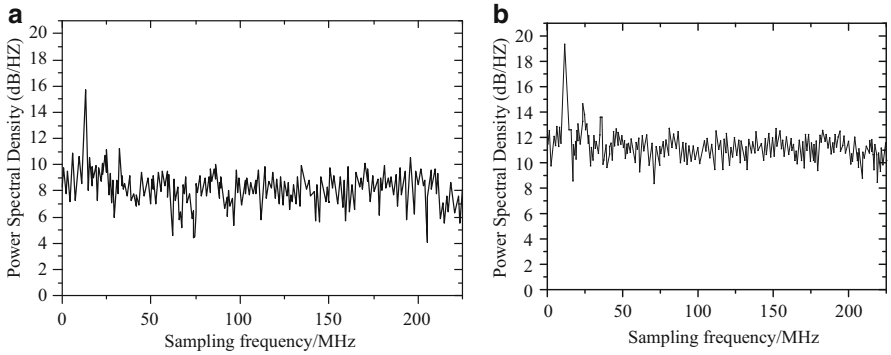

Fig. 28.19 Power spectrum of difference-frequency signal before and after correction [61]. (**a**) Before correction; (**b**) after correction

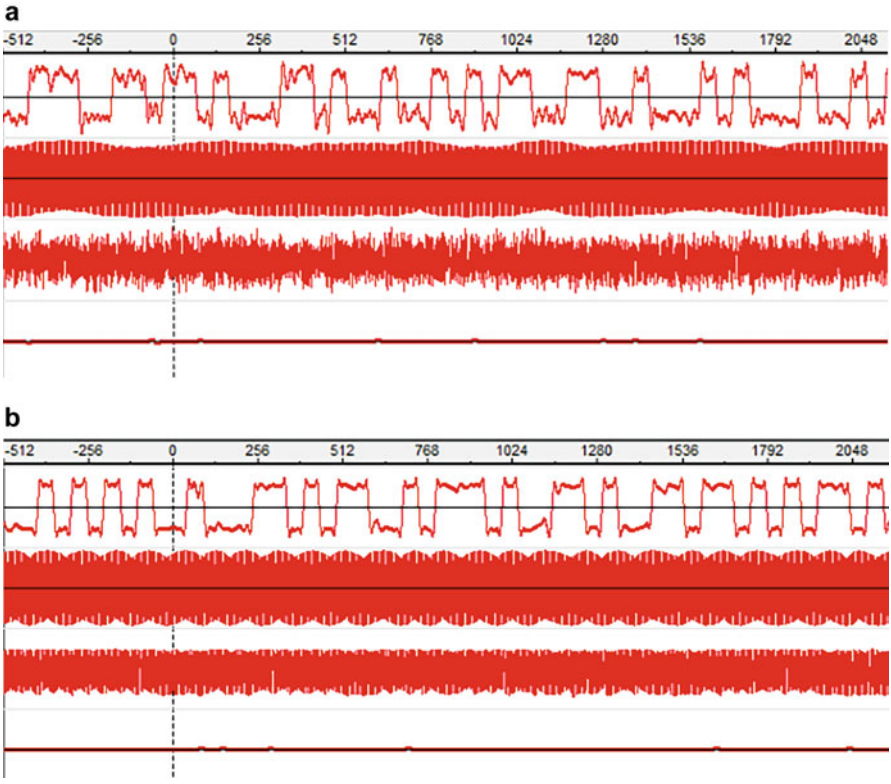

Fig. 28.20 Baseband signal before and after AO correction [61]. (**a**) Before correction; (**b**) after correction

period of the difference-frequency signal. Thus, it cannot meet the minimum amplitude requirements for decoding. The baseband signal output by the decoder is irregular in shape and has many surrounding glitches. After the signal optical-

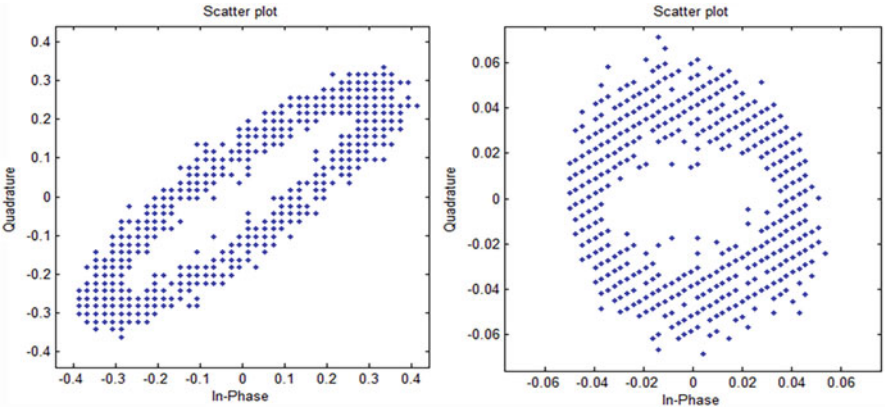

Fig. 28.21 Received signal constellation before calibration [61]

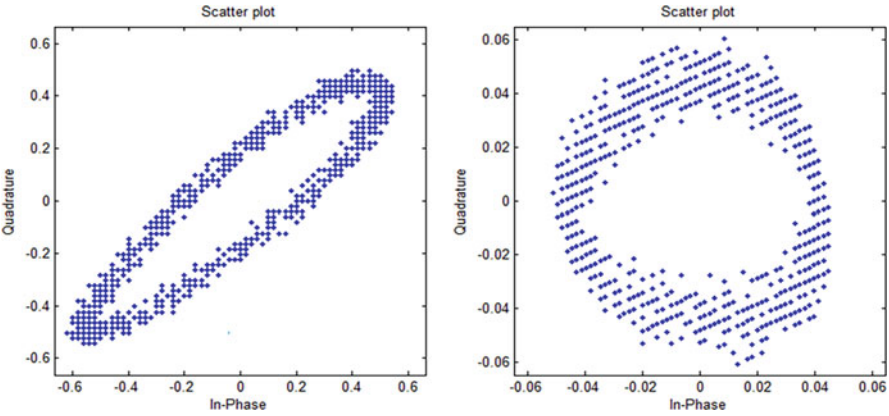

Fig. 28.22 Received signal constellation after correction [61]

wavefront distortion is corrected using AO technology, the amplitude of the difference-frequency signal meets the decoding requirements of the receiving end. The shape of the baseband signal decoded by the decoder and the square-wave approximation can be used to decode the transmitted video signal.

Comparing the constellation maps of the received signal before and after correction in Figs. 28.21 and 28.22, the dispersion between the points in the scatter map before correction is relatively large. After the adaptive-optics system corrects the distorted wave, the distribution of each scatter point in the constellation map of the received signal is relatively concentrated. The bit-error rate of the system after correction is reduced by approximately ten times.

The experimental results show that the amplitude of the photocurrent of the corrected differential-frequency signal can be increased by approximately 1.7 times, and the output signal-to-noise ratio can be increased by approximately three times using the transmissive liquid-crystal spatial light modulator for static

wavefront correction. The field-experiment results show that the amplitude of the output difference-frequency signal after correction increases once, and the bit-error rate of the demodulated signal is greatly reduced, which is approximately ten times less than that before correction.

Adaptive-Optical System of a Dual Liquid-Crystal Spatial Light Modulator

To solve the problem of energy loss of a single liquid-crystal spatial light modulator in the correction of an adaptive optics system, in 2022, Ke and Yang of Xi'an University of Technology designed an adaptive-optics system based on the structure of a dual liquid-crystal spatial light modulator. The dual liquid-crystal system compensates for the polarization-modulation loss caused by the liquid crystal.

The polarization-modulation characteristics of the liquid-crystal wavefront corrector cannot be avoided; however, dual liquid-crystal wavefront correctors can be used to modulate the light waves in the two polarization directions, as shown in Fig. 28.23. This can compensate for the energy loss caused by the polarization modulation of the liquid crystal. Notably, the beam of light combined after correction by the double corrector requires a higher optical-path modulation than that of the single corrector.

Figure 28.24 shows a schematic diagram of the experimental correction structure of the dual liquid-crystal spatial light modulator (LC-SLM) designed by Xi'an University of Technology. LC-SLM 1 distorts the Gaussian beam emitted by the light source. The beam-splitting prism divides the distorted light beam into two beams, one of which is corrected by LC-SLM 2, and the other is corrected by LC-SLM 3. The distorted light is captured by the CCD camera, and the gray-release diagram of the conjugate phase calculated by the Gerchberg–Saxton (GS) algorithm is used to load the light into LC-SLM 2 and LC-SLM 3, thereby realizing a closed-loop correction before the distorted wave [97].

Figures 28.25, 28.6, and 28.27 show light-spot diagrams before and after distorted light-spot correction for Gaussian light beams with strong, medium-strong, and weak atmospheric turbulence, respectively, using the GS algorithm.

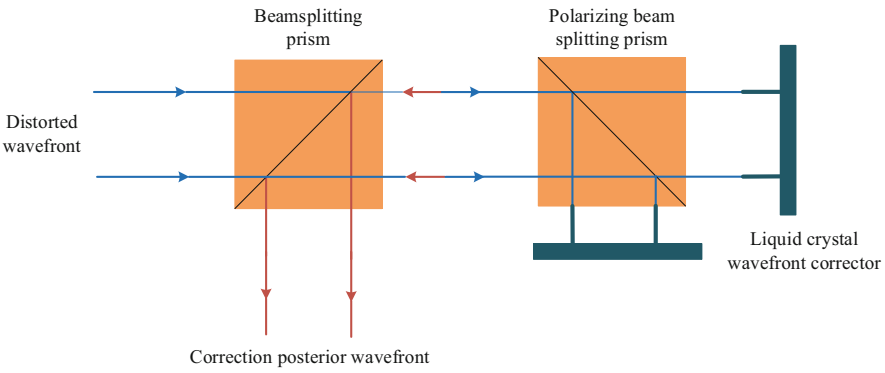

Fig. 28.23 Dual liquid-crystal wavefront corrector correction

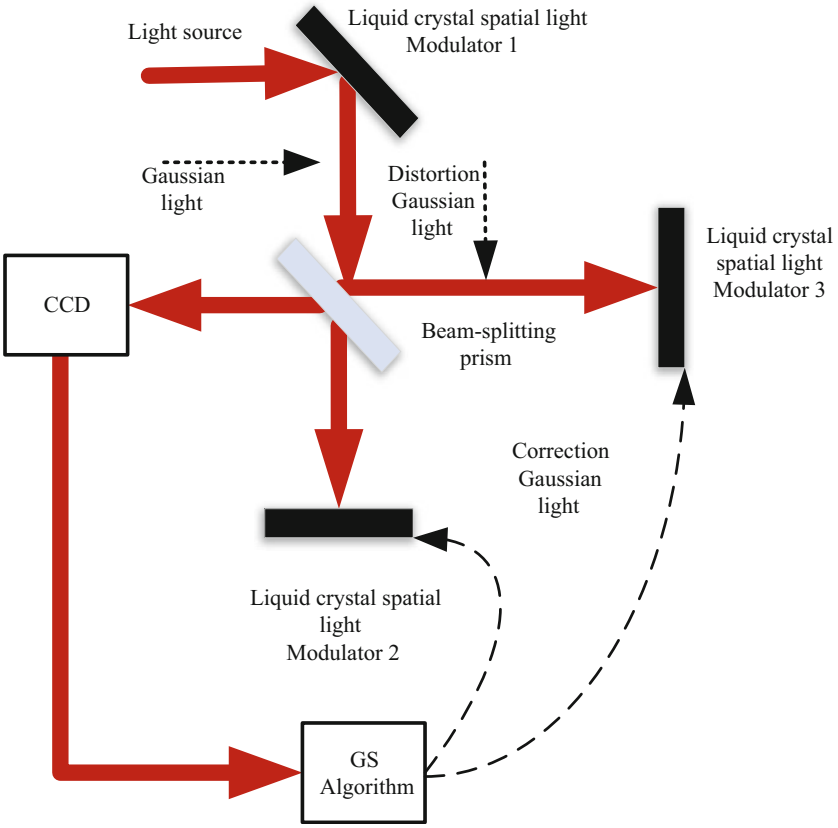

Fig. 28.24 Schematic diagram of the experimental correction structure of a dual liquid-crystal spatial light modulator for distorted light

It can be seen from Figs. 28.25, 28.26, and 28.27 that the Gaussian light beam becomes dispersed and broken after passing through the transmission environment under different turbulence intensities. However, after correction by the system, the light spot condenses, and the energy is greater. The convergence and quality are improved to a great extent.

Figure 28.28 shows the Strehl ratio (SR) variation curve of the distorted wavefront of the system under strong, medium-strong, and weak turbulence environments during simulation after 300 corrective iterations.

It can be seen from Fig. 28.28 that in a strong turbulent environment, the SR ratio of the system increases from 0.22 to 0.75; in a medium-strong turbulent environment, the SR of the system increases from 0.43 to 0.89; in a weak turbulent environment, the SR of the system increases from 0.73 to 0.97. The corrected SR value is improved to a certain extent, which shows that the correction of the dual liquid-crystal system has a certain effect.

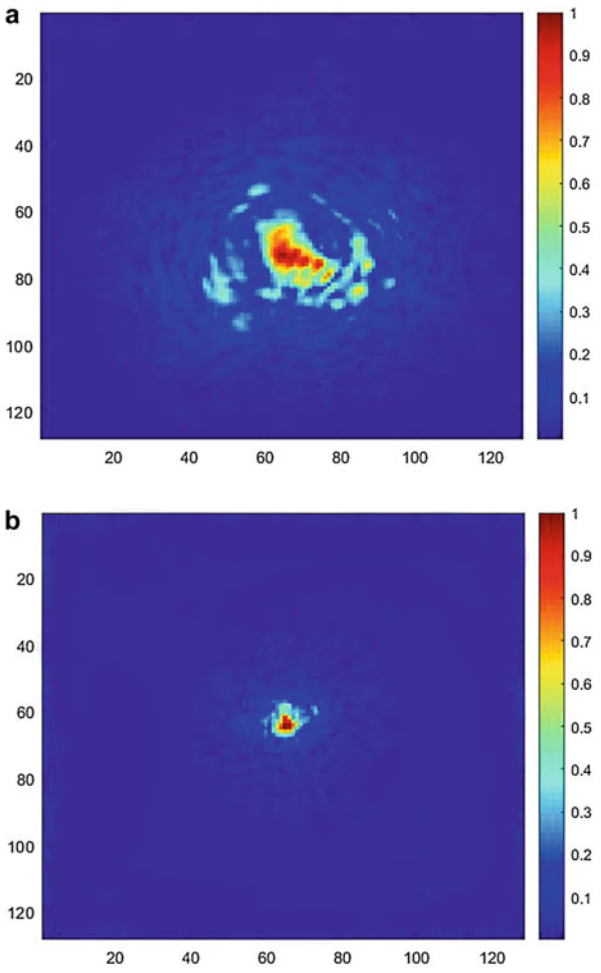

Fig. 28.25 Light-spot diagram before and after algorithm iteration when $D/r_0 = 20$. (**a**) Before iteration; (**b**) after iteration

Combined Liquid-Crystal–Deformable-Mirror Adaptive-Optics System

The deformable mirror has no dispersion problems and can meet the working requirements of a wide band; however, owing to the limitations of the manufacturing process and other reasons, the number of driving units is limited. This cannot meet the correction and imaging requirements of a large-aperture telescope system, and is not suitable for working in the visible and short-wave bands.

Because of its high-density pixel unit, the liquid-crystal spatial light modulator can meet the needs of a large-aperture telescope system for imaging and correction; however, because of its other characteristics, it is difficult to meet the correction and imaging requirements in the long-wave band. Therefore, in 2022, Ke and Yang of Xi'an University of Technology combined the advantages of deformable mirrors and

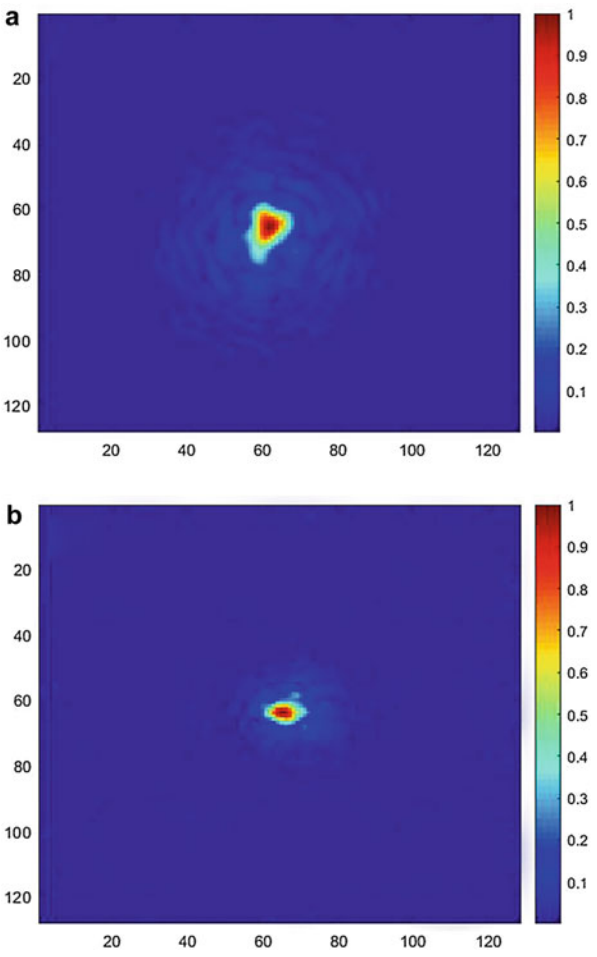

Fig. 28.26 Light-spot diagram before and after algorithm iteration when $D/r_0 = 10$. (**a**) Before iteration; (**b**) after iteration

liquid-crystal spatial light modulators and designed a set of adaptive systems based on both.

Figure 28.29 shows the experimental optical path of the deformable mirror–liquid-crystal spatial light modulator structure for correcting distorted light. LC-SLM 1 was used to distort the phase of the Gaussian light beam emitted by the light source, and the distorted light passed through an 800-nm dichroic chip. For the distorted light beam with a wavelength greater than 800 nm, the deformable-mirror correction loop used the eigenmode method for closed-loop correction. For the distorted light beam with a wavelength less than 800 nm, the liquid-crystal spatial light modulator loop used the GS algorithm for closed-loop correction [97].

Figures 28.30 and 28.31 show the light spots before and after the simulation of the system using the short-band correction loop. For the distorted light beam with

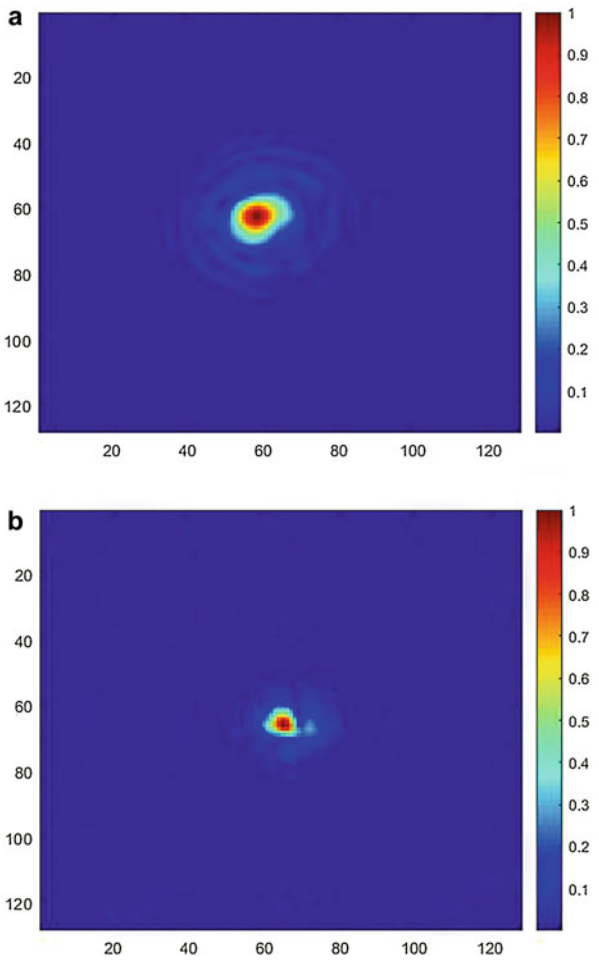

Fig. 28.27 Light-spot diagram before and after algorithm iteration when $D/r_0 = 2$. (**a**) Before iteration; (**b**) after iteration

wavelengths of 520 nm and 632.8 nm in a medium-strong turbulent environment, the GS algorithm iterates 200 times to make the correction. The change trend of the system SR can be observed.

Figures 28.32 and 28.33 show that the system adopts a long-band correction loop during the simulation. For the distorted light beam with wavelengths of 980 nm and 1550 nm in a medium-strong turbulent environment, the deformable-mirror eigenmode method iterates 20 times to make the correction. The light-spot diagram and change-trend diagram of the SR are shown.

From Figs. 28.30, 28.31, 28.32, and 28.33, it can be seen that for medium-strong turbulent environments, the distorted wavefronts of the long and short wavelengths are respectively corrected by the deformable-mirror correction loop and the liquid-crystal spatial light modulator correction loop. A good correction effect was

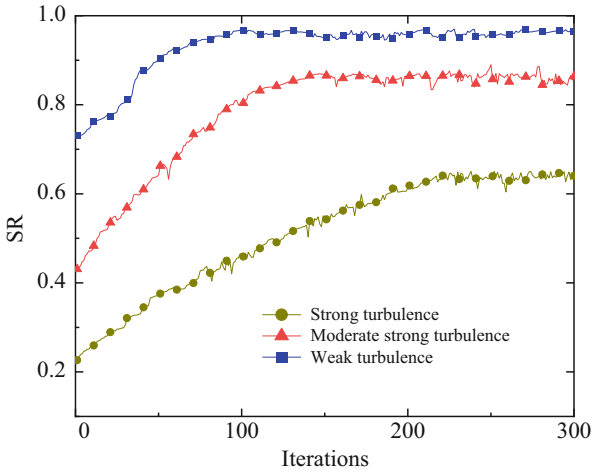

Fig. 28.28 SR variation curve of the system under different turbulence conditions

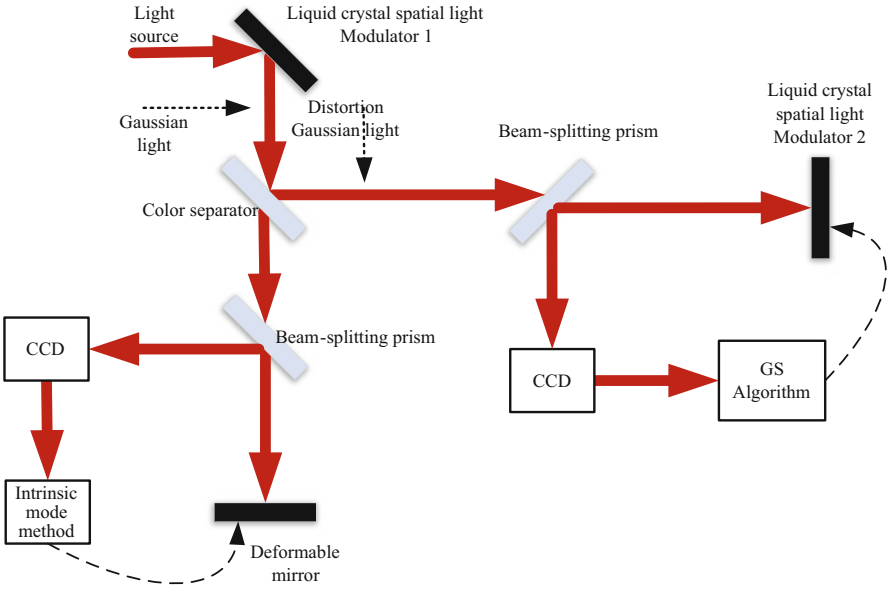

Fig. 28.29 Schematic diagram of the experimental setup for correcting distorted light with the deformable mirror–liquid-crystal spatial light modulator

obtained, and the light spot converged and was concentrated from its discrete and broken state.

In the medium-strong turbulent environment, the system SR value at the 520-nm wavelength increased from 0.37 to 0.74, that at the 632.8-nm wavelength increased from 0.38 to 0.79, that at the 980-nm wavelength increased from 0.45 to 0.75, and

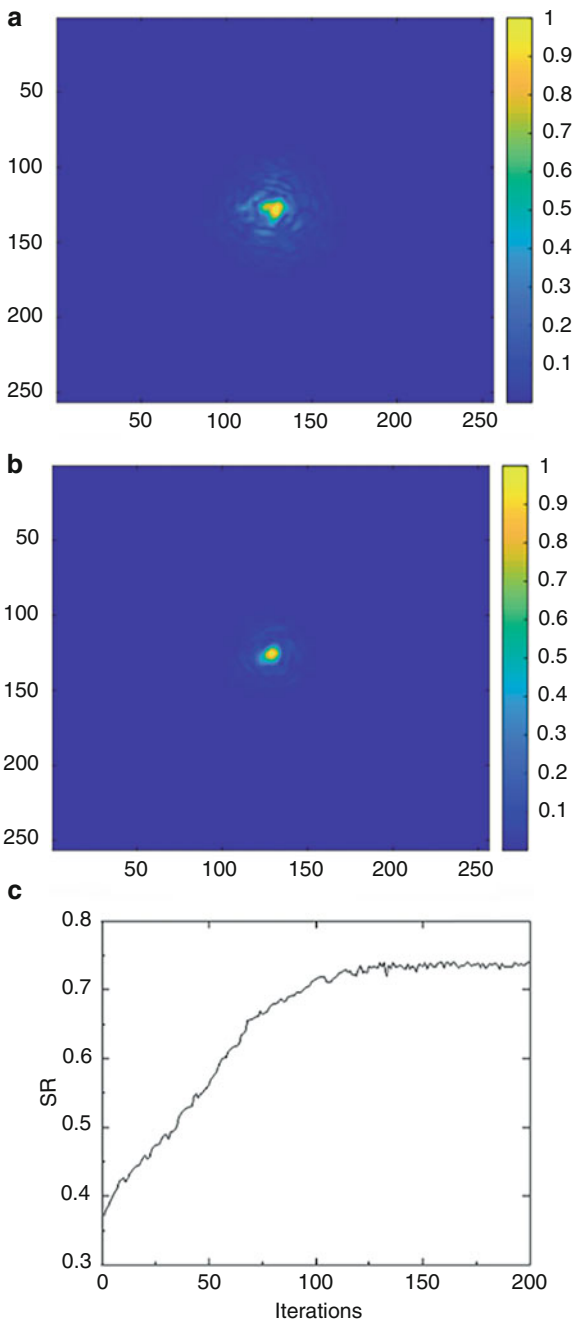

Fig. 28.30 Light spot and before and after algorithm iteration and SR curve when $l = 520$ nm. (**a**) Before correction; (**b**) after correction; (**c**) SR

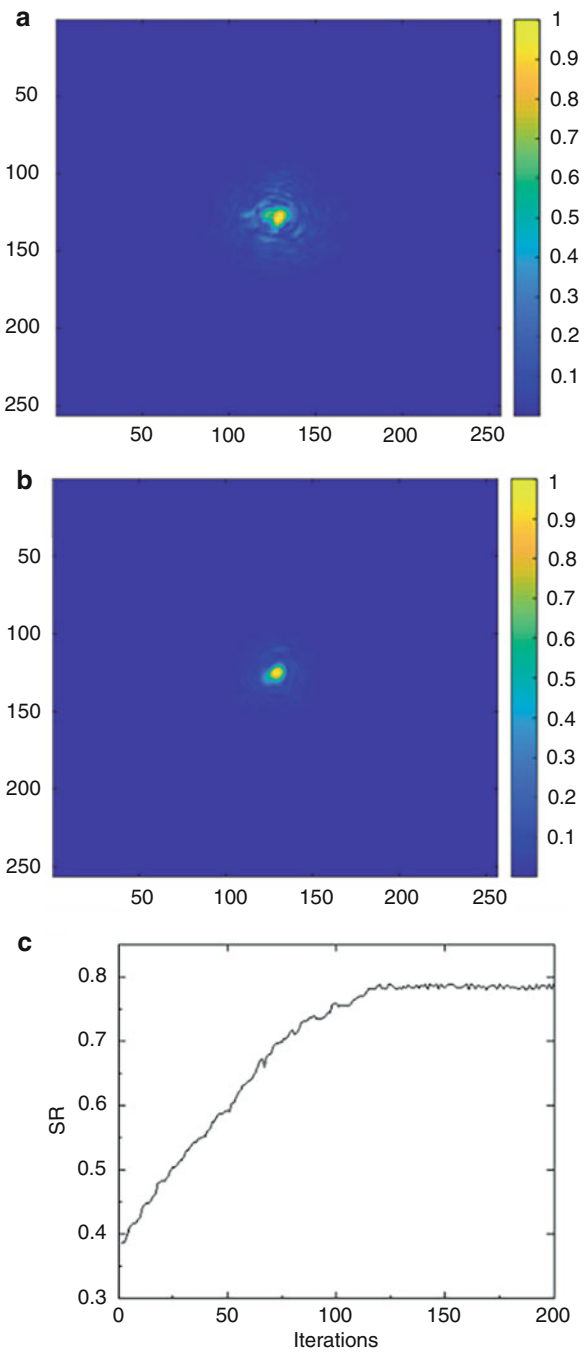

Fig. 28.31 Light spot before and after algorithm iteration and SR curve when $l =$ 632.8 nm. (**a**) Before correction; (**b**) after correction; (**c**) SR

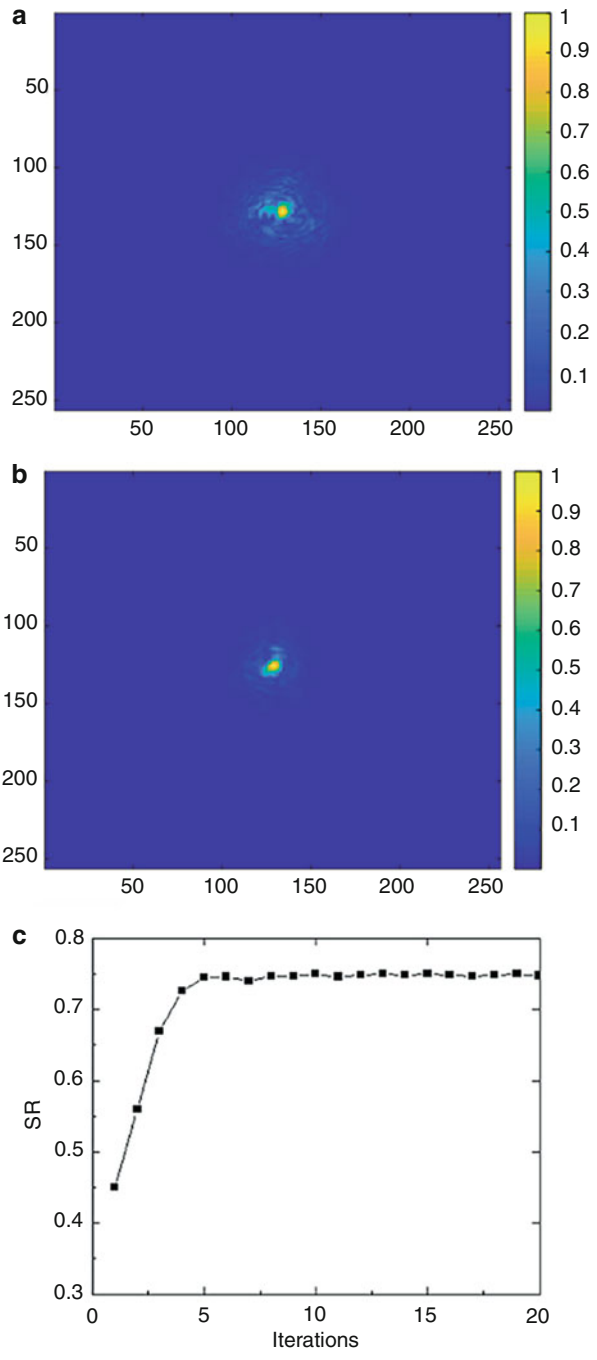

Fig. 28.32 Light spot and SR curve before and after algorithm iteration at $l =$ 980 nm. (**a**) Before correction; (**b**) after correction; (**c**) SR

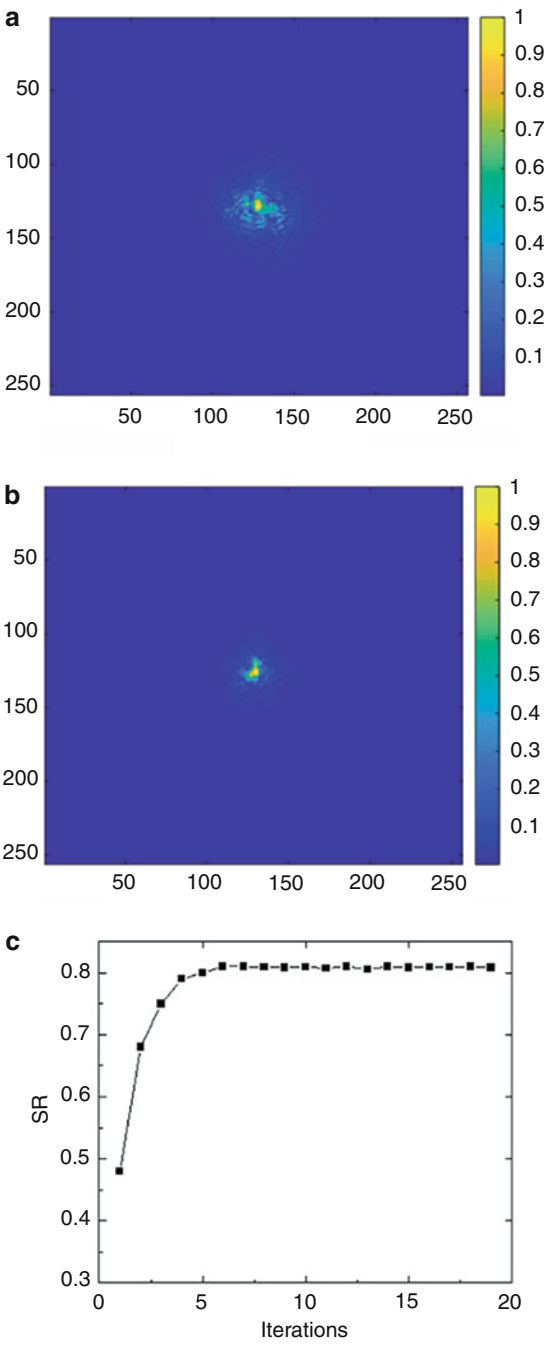

Fig. 28.33 Light spot and SR curve before and after algorithm iteration when l = 1550 nm. (**a**) Before correction; (**b**) after correction; (**c**) SR

that at the 1550-nm wavelength increased from 0.48 to 0.81. The simulation results showed that the post-SR value of each band was improved after the system was corrected. It also shows that the system helped to correct the distorted wavefront.

Summary

A liquid-crystal spatial light modulator is an ideal device for high-precision and high-resolution wavefront control; however, its applicability is low. Pure liquid-crystal spatial light phase modulators can achieve pure phase modulation greater than two without losing light intensity and have broad application prospects in the fields of static and dynamic wavefront control.

With the development of wavefront-control technology, the performance and accuracy requirements for wavefront controllers have increased. Therefore, the performance parameters of the spatial optical liquid-crystal phasers were comprehensively evaluated, and the errors in the devices were compensated and corrected.

High-precision wavefront correction is important. As an ideal device for high-precision and high-resolution wavefront control, liquid-crystal spatial light modulators have broad application prospects in static and dynamic wavefront control. To further optimize the performance of liquid-crystal spatial light modulators and improve the ability of adaptive optics to correct wavefront distortion, the following steps are necessary.

1. Under the action of an external electric field, a liquid-crystal spatial light modulator turns the liquid-crystal molecules to change the refractive index and modulates the wavefront. Because of the relaxation characteristics, the liquid-crystal molecules cannot be immediately steered; thus, their response time remains at the millisecond level. This affects the fast laser pointing and reduces the system performance of the liquid-crystal spatial light modulator. Therefore, methods should be studied to expedite the steering of the liquid-crystal molecules, improve the response speed of the liquid-crystal spatial light modulator, and improve the performance of the adaptive optical system.
2. Liquid-crystal spatial light modulators are used for wavefront correction. The phase-modulation accuracy of the spatial light modulator is affected by factors, such as the experimental environment. Therefore, the phase of the liquid-crystal spatial light modulator should be calibrated. The same liquid-crystal spatial light modulator can be calibrated multiple times using different methods to improve the measurement accuracy and wavefront correction.
3. When a liquid-crystal spatial light modulator was used in the dynamic wavefront-correction experiment, its response speed was slow, and the reading delay of the gray-release image was large. Therefore, to generate a more accurate gray-release phase image, a nonlinear phase-compensation method can be used, or the existing phase-recovery algorithm can be further improved to increase the calculation efficiency and optimize the homogenization effect.

Abstract

Mixer is an indispensable component in electronic communication system, and it is the frontend circuit of heterodyne receiver and microwave measuring instrument, which is used in microwave communication, radar, and many microwave measurement systems. With the development of optical communication, optical mixing devices in coherent optical communication also play an important role in coherent receiving terminals and optical measurement systems.

Starting with the electric mixer, this paper describes the working principle and development status of the optical mixer and the terahertz mixer and briefly introduces the work of Xi'an University of Technology in the field of optical mixer. Finally, the future development trend and prospect of the mixer are prospected.

Keywords

Microwave circuit · Coherent optical communication · Microwave mixer · Optical mixer

Introduction

The world's first microwave mixer was developed by Armstrong in 1924, when it was mainly used to increase the detection range and reception sensitivity of radar [1]. Mixers at that time were frequency conversion elements based on variable resistance nonlinear diodes; however, the slow development of electron tube devices led to the slow development of mixers [2].

Mixers are mainly used in electronic countermeasures, radar, radio measurement, and coherent optical communication and can also be used as frequency multipliers, frequency dividers, and phase discriminators. As the key device in receiving end points, research on microwave mixers is of great significance in optical communication systems.

A mixer has a circuit structure that uses the nonlinear effect of nonlinear devices to transform signals of different frequencies or local oscillator signals into differential frequency signals, or sum frequency signals of the two [3]. Frequency conversion circuits can be divided into up converters and downconverters, according to the numerical relationship between the input signal, local oscillator signal, and output signal. The down converter is also called a mixer [4]. The mixer loads the received signal carrier and the local oscillator signal together onto a nonlinear device

to mix them. This converts the radiofrequency (RF) to an intermediate frequency signal. The nonlinear effect of the diode is essential to the mixing effect.

According to the principle of nonlinear devices, mixers can be divided into active devices and passive devices. A mixer using transistors and field effect transistors (FETs) as the infrastructure is called an active device mixer. It can obtain a higher gain and the combined interference is small; however, the circuit is complex and requires a DC bias.

A mixer using a diode as the infrastructure is called a passive device mixer or a resistive mixer. This type of electric mixer has a simple structure, easy integration, stable performance, and consistent electrical characteristics. Therefore, nonlinear electric mixers are mainly used. In addition, according to the circuit structure, electrical mixers can be divided into single-ended mixers, single-balanced mixers, double-balanced mixers, etc.

Tube Mixers

In 1918, Armstrong developed the superheterodyne architecture, which enabled an easy-to-use radio. The superheterodyne receiver had gain capability and additional noise reduction advantages and also provided an intermediate frequency current signal. It was the prototype of the early mixer concept based on the electron tube structure [5].

As shown in Fig. 29.1, the vacuum tube tunes the input signal and the independent heterodyne device (local oscillator signal) into a combined oscillation signal, and the multi-vacuum tube forms a high-frequency amplifier to heterodyne process and detects the combined signal. Through this method, the radiofrequency signal can be efficiently converted into a stable output intermediate frequency signal. The signal can be amplified simultaneously, which is the sum–difference product of a typical mixer. The circuit schemes of the electron tube mixer and the transistor mixer are compared, as shown in Fig. 29.2.

According to Armstrong's patent [6], the first-stage circuit structure consists of a vacuum tube rectifier system that utilizes the rectifying properties of the tube to

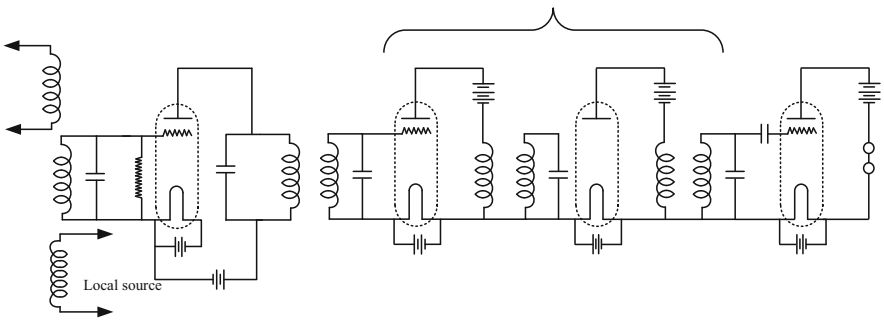

Fig. 29.1 Vacuum tube mixer structure [5]

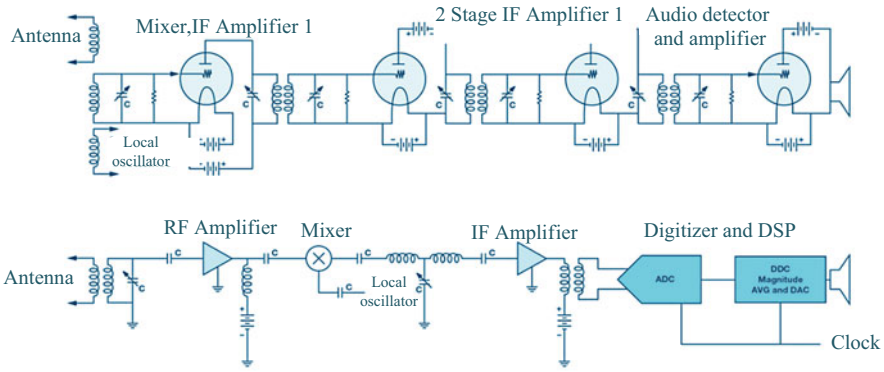

Fig. 29.2 Comparison of the tube mixer and transistor mixer [5]

generate a typical mixing product that mixes the target signal with the local oscillator signal. The only fundamental difference between Armstrong's original patent application and the modern design is the stand-alone RF amplifier placed before the mixer. By World War II, some tube designs used frontend amplifiers comparable to today's FET frontends.

Mixer design structures today are highly similar to those of 100 years ago. However, owing to today's advances in materials, integration techniques, and materials disciplines, mixers based on diode and transistor structures have smaller sizes, higher sensitivities, higher bandwidths, and higher operating spectral ranges.

RF Mixers

Schottky-Diode Mixers

As early as the 1980s, American scientists developed GaAs Schottky-diode mixers with operating frequencies in the 1–10 THz range [7]. Subsequently, scientific research groups in the United States, Japan, the United Kingdom, and other countries launched research on Schottky diodes, including die designs, junction capacitance parallel effect, skin effect, plasma resonance, and other aspects [8].

The voltage and current of the Schottky diode have a nonlinear relationship, and the superconducting transformation can be completed without depending on the temperature conditions. It works at room temperature and has a low noise figure, wide operating bandwidth, and fast speed. It is an important diode mixer type at present. Commonly used structures in Schottky diode fundamental mixers include the cross-rod structure, ring bridge structure, and three-dimensional fin waveguide structure [9].

Schottky diode harmonic mixers can be divided into two circuit forms: monolithic integration and hybrid integration [10]. In the early stages, the working frequency band of high-order harmonic mixers was in the millimeter wave frequency

band. This was mainly because the high-frequency high-order harmonic mixer had higher requirements for the driving power of the local oscillator signal and was limited by the initial processing technology and research conditions.

Since then, domestic and foreign Schottky-diode mixers have been further developed, and hybrid integration technology has gradually matured and become practical. Diodes are attached to the substrate in hybrid-integrated harmonic mixers. Although some assembly errors are introduced, the mixers are widely used, owing to their simple process and low cost [11].

Common mixing structures are single-tube, single-balanced [12], and double-balanced [13]. In a simple Schottky diode-based mixing circuit, the harmonic components contained in the loaded local oscillator signal are mixed with the radiofrequency signal. The type of mixer can be used for both odd-order and even-order harmonic mixing. This structure has a simple design and small size, but poor isolation and noise figures; therefore, it cannot suppress clutter. To reduce frequency conversion losses, harmonic mixing circuits mostly use diode pairs in series or parallel.

Diode Types

Schottky Barrier Diodes

Schottky barrier diodes are widely used in the design of mixing devices. The key technology is the Schottky junction formed by the contact between the metal and N-type semiconductors, also known as the metal–semiconductor junction. Schottky junctions rely on carriers to transfer the current and have high electron mobility. With the advancement of modern semiconductor technology, Schottky contacts have been reduced to the order of microns. At present, diodes with cutoff frequencies of more than 10 THz have been developed, which can be used in terahertz circuit design.

As shown in Fig. 29.3, the diode is fabricated on an N-type semiconductor substrate with high electron mobility. Then, a high-purity, high-conductivity heavily doped N-type buffer layer is continuously grown on the substrate. This prevents substrate impurities from entering the epitaxial layer during the manufacturing process while ensuring a low series impedance. The buffer layer is generally doped with as many extra electrons as possible. For example, the doping concentration of GaAs is usually on the order of 10^{18} cm^{-3}.

The shallow-doped epitaxial layer continues to grow on top of the buffer layer, and its doping concentration is on the order of 10^{16}–10^{17} cm^{-3}. The metal anode contacts the epitaxial layer to form a Schottky junction; gold is often used to make air bridges (planar Schottky diodes) or whisker contacts (whisker Schottky diodes) [14].

Planar Schottky Diodes

Planar Schottky diodes first integrate the anode and cathode of the diode on the same metal substrate and then contact the metal anode with part of the barrier to form a semiconductor doped epitaxial layer, an N++ doped enhancement layer, and a metal cathode, in turn. With proper control, planar Schottky diodes can be manufactured entirely through photolithography, which greatly improves their repeatability. At

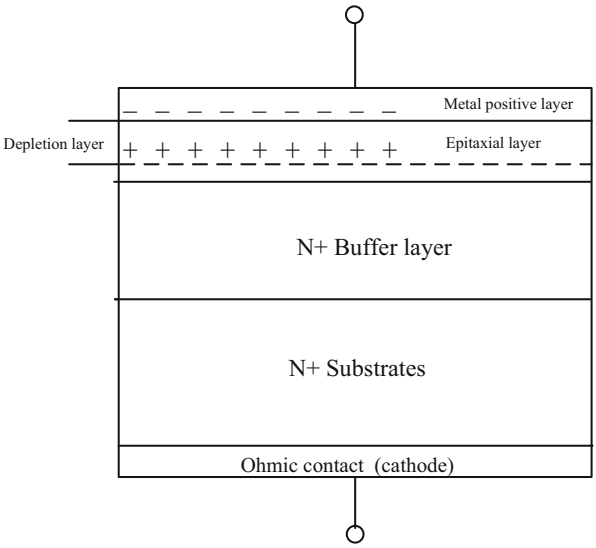

Fig. 29.3 Cross-sectional view of a Schottky barrier diode

present, two main types of planar Schottky diodes exist: quasi-vertical and surface channel [15].

The quasi-vertical Schottky diode improves the conductive structure using a tentacle contacting the Schottky diode. While retaining the same tube–honeycomb operation as in the Schottky-diode manufacturing process, crystal tentacles are applied using planar-circuit integration technology [16].

At present, the most mature planar technology is the surface channel planar diode. In recent years, surface channel diode technology has been rapidly developed in Lille, France, and the United Kingdom and has been applied to mixers [17, 18]. The physical structure of the surface channel diode is shown in Fig. 29.4. The parasitic capacitance introduced by this structure is greatly reduced, compared with the whisker structure Schottky diode, although compared with low-temperature superconducting mixing technology, its conversion loss is unsatisfactory [20].

Planar Schottky-diode development has gone through several core-technology innovations: the first was the development of flip-chip technology. In 2010, the GaAs substrate with high dielectric loss was removed, and the Schottky diode and its circuit were integrated. Using a quartz substrate with a low dielectric constant, the parasitic capacitance was further reduced [19].

In 2013, the Jet Propulsion Laboratory of the National Aeronautics and Space Administration (NASA) used a micro-integrated process to further generate a microstrip filter circuit, including a radiofrequency/local oscillator and intermediate frequency on a quartz substrate. This reduced the assembly error between the diode and surrounding circuits and removed the welding effect of the diode. In view of the original defect of upside-down diode technology—that is, the conductive glue overflowed the surface air channel and increased the parasitic capacitance when

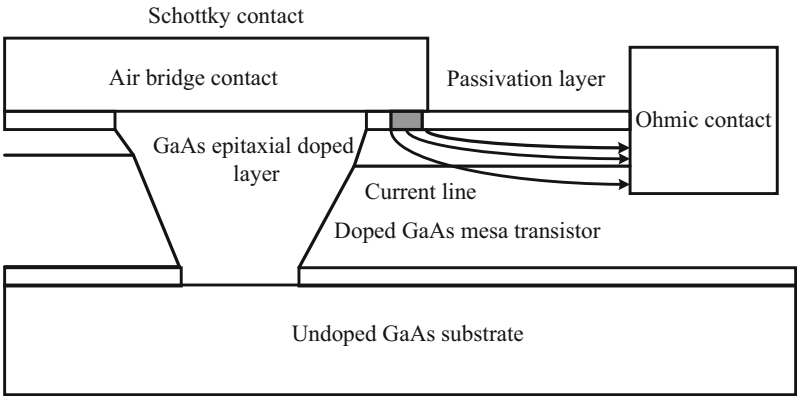

Fig. 29.4 Surface channel planar Schottky diode

pasted—the University of Virginia in the United States proposed conductive glue etching technology, which reduced the mixing loss of the mixer by 20–30% [20].

In contrast to the barrier material of traditional Schottky diodes, planar Schottky-diode barriers can be fabricated from several types of III-V materials, including gallium arsenide, indium gallium arsenide, or indium phosphide, or in combination, such as adding indium gallium arsenide to indium phosphide to make Schottky barriers.

If the semiconductor is to have high barrier performance, GaAs must be used to manufacture the Schottky barrier [21] because diode mixers made of other materials require a higher local oscillator drive power [22]. In addition, in the terahertz-frequency band, most semiconductor devices are made of GaAs, owing to its high electromigration rate and high breakdown voltage. For the above reasons, most planar Schottky diodes are currently made of GaAs and operate in frequency bands up to 600 GHz [23].

Diode Mixers

In 1971, Dominic A analyzed the nonlinear characteristics of Schottky barrier mixing diodes, produced a nonlinear model of them, and conducted a detailed analysis [24].

In 1973, Araki [25] designed a narrowband integrated balanced mixer. The mixer used two GaAs surface barrier diodes, and the circuit consisted of three couplers, a low-pass filter, and a transition joint from the waveguide to the microstrip. This circuit was representative of those for making microwave balanced mixers.

In 1977, McColl [26] analyzed the conversion loss of Schottky-diode mixers and explained in detail the effects of various factors, such as the diode junction capacitance, package-parasitic parameters, and impedance mismatch, on the conversion loss of mixers.

In 1977, Xie designed a fin-strip Schottky-diode W-band mixer. The frequency conversion loss of the mixer in the 85–95 GHz frequency band was less than 15 dB.

The fin-line coplanar-waveguide structure integrated mixer was studied accordingly and achieved a gain of 9 dB [27].

In 1978, Champlin et al. [28] extended factors, such as the skin effect, carrier inertia, and displacement current, to the traditional high-frequency model of non-epitaxial Schottky barrier diodes. The cutoff frequencies of the n-GaAs and n-Si extended models were calculated. Compared with the predicted results of the traditional model, both materials showed a wider operating frequency band.

In 1986, Adams et al. [29] proposed a new boundary condition for studying Schottky barrier diodes. Based on this modified boundary condition, the depletion of Schottky boundary electrons was predicted, and the current-dependent surface composite carrier-velocity distribution was studied. The electron-transport analysis was extended to higher bias voltages.

In 1993, Jelenski et al. [30] described GaAs Schottky barrier diodes with approximately ideal electrical and noise characteristics in terahertz mixing applications. The traditional formulas used to describe these characteristics were only valid within a limited forward-bias range, and the current was much smaller than the operating current under submillimeter mixing. The authors extended it to generalized analytical expressions of I-V and C-V properties of metal–semiconductor Schottky junctions over the entire bias range and proposed a new numerical diode model that occurred at the Schottky junction. This involved current-related recombination and drift phenomena, considering changes in the electron mobility and electron temperature in the unexhausted epitaxial layer.

In 1997, Lipsey et al. [31] observed that the harmonic circuit model of the diode equivalent-circuit model used to design high-frequency Schottky frequency doublers at that time could not accurately predict the characteristics of high-frequency circuits above 100 GHz. The physical principles of electronic transmission were analyzed.

In 2000, Hu et al. [31] developed a single-balanced mixer with a 93–96 GHz frequency and a conversion loss of less than 9 dB. In 2002, Dong et al. [32] developed a balanced mixer with a fin-coplanar structure of 92–96 GHz and a conversion loss of less than 15 dB; the port isolation was greater than 20 dB.

In References [51, 56], a fin-line balanced mixer with a 47-GHz structure was developed. The test results showed that the conversion loss was less than 3.5 dB, while the isolation between the local oscillator signal and the radiofrequency port could reach 20 dB. In 2008, Li Kan [33] developed a fourth-order harmonic mixer working in the Ka band, and its conversion loss was less than 11.8 dB at 34.36 GHz.

In 2003, Buffey et al. [34] developed a fin-line microwave mixer with a 350-GHz frequency, and its noise temperature reached 90 K. In 2005, Kyo Lee et al. [35] developed a new type of fin-line-coplanar line-structure balanced microwave mixer. The local oscillator power of the microwave mixer was as low as 6 dBm, the conversion loss reached 10 dB, and the signal isolation of the local oscillator port and the radiofrequency port was greater than 29 dB. In 2009, Thomas et al. [32] developed a sub-harmonic mirror rejection mixer. In its passband range of 320–340 GHz, its image rejection was as high as 7.2–28.1 dB.

In 2009, Siles et al. [36] believed that the traditional boundary conditions of the previous drift diffusion model at the Schottky contact were limited and could not

correctly predict the working characteristics of the Schottky-diode mixer. This resulted in large differences between the simulation and the actual measurements. Therefore, a Monte Carlo simulator was used to study the working characteristics of Schottky diodes in flat band mode, which improved the Schottky boundary conditions, enhanced the validity of the drift diffusion model, and accurately predicted the mixer's state in the flat band state. The diode model considered factors, such as barrier lowering, tunneling, carrier-velocity saturation, and mobility field-related effects.

In 2011, Chao et al. [37] developed a Schottky barrier varactor diode that could be applied to microwave-frequency doubling circuits using standard microelectronic technology. The planar-structure manufacturing process was used to overcome the difficulty of traditional manufacturing process integration. The doping concentration in the N-type layer was exponential, which made the varactor ratio higher than that of the traditional uniform-doping structure. This improved the operating frequency and output power of the frequency doubling circuit.

In 2012, Saber [38] conducted a detailed study of the thermal properties of terahertz Schottky diodes based on self-heating effects. The thermal distribution of diodes at different physical sizes was analyzed, including the maximum junction temperature, thermal resistance, and thermal time constants.

In 2013, Yan et al. [39] proposed a Schottky barrier diode based on physical parameters, such as anode area, ohmic contact area, doping distribution of epitaxial layers and substrate layers, thickness, barrier height, contact resistance, and device temperature. The physical base model of the diode considered other factors, such as the reduction of the barrier height, owing to the mirror force of free electrons close to the barrier, the nonlinear resistance of the epitaxial layer, and thermal electron noise. The physical base model of the diode was applied to a reverse-parallel Schottky diode. The simulation results were basically consistent with the measured results of the I-V and C-V characteristics.

In 2014, Pérez-Moreno et al. [40] proposed a physical-based Schottky-diode numerical electrothermal model that characterized the effect of self-heating on the performance of terahertz inverter devices and circuits. The model consisted of a drift diffusion equation enhanced by a heat-conduction equation, which considered the interaction between electrons, holes, and lattice subsystems in semiconductor devices. Introducing lumped thermal resistance, a thermal resistance matrix of diodes was established to characterize the thermal interaction between anodes. The established electrothermal model was integrated into a harmonic balance circuit simulator, and the Schottky-diode circuit was analyzed, designed, and optimized. The simulation results of the 200-GHz frequency multiplier based on the diode physical base model were consistent with the measured results at high input power.

In 2020 and 2021, Orfao et al. [41] used two-dimensional (2D) integrated Monte Carlo simulations to study the surface charge and edge capacitance effects of GaAs and GaN Schottky barrier diodes. The edge effect parameters were defined, and the effects of process parameters, such as the insulating material, insulation thickness, and epitaxial layer thickness, on the C-V characteristics of Schottky diodes were analyzed. Parameters, such as the insulating material used

for passivation, its width, and the lateral extension of the epitaxial layer, significantly affected the edge capacitance, thereby increasing the total capacitance value above the ideal value. The diode edge effect of high-dielectric-constant insulating materials was more obvious and strengthened the electric field extending laterally from the epitaxial layer. Compared with the models of foreign countries, the research level and depth of domestic terahertz Schottky-diode models have great room for improvement [42].

Owing to the complex physical mechanism of Schottky diodes in the terahertz frequency band, the frequency conversion circuit places high requirements on model accuracy. Therefore, it is necessary to deeply explore the physical mechanism of Schottky diodes in the terahertz frequency band, establish an accurate Schottky-diode model, guide the manufacture and design of Schottky diodes, and lay a solid foundation for creating high-performance terahertz frequency multipliers and mixers.

CMOS Mixers

CMOS mixers can create high-performance integrated modular circuits with low cost and high integration. They have become a research hotspot in RF integrated circuit design. RF circuit structures and design technology based on the CMOS process have been proposed. Gradually, mature CMOS mixer products and designs have been introduced and have achieved great results.

In 1984, Tang designed a CMOS switching circuit mixer [43]. This mixer was completely different from the then-current CMOS mixer. It used four analog–digital bidirectional switches to do the mixing, instead of using an integrated mixer chip. The analog–digital switch of this circuit had a limited frequency, could not be used at high frequencies, and had a large conversion loss.

In 1996, foreign research on high-linearity mixers began. Toole, El-Masry, and Manku designed a high-linearity mixer. It was a subsampled mixer, which is different from the mixers commonly used today. Although its other performance metrics were poor, the linearity was very high. The power of the third-order intermodulation component signal was as high as 35 dBm, and the power consumption was as low as 2 mW [44].

Since 1998, the performance indicators of CMOS mixer chips have been increasingly optimized, and mixer designs have begun to diversify. Giustolisi et al. proposed a mixer with a low power supply voltage in 2018. Although the common active double-balance structure was used, the power-supply voltage was reduced from 5 V and 3 V to 1.5 V, and the power consumption was relatively low, only 3.4 mW [45].

In 1998, Wang proposed a low supply-voltage mixer, which only required 1 V to work normally. The lowest power consumption was only 0.14 mW. Li et al. analyzed the noise in the mixer in 2019 [46–48].

Since 2003, research on CMOS mixers has increased, design ideas have matured, and integrated chip mixer designs have begun [49]. Shi and Chi designed a down-conversion mixer operating at a 2.4-GHz frequency with a 0.18-mm CMOS process in 2003. The mixer was active and used the most commonly used double-balanced

structure [50]. Although its performance seems low now, it is still very valuable for learning [45].

In 2003, El-Shewekh and El-Saba proposed a broadband mixer with an RF input range from 30 MHz to 1 GHz, a port isolation power of up to 29.5 dBm at a gain of up to 29.1 dB, with low noise and power consumption [51].

In 2004, Cui used a 0.35-mm CMOS process to design up-conversion and down-conversion mixers working at 2.4 GHz [49]. Both mixers used an active double-balanced structure and were improved on this basis. In addition, this study revealed one of the development trends of future mixers: the power-supply voltage consistently decreased [52, 53].

In 2005, Dong proposed a new design structure for ultra-wideband mixers. The RF input range was approximately 3.1–5.15 GHz, the output was close to 1 GHz, and its bandwidth was very wide [52]. The development trend of future mixers is increasingly wide bandwidth [54, 55].

In October 2005, Wei et al. analyzed the linearity of a mixer based on a low power supply voltage, and the port-output linearity reached 7.4 dBm [56]. It revealed that future mixers will have increasingly high linearity [57, 58].

In 2006, Luo et al. analyzed the noise of active mixers [59], analyzed the source of the noise in active mixers, and studied the influence of factors, such as the transconductance stage, switch tube, and local oscillator signal size, on the noise. Low-noise mixers have also received attention and research [60, 61].

As mixers have been developed, special mixer structures have appeared. In 2010, Yuan proposed a current-mode mixer. Unlike voltage-mode mixers, current-mode mixers mix current signals. Compared with traditional voltage-mode mixers, current-mode mixers are more suitable for low-voltage, high-linearity designs [62].

Beginning in 2012, low-power mixers [63] began to increase, and since then, the power-supply voltage of low-voltage mixers has been lower than 2 V [63]. In 2012, Shen and Zhang proposed an ultra-low-power mixer for aerospace applications. The power consumption was only 0.76 mW and the power-supply voltage was only 0.6 V. This power consumption and power-supply voltage are also very low today [64].

Since 2013, owing to advancements in the process, the operating frequency of CMOS mixers has increased. Unlike the previous several GHz, the operating frequency of mixers at that time could reach tens or even hundreds of GHz. In 2013, Wang used a Schottky barrier diode to design a mixer that worked at a frequency of up to 340 GHz [65]. In 2000, Terrovitis and Meyer analyzed the linearity of a mixer and provided a theoretical basis for the subsequent improvement of high-linearity mixer designs [65].

Mixer Circuit Structures

Single-Ended Structures

Unbalanced mixer circuits are more commonly used; the circuit is usually composed of a single transistor, FET, or double-gate FET. Its principle circuit diagram is shown in Fig. 29.5. The information-carrying signal and the local

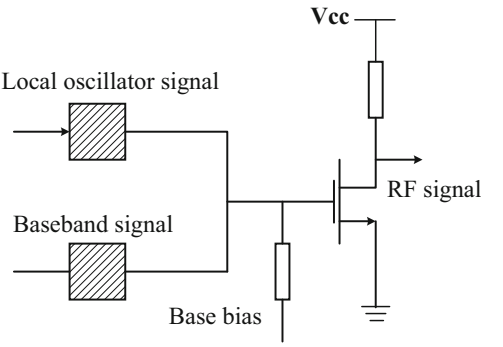

Fig. 29.5 Unbalanced mixer [66]

oscillator signal are simultaneously received by the base of the transistor, and the RF signal is output at the collector. The local oscillator signal and the transistor bias voltage are used together as the bias signal. At this time, the transconductance g_m of the transistor becomes a time-varying transconductance.

If the baseband input signal is V_{BB}, the output current of the mixer can be expressed as

$$i_{RF}(t) = v_{BB}(t) \cdot g_m(t) \approx \frac{1}{2} g_m V_{BB} \cos(\omega_{LO} - \omega_{BB})t.$$

The unbalanced mixer has a simple structure and therefore has good noise performance. However, because the local oscillator signal is unbalanced, the mixer cannot suppress the signal crosstalk from the local oscillator port to the radiofrequency port; thus, the isolation between the ports is low [66].

Single-Balanced Structures

The most commonly used structures in the antiparallel diode pair (APDP) circuit structure in a single-balanced mixer include the microstrip-branch type [67], duplex-tube-pair parallel type, and duplex-tube-pair series type [68]. The structures are shown in Fig. 29.6.

Figure 29.7 shows the structure of a single-balanced active mixer. It consists of a baseband signal-driven transconductor and a local oscillator signal-driven differential pair.

Compared with the unbalanced mixer, the single-balanced mixer reduces the leakage of the local oscillator signal to the radiofrequency signal, owing to the balanced input of the local oscillator signal, and improves the isolation between the mixer ports. Moreover, owing to the characteristics of the switch tube, it can achieve good switching-performance linearity at a lower local oscillator driving voltage and reduce the system power consumption.

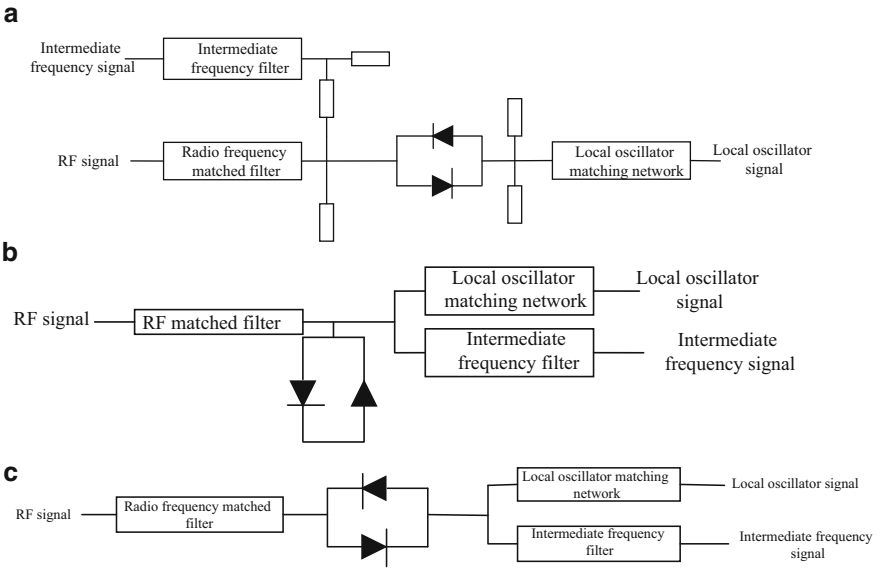

Fig. 29.6 Schematic diagram of typical mixer structures [20]. (**a**) Microstrip-branch structure, (**b**) duplex-tube-pair parallel structure, (**c**) duplex-tube-pair series structure

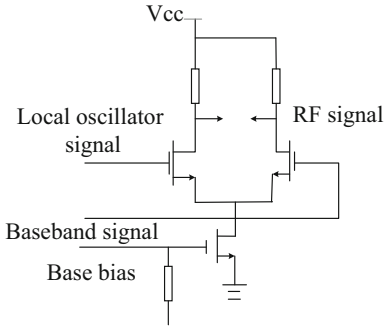

Fig. 29.7 Structure of a single-balanced active mixer

Double-Balanced Structures

Combining two single-balanced mixers so that the baseband signal is also input by differential means constitutes a double-balanced mixer. The Gilbert double-balanced mixer is the most common double-balanced mixer in integrated circuits. As shown in Fig. 29.8, it mainly consists of two differential pairs of six transistors: two transistors form a differential structure, which converts the input baseband signal into current; four transistors are each turned on under the driving of a large local oscillator signal, and then, the current converted by the baseband signal is modulated.

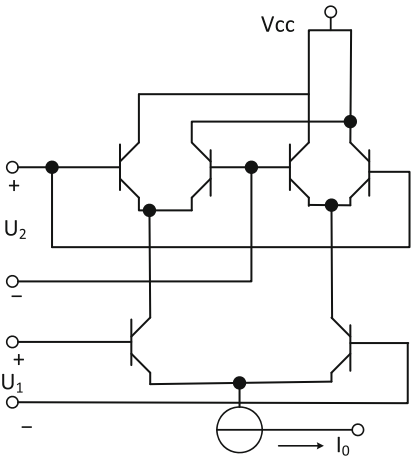

Fig. 29.8 Gilbert double-balanced mixer [69]

The Gilbert double-balanced mixer mainly has the following advantages:

1. Small footprint and low power consumption.
2. The output can effectively suppress DC, local oscillator, and other odd harmonic components.
3. It can use relatively small local oscillator power in the form of differential switching.
4. It adopts a double-balanced structure, which has higher isolation than other structures while ensuring certain linearity, and is very suitable for direct-conversion transmitter designs.
5. It has a good yield in the production of integrated circuits.
6. Therefore, it is widely used in radiofrequency integrated circuits.

Unfortunately, the linear response range of the traditional Gilbert mixer is relatively low, and noise analysis is difficult. Specifically, it adopts a three-layer transistor structure, which makes it difficult to achieve a low voltage and increases the system power consumption.

Research on double-balanced mixers has been mature since the 1980s, with many reports in the literature. Hybrid-integrated millimeter-wave mixers in the form of fin lines, coplanar lines, and suspended microstrips have developed rapidly. In 1982, Howe et al. developed a novel broadband double-balanced mixer with a frequency range of 21–40 GHz. The design balanced the microstrip-line coupling signal and local oscillator signal by balancing the slot line and the branch line to the beam-lead Schottky diode encapsulated in a star structure [70].

Triple-Balanced Structures

In the 2010s, triple-balanced mixer structures could be used to make wider-band mixers, which were favored because of their advantages, such as high dynamic range and intermodulation rejection [71]. In 2010, Ton et al. developed an X-band monolithic dual-balanced mixer with a third-order intermodulation input of 20 dBm. When the local oscillator power was 20 dBm, the output power of its 1-dB compression point was 3.6 dBm. In the range of 7–10 GHz, the conversion loss was less than 10 dB, and the intermediate frequency was 5 GHz. This high-input third-order intermodulation mixer was a key technology in high dynamic range receivers, and the successful development of this technology greatly promoted the development of integrated monolithic receivers [72].

The development of GaAs processes and monolithic technology has pushed research on submillimeter-wave and millimeter-wave integrated mixing circuits to a new height. In 2015, John et al. invented a new planar double-double-balanced monolithic-microwave integrated circuit (MMIC) mixer structure. The structure used a mixture of slot lines, coplanar waveguides, and coplanar lines and was mounted on a substrate with eight Schottky diodes. The mixer implemented with this structure had a radiofrequency of 6–20 GHz, a local oscillator frequency of 8–18 GHz, an intermediate frequency of 2–7 GHz, and a conversion loss of 6.2–9.8 dB. The successful development of this mixer laid the foundation for the development of planar-structure double-balanced mixers [73].

Mixer Linearity

The linearity of the mixer directly determines the dynamic range of the receiver; therefore, improving the linearity has become a key topic in the mixer research field. The main reason for the third-order distortion of active mixers is the nonlinearity in the transconductance stage. Consequently, research work on mixer linearity mainly focuses on the problems related to the transconductance stage of the mixer.

In 2002, Salem et al. proposed a radiofrequency input technology without a tail current, which greatly improved the linearity of the mixer; however, the structure has a low common mode rejection ratio [74]. Another common method to improve linearity is the source-level inductance negative feedback method.

In mixer-linearization research, the main linearization techniques are as follows:

1. Class AB transconductance stage. In 2004, Wei et al. proposed a mixer composed of class AB transconductance stages. This method improved the linearity of the mixer; however, using the transconductance stage increased the power consumption of the mixer. Moreover, spurious components were generated in the output stage [75].
2. Piecewise linear technology. Shen et al. [76] adopted piecewise linear technology, which uses multiple differential pairs with independent base bias voltages in parallel. Because each differential unit is linear in the input range, many such

differential pairs are reasonably moved along the input, and the output appears as the superposition of multiple linear intervals, generally obtaining a large linearity. However, as the number of differential pairs increases, the power consumption and input capacitance will increase accordingly.

3. Feedback technology. Aparin et al. [77] used feedback technology to improve the linearity. Observing the DC transfer characteristics of field effect transistors, the third-order derivation changes from positive to negative in the inverse region, which is the main source of third-order nonlinearity. Feedback technology can improve linearity by canceling this nonlinear effect. However, the transistor must be biased at just the right static operating point, which limits the transconductance of the input stage, resulting in a decreased gain and increased noise figure.
4. Derivative superposition (DS) and improved DS technology. Webster et al. [78] first proposed the concept of DS technology. It is realized by connecting in parallel two transistors working in the weak and strong inversion regions, respectively. By carefully selecting the width and bias voltage of the transistors, the positive third-order derived peaks working in the weak inversion region and the negative third-order derived peaks working in the strong inversion region cancel each other out. In this manner, the third-order derived term will be close to zero, resulting in a greatly improved linearity.

   Reference [79] adopts this method to increase the low noise compensation amplifier from 5.5 dBm before compensation to 15.6 dBm, while the frequency cutoff point of the third-order harmonic signal of the mixer is increased from 2.5 dBm before compensation to 9 dBm. Because the auxiliary metal oxide semiconductor field effect transistor (MOSFET) works in the weak reflection region, this method does not increase the power consumption of the mixer.

   Traditional DS technology only considers how to eliminate the third-order transconductance; it does not consider the influence of second-order transconductance on the circuit. When the third-order transconductance of the circuit is close to zero, the second-order transconductance becomes the main factor that produces the third-order nonlinearity [79].

   Reference [20] proposes an improved derived term superposition technique that considers the effects of the second-order nonlinearity. This method uses two inductors to tune the second-order and third-order nonlinearities that have a major impact on the third-order intermodulation term. The amplitude and phase of the order nonlinearity make the amplitudes equal and phases opposite. Thus, the M_3 term is zero at the output, and the port isolation of the low-noise amplifier (LNA) is increased from 10.5 dBm before compensation to 19.2 dBm [80].
5. Current injection method. A current source is added to the common source node of the local oscillator stage to increase the DC current of the transconductance stage without affecting the current of the local oscillator stage. Thus, the linearity and gain are increased without affecting the noise, producing good linearity and noise characteristics [81].

Optical Mixers

Optical communication technology modulates the information to be transmitted onto a beam of light and transmits it in a channel. Optical communication can be divided into two ways, according to the modulation method at the transmitting end: incoherent optical and coherent optical.

Incoherent optical communication uses high-frequency light intensity modulation to load information onto the light beam and receives the transmitted optical information through direct detection. Its transmission bandwidth is limited and the detection sensitivity is low. Therefore, in addition to modulating the light intensity, coherent optical communication modulates the optical amplitude, frequency, and phase, with various modulation and demodulation methods at the receiving end. The heterodyne-receiving sensitivity is about 20 dB higher than that of the direct detection method and has good filtering performance.

The receiving equipment is easy to integrate and is suitable for long-distance and large-capacity communication. The system is mainly composed of three parts: a modulation transmitter, transmission channel, and digital coherent receiver. The coherent receiver is composed of an optical mixer and a balanced detector. The received optical signal and local oscillator signal are input to a 90° optical mixer for mixing, and the balanced detector completes the photoelectric conversion.

Because the optical mixer is the main component of the digital coherent receiver, its performance directly determines the coherent receiver signal-to-noise ratio and reception sensitivity, which affect the communication quality of the entire coherent optical communication. Therefore, optical mixer research mainly improves the digital coherent receiver. The key to sensitivity is also a key research area in the field of coherent optical communication.

Working Principle

The optical mixer interferically mixes the received signal light and the local oscillator light and outputs the mixed optical signal. The balanced photodetector detects the mixed optical signal and outputs the intermediate frequency current signal, and the demodulation circuit demodulates the signal to extract the original signal. In addition to its wide application in the field of coherent optical communication, optical mixing has many applications in photon imaging [81], lidar [82], biomedical sensing [83], and other fields.

As shown in Fig. 29.9, the main function of the optical mixer is to accurately guide the input signal light, interfere with the local oscillator light, split the light, and change the phase. Finally, the intermediate frequency signal is output and demodulated through balanced detection.

Current optical mixers can be divided into two categories according to their output forms: two output 180° optical mixers and four output 90° optical mixers. Most coherent communication receiving systems use a 90° optical mixer, which is a six-port device with two ports for input and four ports for output [84].

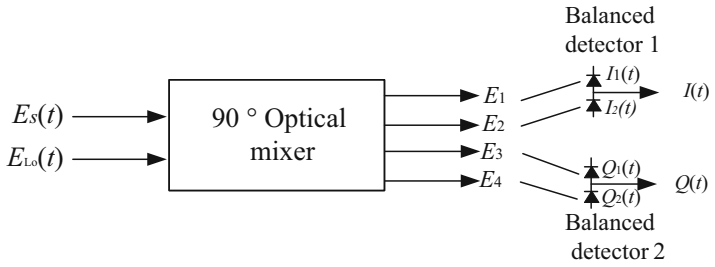

Fig. 29.9 Schematic diagram of the working principle of the 90° optical mixer

The signal light and local oscillator light can be expressed as

$$E_s(t) = \sqrt{P_s}\exp(j\omega_s t + j\varphi_s(t)) \tag{29.1}$$

$$E_{LO}(t) = \sqrt{P_{LO}}\exp(j\omega_{LO} t + j\varphi_{LO}(t)). \tag{29.2}$$

At the receiving end of coherent optical communication, the signal light is first mixed with the local oscillator light, where P_s and P_{LO} are the optical powers of the signal light and local oscillator light, respectively, w_s and ω_{LO} are their angular frequencies, respectively, and $j_s(t)$ and $j_{LO}(t)$ are their initial phases, respectively. Their phase difference $\Delta\phi(t) = \varphi_s(t) - \varphi_{LO}(t)$, that is, the information to be demodulated. The signal light and the local oscillator light pass through an ideal 90° optical mixer to obtain the output optical signal:

$$E_1 = \frac{1}{2}(E_S + E_{LO}) \tag{29.3}$$

$$E_2 = \frac{1}{2}(E_S - E_{LO}) \tag{29.4}$$

$$E_3 = \frac{1}{2}(E_S + jE_{LO}) \tag{29.5}$$

$$E_4 = \frac{1}{2}(E_S - jE_{LO}). \tag{29.6}$$

After being detected by the balanced detector, the corresponding four output electrical signals can be obtained:

$$I_1(t) = \frac{R}{4}\left(P_s + P_{LO} + 2\sqrt{P_s P_{LO}}\cos(\Delta\omega t + \Delta\phi(t))\right) \tag{29.7}$$

$$I_2(t) = \frac{R}{4}\left(P_s + P_{LO} - 2\sqrt{P_s P_{LO}}\cos(\Delta\omega t + \Delta\phi(t))\right) \tag{29.8}$$

$$Q_1(t) = \frac{R}{4}\left(P_s + P_{LO} + 2\sqrt{P_s P_{LO}}\sin(\Delta\omega t + \Delta\phi(t))\right) \tag{29.9}$$

$$Q_2(t) = \frac{R}{4}\left(P_s + P_{LO} - 2\sqrt{P_s P_{LO}}\sin(\Delta\omega t + \Delta\phi(t))\right), \tag{29.10}$$

where R is the response of the detector and $\Delta\omega = \omega_s - \omega_{LO}$ represents the angular frequency difference between the signal light and the local oscillator light. Using zero difference detection, $\Delta\omega = 0$. The current values of the obtained I channel and Q channel are

$$I(t) = I_1(t) - I_2(t) = R\sqrt{P_s P_{LO}}\cos(\Delta\phi(t))$$

$$Q(t) = Q_1(t) - Q_2(t) = R\sqrt{P_s P_{LO}}\sin(\Delta\phi(t)).$$

After subsequent digital signal processing, the original signal and the information to be transmitted can be extracted [85].

Research Progress and Current Status

Optical mixers can be mainly divided into optical fiber, free space, and planar waveguide types. In addition, there are many structures in different types of mixers. Optical mixer structures have several important types, such as the 3-dB coupler-type, multimode interference (MMI) coupler-type, crystal refraction type, and waveguide technology [86]. According to the coupling method, optical mixers can also be divided into optical fiber and spatial optical coupling types [87]. According to the integrated substrate, they can be divided into silicon dioxide substrate types and polymer waveguide base types [88]. Next, we introduce optical mixers of different coupler and base types and discuss their applications in the field of coherent optical communication.

3-dB Coupler and Phase Shifters

A widely used optical mixer structure combines a 3-dB coupler and a phase shifter. This structure can output the mixed optical signal in a specific polarization state and can be integrated and prepared on lithium niobate material or silicon dioxide material. It has a small output phase difference and stable performance.

In 1983, Yuen first proposed using a polarization splitting prism to mix two beams of coherent light [89] and extracted information through coherence. This was the prototype of the early concept of optical mixers. Subsequently, in 1985, Abbas added filters and noise amplifiers to the Yuen simple-mixer structure [90]. It could simultaneously filter the local oscillator noise and amplify weak signals.

In 1987, Gimlett [91] designed a 90° optical mixer based on a 3-dB fiber-optic coupler with polarization beam splitters (PBS), as shown in Fig. 29.10, to achieve

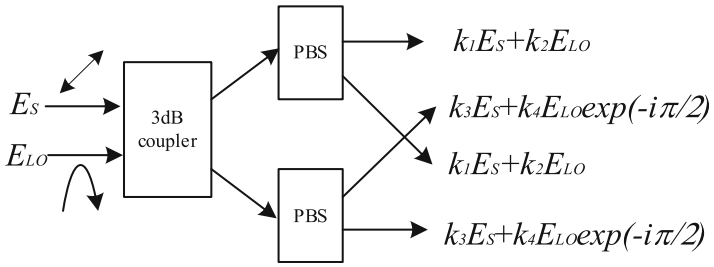

Fig. 29.10 Schematic diagram of an optical fiber 3-dB coupler type mixer [95]

frequency shift keying (FSK) at a rate of 2 Gbit/s. When the bit error rate was 10^{-9}, the sensitivity of the coherent receiver reached −36.7–39.2 dBm.

In 2010, Nara [92] used a directional coupler instead of a 3-dB coupler to couple light beams and combined the structure with a phase shifter to make a 90° optical mixer using silicon dioxide. The insertion loss of the device in the C band was less than 10 dB, the polarization extinction ratio exceeded 20 dB, and the phase deviation was less than 1°.

In 2021, Chen et al. [93] designed a planar waveguide optical mixer using a combination of a 3-dB coupler and a 90° phase shifter. The mixer used silicon dioxide with a high refractive index difference as the base material to improve the phase shifter. The waveguide was increased to 2.2 to 3.6 times that of the length difference scheme. In the experiment, the phase error of the optical mixer was less than 2°, the loss at the same phase end was less than 1.18 dB, and the insertion loss of the entire optical mixer was less than 1.22 dB.

The optical mixer based on the 3-dB coupler and phase shifter has a relatively simple structure, low manufacturing process requirements, and relatively mature manufacturing technology. Therefore, it has the advantages of a small phase deviation, strong adaptability to the environment in practical applications, and stable working performance. It is widely used in optical-fiber communication and space optical communication; however, the device size is large, and the characteristics of the silicon-based platform and 3-dB coupler structure make it inconvenient to integrate.

Mach–Zehnder Interference Optical Mixers

Mach–Zehnder Interference Optical Mixer Structure

An optical mixer with a Mach–Zehnder interference structure generally consists of three parts. The schematic diagram of the structure is shown in Fig. 29.11. The first part is a coupling region with a length of L_1, which produces a coherent beam of light with a certain amplitude ratio and phase difference. The second part is a non-coupling region, which introduces a length difference of ΔL in one arm to generate a phase difference related to the wavelength; it then adjusts the phase

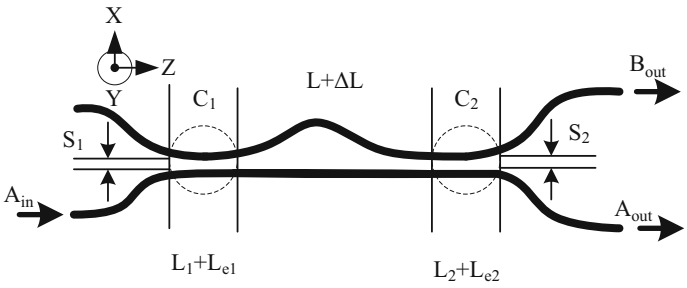

Fig. 29.11 Principle of a Mach–Zehnder interference mixer [94]

difference of the two beams of light, that is, performing phase compensation. The third part optimizes the coupling ratio region to control the coupling ratio of the output beam. By simultaneously optimizing the lengths of these three parts, wavelength independence for different coupling ratios can be achieved [94].

The expression for coupling efficiency is as follows:

$$\eta = \frac{|B_{\text{out}}|}{|A_{\text{out}}| + |B_{\text{out}}|} = a^2 + b^2 + 2ab\cos(\beta \Delta L), \tag{29.11}$$

where h is the coupling efficiency, A_{out} and B_{out} are the two output power signals, respectively, β is the refractive index coefficient of the mixer, and ΔL is the length of the mixer. Equation (29.11) is the mixing-efficiency formula of the Mach-Zehnder interferometric mixer, wherein parameters a and b are related to the length of the interference cavity. The specific expressions are shown in Eqs. (29.12) and (29.13), respectively.

$$a = \cos\left[\frac{\pi}{2L_{\text{c1}}}(L_1 + L_{\text{e1}})\right] \sin\left[\frac{\pi}{2L_2}(L_2 + L_{\text{e2}})\right] \tag{29.12}$$

$$b = \sin\left[\frac{\pi}{2L_{\text{c1}}}(L_1 + L_{\text{e1}})\right] \cos\left[\frac{\pi}{2L_2}(L_2 + L_{\text{e2}})\right] \tag{29.13}$$

Mach–Zehnder Interference Optical Mixing

In 2003, Chen [95] used the waveguide of a fluorine-doped polymer material (polyimide) to theoretically achieve a coupling ratio that fluctuated by 0.8% in the 160-nm wavelength range in the Mach–Zehnder interference optical mixer. It also achieved polarization insensitivity.

In 2005, He et al. [96] developed an optical mixer structure, based on the Mach–Zehnder structure and using a genetic algorithm. They theoretically achieved a coupling ratio in a silicon dioxide waveguide in the 200-nm wavelength range with a $5 \pm 1.5\%$ coupling ratio.

In 2013 and 2014, Alam [97] improved the Mach–Zehnder structure, using a hybrid plasma-waveguide structure for phase compensation, and implemented a compact large-bandwidth Mach–Zehnder interferometric optical mixer in a silicon-on-insulator (SOI) waveguide.

In 2010, Zhou et al. [98] designed a 2×4 90° optical mixer for free space optical communication and applied a zero difference interference-detection receiver, the basic structure of which is shown in Fig. 29.12. The asymmetric Mach–Zehnder interference mixer split the signal light into two channels, interfered with the local oscillator light, and recombined the two signals. The balanced detector received the mixed light and converted it into an intermediate frequency current output. The contrast ratio of the interferometer ground modulation or signal-to-noise ratio depends on the wavefront interference process, rather than the wavefront quality, so no wavefront compensation technology or frequency locking is required. This scheme effectively eliminates the influence of wavefront distortion on the coherent detection process.

Optical mixer schemes, such as waveguide, 3-dB coupler-type, and prism-type optical mixers, only have a down-conversion function. In practical applications, the optical mixer must have simultaneous up-down conversions. Therefore, an optical

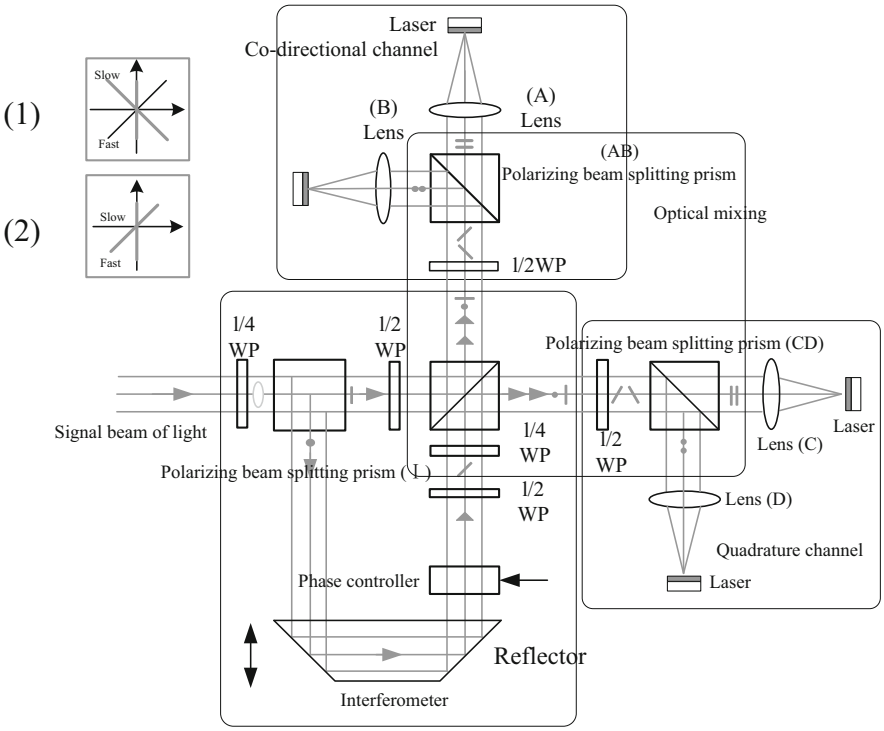

Fig. 29.12 High-precision 90° spatial optical mixer [98]

mixer was designed, using the down-conversion principle realized by Mach–Zehnder interference modulation [99].

In 2021, Zhang et al. [100] proposed an optical mixer design scheme using a dual Mach–Zehnder interference modulator. In this scheme, the signal light and the local oscillator light, respectively, realize the local oscillator light and the signal light in the Mach–Zehnder interferometer. Single-sideband modulation modulates the phase difference between the upper and lower arms of the Mach–Zehnder interference, so that the optical carriers cancel each other, and outputs the intermediate frequency signal of the optical signal or the up-conversion signal. This scheme realizes up-down conversion and further streamlines the transceiver module of a coherent optical communication system.

Polarized Optical Mixers

Polarized Optical Mixer Structure

Garreis et al. [101] designed a 90° space optical mixer with a block structure in the late 2010s. This scheme has been used many times in the laser communication end points developed by NASA and the European Space Agency. The principle is shown in Fig. 29.13.

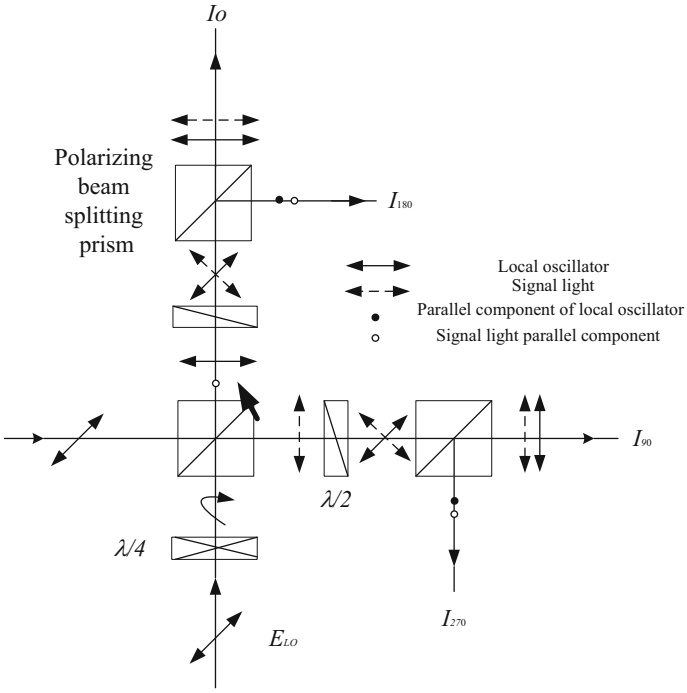

Fig. 29.13 Schematic diagram of a polarized light mixer [101]

The stability of the laser performance, channel conditions, encoding method, randomness of atmospheric transmission, platform vibration, etc., will all affect the polarization state of the signal light. The interior of a spatial light mixer mostly contains polarization-sensitive optical elements. The mismatch and change of the polarization states of the signal light and the local light seriously affect the intensity and phase relationships of the output mixed light, which, in turn, limit the mixing efficiency of the spatial light mixer, and even affect the detection efficiency of the entire coherent optical communication system for signals [102]. Compared with linearly polarized light, circularly polarized light and elliptically polarized light have stronger adaptability to the atmosphere, which helps improve the certainty of the polarization state of the communication light.

The polarization characteristics of the light beam introduce compatibility problems to the working mode of the integrated device and the fiber-input mode. This is because the light mode is affected by other factors and changes randomly. Silicon-based integrated devices are polarization dependent, so the device performance is not guaranteed. Polarization control is necessary to take advantage of the advantages of polarization sensitivity or avoid its disadvantages [103].

The basic principle of polarization diversity [104] is as follows: First, the input light is divided into two mutually orthogonal polarization states, transverse-electric (TE) mode and transverse-magnetic (TM) mode, after passing through a polarizing beam splitter (PBS). The polarization rotator converts the light of one of the polarization states into an orthogonal polarization state and then inputs it into two identical silicon-based integrated devices; then, one of the output lights is converted back to the initial polarization state. Finally, the two orthogonal polarization states are combined into a light beam through a polarization beam combiner. Therefore, a large number of polarization splitting prisms and optical mixer structures based on them have appeared for the polarization characteristics of light beams.

Research Progress of Polarization Optical Mixers

In 1968, Teich [105] of the Massachusetts Institute of Technology (MIT) designed an optical mixer based on a beam splitter, which obtained an intermediate frequency signal by the coherent superposition of a signal light and local oscillator light.

In 1969, Kleinman of Bell Labs [106] used a polarizing beam splitter to transmit and reflect light beams of two specific wavelengths and then realized an optical mixing function. The working principle is shown in Fig. 29.14. The system uses a polarization splitting prism, a visible light laser, and a photomultiplier tube to detect the optical signal generated by the sum or difference frequency. The signal light and the local light pass through the polarization splitting prism to produce interference mixing, and the balanced detector receives and converts it into an electrical signal.

In 1989, Langenhrost et al. [107] designed a compact block optical mixer, which used a gradual-change refractive index lens to shape the input and output light beams, so that the input beam was quasi-straight and the output beam was focused. The polarization splitting prism coupled the signal light, and the calcite crystal separated the beams according to the polarization state. The insertion loss of the mixer was only 2 dB, and the average coupling efficiency reached 63%.

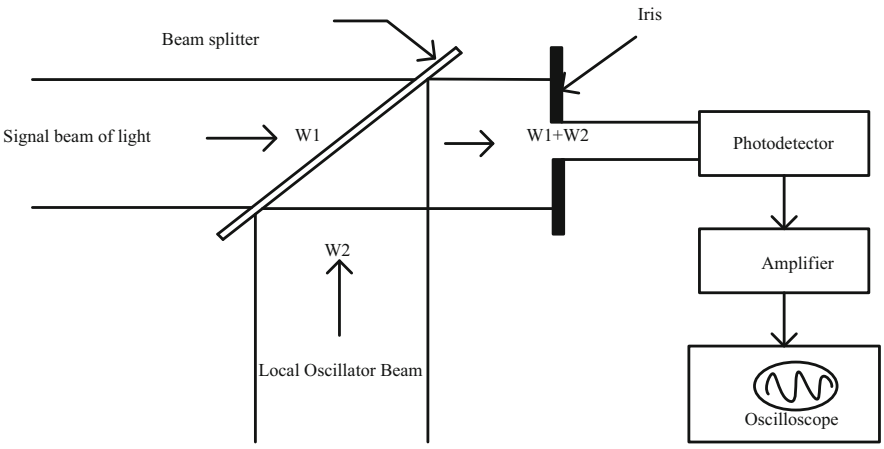

Fig. 29.14 Spatial light mixer using a beam splitter [106]

In 2011, Garreis [108] proposed a six-port 90° spatial optical mixer composed of a polarized spectroscopic prism and a non-polarized spectroscopic prism. The mixer had a simple structure, high stability, and easy processing. The structure has been used by TESAT many times.

In 2016, Zhang et al. [109] designed a polarized 90° spatial light mixer. The optical path of the mixer is shown in Fig. 29.15. After the signal light is incident, it interferes and mixes with the local oscillator light. The signal light after mixing passes through different waveplate units to generate four optical signals with a 90° phase difference. Considering the special needs of optical mixers in laser communication systems, a 90° mixer with spatial light input and local oscillator light input using a polarization maintaining fiber was designed and completed.

In 2017, Zhang et al. [110] designed a 90° spatial optical mixer with adjustable branch energy. By controlling the incident ray polarization state, it controlled the reasonable distribution of optical energy between the communication branch and the phase locked branch to improve the system performance. In addition, a 90° spatial mixer using a single crystal was also designed (Fig. 29.16).

In 2013, Kawashima [111] designed a polarization diversity 90° spatial light mixer, which used a polarization beam splitter and waveplate to mix the local oscillator light with the signal photosynthetic beam. It then split the beam to adjust the phase, so that the four output signals had a 90° phase difference, to achieve coherent mixing. In the actual prototype, the four output lights all use optical fiber as the output interface, as shown in Fig. 29.18.

In addition to the waveplate structure, there are also applications with polarizing beam splitters and Mach–Zehnder interference modulators. The light loss of these optical structures is small, the contrast of the interference modulation is high, and the interference technology is based on the phase difference, rather than the beam. The wavefront quality of light thus greatly reduces the impact of wavefront distortions on the mixing efficiency.

Crystal Optical Mixers

Material Properties of Crystal Optical Mixers

Crystal type optical mixers use the optical properties of uniaxial crystals, such as birefringence, double reflection, or electro-optical effects, to coherently mix the signal light and local oscillator light and generate a phase shift through the electro-optical effect. Commonly used crystal materials are lithium niobate, polymers, calcite, and yttrium orthovanadate [112].

Optical mixers require a low insertion loss, high isolation, high common mode rejection ratio, and small polarization loss. Therefore, crystal type optical mixers have high optical quality requirements for crystals:

1. The refractive index difference of crystals in the communication window band should be greater than 0.1.
2. The temperature sensitivity should be low, with stable performance in high- and low-temperature regions.
3. The transmittance in the window band should be high, and the insertion loss should be low.
4. They should have a small thermal expansion coefficient, small thermo-optical coefficient, and the suitable hardness should stay consistent.
5. Crystals are easy to grow, easy to use for optical processing, and inexpensive.

Table 29.1 lists the main birefringent crystal materials currently used in optical mixers and compares the parameter characteristics of the materials [113].

The yttrium orthovanadate (YVO_4) crystal has large refractive and discrete angles, excellent temperature stability and refractive index characteristics, and good physical and mechanical properties. The titanium dioxide (TiO_2) crystal has the largest refractive index difference; however, its extreme hardness makes optical processing difficult. Although lithium niobate ($LiNbO_3$) has mechanical and physical properties similar to YVO_4, its crystal growth technology is relatively mature. Its birefringence index is three times smaller than that of YVO_4, which increases the required crystal size. Therefore, YVO_4 is currently the best material for use in photoisolator birefringent crystals.

Uniaxial crystals are the main components for making optical mixers. The uniaxial crystal materials commonly used in making spectroscopic devices include calcite ($CaCO_3$), yttrium orthovanadate, and lithium niobate [114]. The specific properties and production and processing of these materials are compared, as shown in Table 29.2.

A synthetic positive uniaxial yttrium orthovanadate crystal has high transmittance, easy growth, moderate hardness, mature coating processing technology, easy

Table 29.1 Crystalline materials for optical mixers [113]

Crystal	YVO_4	TiO_2	$CaCO_3$	$LiNbO_3$
Space group	*I*41 /*amd*	*P*42 /*mnm*	$R\bar{3}C$	*R*3*C*
Birefringence (ne-no)	0.2039 (1.55 ìm)	0.256 (1.53 ìm)	−0.1572 (1.497 ìm)	−0.0738 (1.44 ìm)
Discrete angle (45°)	5.67°	5.63°	4.33°	1.96°
Through the band(μm)	0.4–5	0.4–5	0.35–2.3	0.4–5
Coefficient of thermal expansion $\times 10^{-6}$/°C	*c* axis: 11.4 *a* axis: 4.4	9.2 7.1	30.3 5.4	19.7 7
Mohs hardness	5	6.5	3	5
Deliquescence	None	None	Weak	None

Table 29.2 Comparison of the performance and production processes of crystals commonly used to make light beam separators

Crystal material	Optical quality	Transmittance	Birefringence	Processing hardness	Mass production
Yttrium orthovanadate	Good	Good	Very good	Moderate	OK
Lithium niobate	Good	Good	Bad	Moderate	OK
Calcite	Bad	Good	Good	Too soft	Difficult
Rutile	Good	Good	Very good	Too hard	Very difficult

mass production [115], and excellent birefringence performance [116]. The birefringence index difference is three times that of a lithium niobate crystal, that is, the beam of light has a large deviation angle, which can completely separate the beam of light in a short distance. This further improves the optical mixer integration [117, 119].

Crystal Optical Mixers

In 2003, Arkady et al. [118] used lithium niobate crystals to fabricate a 90° optical mixer. The structure of the optical mixer is shown in Fig. 29.19. The mixer has an in-phase optical path and an orthogonal optical path. The phase shifter and the Mach–Zehnder interferometer modulate the amplitude and phase of the two light channels. They control the voltage of the upper and lower arms of the four couplers to evenly distribute them at the output of the directional coupler; the phase difference between the two arms of the waveguide is 90°. The biggest advantage of the lithium niobate crystal chip is the high degree of internal integration, which greatly reduces the size of the entire optical mixer and enables the optical mixer to be integrated on a balanced detection chip (Fig. 29.17).

In 2009, Wan et al. [119] proposed an electronically controlled phase shifting spatial mixer based on crystal birefringence and electro-optical effects. The structure used the birefringence effect of a $LiNbO_3$ crystal to mix the local oscillator and signal lights and then used the electro-optical effect to shift the phase. Its basic structure is shown in Fig. 29.18. The size of the entire mixer is 50 mm × 20 mm × 20 mm, the adjacent size of the four output beams is 4.4 mm, and the control voltage is 100 V.

In 2010, Hou et al. [120] proposed, made, and experimentally verified an electronically controlled phase shift 2 × 4 90° crystal spatial light mixer. The specific principle involved splitting and coupling the signal light and local oscillator light through four crystals with the same structure, and the electronically controlled phase shift plate provided the required phase shift. The mixer had a controllable phase shift, but needed to provide power to the system.

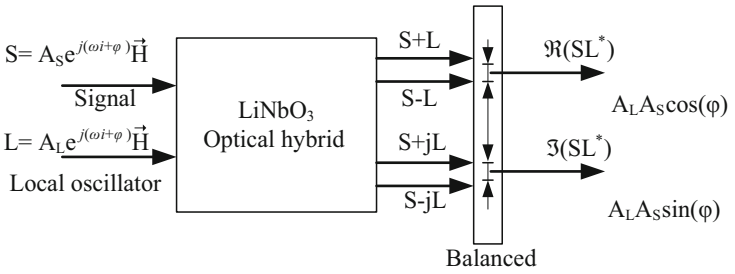

Fig. 29.17 Lithium niobate optical mixer [118]

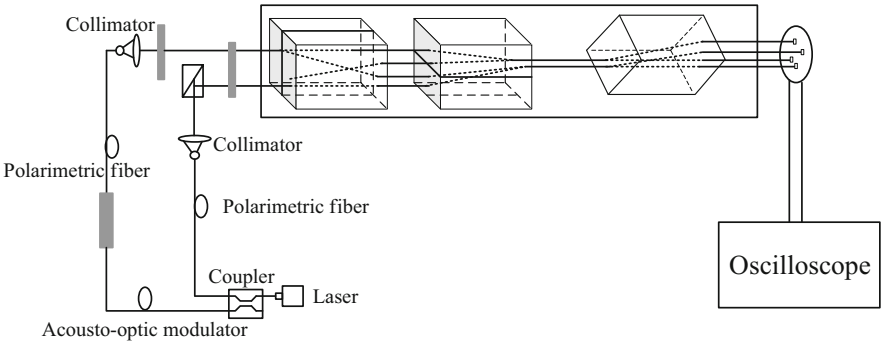

Fig. 29.18 90° spatial light mixer based on a birefringent crystal [119]

In 2013, Ke et al. [121] designed a 90° optical mixer based on crystal birefringence. To address the loose structure and poor temperature stability of discrete optical mixers, polarizing beam splitters, waveplates, yttrium orthovanadate crystals, and other devices, a spatial optical mixer with a compact structure, easy processing, and temperature insensitivity was designed.

In 2015, Zheng et al. [122] used two fast birefringent crystals, different phase-difference waveplates, and other optical components to design and then improve a tiled optical mixer. The improved optical path can be folded, reducing the size of the optical bridge in the mixer. However, the large number of structural elements in this design led to a large loss of light energy in the beam, resulting in a half-wave loss.

In 2018, Song et al. [123] designed a 2 × 4 90° spatial light mixer using electronically controlled birefringent crystals and polarizing birefringent crystals. Through the electronically controlled birefringent crystals, the signal light and local oscillator light are mixed by being double-reflected four times inside the crystal. The mixer could control the crystal voltage and the phase. It was simple in construction and easy to integrate.

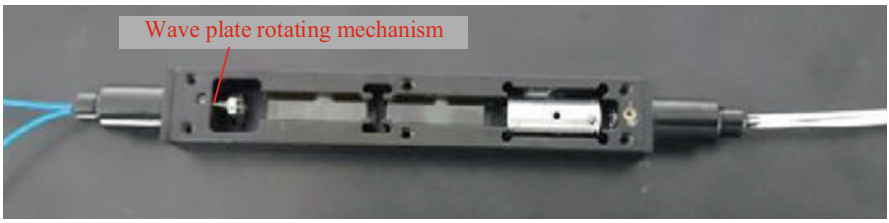

Fig. 29.19 2 × 4 90° crystal-shaped spatial light mixer [124]

In 2020, Han of Xi'an University of Technology [124] designed a 2 × 4 crystal-shaped 90° spatial light mixer based on the crystal birefringence effect, as shown in Fig. 29.21. Reference [124] describes the basic working principle and parameters. The integrated optical fiber and collimating lens at both ends of the mixer improved the quality of the beam entering the optical mixer. The waveplate was controlled by a rotating mechanism. The return loss of the test was 55 dB, and the external dimensions were 99 mm × 15 mm × 15 mm (Fig. 29.19).

The development of materials has produced optical mixers based on crystals. This type of optical mixer has the advantages of a low insertion loss, simple structure, and easy installation and adjustment, which are conducive to miniaturization and integration. However, because the crystal mixers control the phase through electro-optical effects, the crystal must be plated with electrodes; the device process is complex and additional power is required. Table 29.2 lists the properties of several commonly used crystals.

Other Types of Optical Mixers

In addition to the 90° optical mixer, the most commonly used mixers in coherent optical communication systems include 45°, 60°, and 120° optical mixers. Among them, the 120° optical mixer is essentially a 3 × 3 symmetric optical coupler. The coherent receiver based on the 120° optical mixer does not require a balanced detection module, which reduces the overall structure of the coherent receiver while saving costs [125].

In 1989, Nicholson et al. [126] first proposed a 120° optical mixer, and its basic structure is shown in Fig. 29.23. Based on the analysis, simulation, and demonstration of its basic principle, a 120° optical mixer was fabricated and used in a differential phase shift keying coherent optical communication system. When the laser frequency deviation was less than 1% of the bit rate, the performance of the coherent receiver based on the 120° optical mixer was consistent with that of a heterodyne receiver, and even more stable (Fig. 29.20).

In 2014, Dong et al. [127] designed a 120° coherent optical communication optical mixer based on a polarization prism. The mixer used an inverted-cone optical coupler integrated with the fiber and the chip, a polarization splitting prism, and a 3 × 3 MMI 120° optical mixer structure. The heterodyne communication

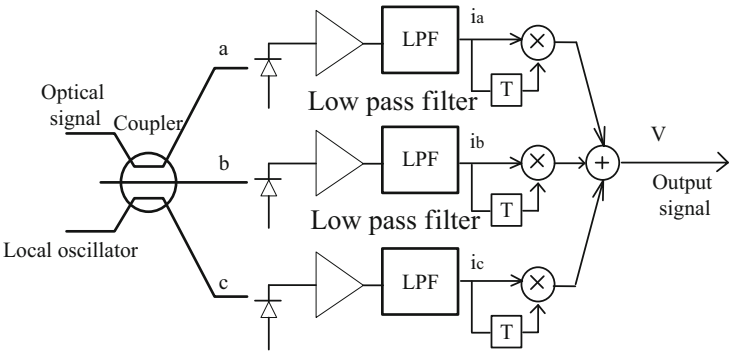

Fig. 29.20 Schematic diagram of a 120° optical mixer [126]

performance of a coherent optical receiver made of this type of optical mixer in the 1500-nm band can meet the standard of commercial coherent receivers.

Multimode Interference Coupler Optical Mixer

At present, domestic and foreign solutions for realizing optical mixers on planar waveguides mainly include star couplers [128], arrayed waveguide gratings [129], and multimode interference (MMI) couplers [130, 131]. Star couplers and arrayed waveguide grating optical mixers have complex structure designs, large device sizes, and poor transmission efficiency. Therefore, domestic and foreign research groups use multimode interference couplers for optical mixing.

According to the different implementations of MMI couplers, 90° optical mixers based on MMI couplers can be summarized into three categories: 4 × 4 MMI couplers [132], 2 × 2 MMI coupler combinations [133], and 2 × 4 MMI coupler combinations [134].

4 × 4 MMI Coupler Combination Types

In 2009, a 4 × 4 MMI coupler type 90° optical mixer was reported, based on the InP platform [124, 129]. The device size was 15 × 497.5 mm^2, and the additional loss in the C band range was less than 1 dB.

In 2011, Voigt et al. [135] reported a 90° optical mixer for silicon nanowire waveguides fabricated on a silicon-on-insulator (SOI) platform. The device has a size of 10 × 185 mm^2, an additional loss of less than 0.5 dB, and a phase deviation of less than 5° in the C band range. Compared with the 90° optical mixer made of four SOI ridge waveguides, a better phase accuracy was obtained.

In 2011, Fujitsu Corporation [136] proposed a wedge-shaped 4 × 4 MMI coupler type 90° optical mixer on the InP platform. The optical mixer had an additional loss of less than 1.4 dB in the 1530 nm–1600 nm wavelength range, and the phase deviation was less than ±5.4°.

In 2018, Xu et al. [137] reported a 90° optical mixer designed on the SOI platform, which utilized a subwavelength grating to adjust the effective refractive index of different modes in the waveguide. It then changed the beat frequency to achieve an efficient self-mapping effect.

In 2018, Wang et al. [138] first proposed a 90° optical mixer based on a hybrid plasmon waveguide, as shown in Fig. 29.13. The phase deviation at the 1550 nm wavelength was less than 0.7°. However, its additional loss was large and it was only suitable for short-distance coherent optical systems.

In addition to 90° optical mixers that can be implemented on platforms with high relative refractive indices, such as InP and SOI, optical mixers can also be implemented on polymer platforms with low relative refractive indices [139]. These devices tend to be low cost and have good polarization demultiplexing performance; however, owing to polymer limitations, the bandwidth and durability of the device are often limited. There are also reports of 4 × 4 MMI coupler-based optical mixers using silicon nitride waveguides with moderate refractive indices [140].

2 × 2 MMI Coupler Combination Types

In 2010, Japan's NTT Corporation [141] reported a 90° optical mixer with a refractive index difference of 1.5% on a silicon dioxide platform. The 90° optical mixer consisted of four 2 × 2 MMI couplers plus a 90° phase shifter. In the C band and L band ranges, the 90° optical mixer had a phase deviation of less than 0.7°.

In 2011, NTT Corporation [142] proposed replacing one of the traditional four 2 × 2 MMI couplers with a Y branch, which reduced the use of a 90° phase shifter. In the C band and L band ranges, the 90° optical mixer phase deviation was less than 3°.

In 2017, Elenion Technologies [143] reported a low-loss 90° optical mixer on the SOI platform. The optical mixer used a novel topology including a Y branch, three 2 × 2 MMI couplers, and four 90° curved waveguides. The size of the entire device was reduced to 21 mm × 31.9 mm. In the C band range, the insertion loss of the device was less than 0.5 dB, the phase deviation was less than 30°, and the common mode rejection ratio was less than 30 dB.

Different Phase Demodulation Types of MMI Couplers

To obtain higher spectral efficiency, the *m*-ary phase modulation format is used. In addition to common optical mixers are optical mixers with different phase demodulations.

In 2010, Fujitsu [144] reported a 45° optical mixer based on the InP platform, which was based on a combination of a 2 × 8 MMI coupler, three pairs of phase shifters, and three 2 × 2 MMI couplers. In a 32-nm bandwidth, the phase deviation was less than 5°. This optical mixer was smaller in size than traditional octal differential phase shift keying (DPSK) demodulators.

In 2011, Fujitsu Corporation [145] proposed a 60° optical mixer based on the InP platform. It was based on a combination of a 2 × 6 MMI coupler, two pairs of phase

shifters, and two 2 × 2 MMI couplers and was integrated with a balanced monolithic photodetector. At a 40-nm bandwidth, the phase deviation of the device was less than 5°.

In 2017, a Canadian group [146] reported a 120° optical mixer based on a 3 × 3 MMI coupler. The device had a phase deviation of less than 10° in the 55-nm wavelength range of the C band and L band and could be applied to high-speed passive optical networks (PONs). In 2021, the Institute of Semiconductors, Chinese Academy of Sciences [147], designed a 72° optical mixer based on a non-overlapping mapping of 2 × 5 MMI couplers on the SOI platform. The device length was 89.5 mm and the width was 8 mm.

MMI Optical Mixer Classification

Owing to the different positions of the input light field, the light-field modes excited by multimode waveguides are different. According to the position of the input light field and the excited light-field mode, MMI couplers are classified into general interference, paired interference, and symmetric interference MMI couplers [148].

Interference-Coupled MMI Coupler

All light field modes in the interferometric MMI coupler are excited; hence, the position of the input light field does not affect the mixing efficiency or other performance parameters of the optical mixer. When the multimode waveguide length $L = p(3L_\pi)$, $p = 0, 1, 2, \ldots$, the output optical field expression in the multimode waveguide is

$$\psi(x, L) = \sum_{v=0}^{m-1} C_v \psi_v(x) \cdot (\pm 1). \tag{29.14}$$

In the formula, C_v is expressed as the field excitation coefficient of the v-order mode, $\psi(x, L)$ is the output light-field mode, and $\psi_v(x)$ is the mode field distribution of the v-order mode. At this time, the light field of the output port is distributed.

The reproduction or mapping of the light field of the input port can obtain the length of N reimages as

$$L = \frac{P}{N}(3L_\pi), \tag{29.15}$$

where L is the length of the modular field and N is the multiplicity of the mapping. There is no common divisor between P and N. For a more compact design, the MMI coupler selects the first self-mapping point. At this time, $P = 1$. Using Fourier space decomposition, the form of the output light field after the input light field passes through the length L can be obtained:

$$\psi(x,L) = \sum_{v=0}^{\infty} C_v \psi_v(x) \exp(-j\beta_v L), \tag{29.16}$$

where C_v is expressed as the field excitation coefficient of the v-order mode, $\psi(x, L)$ is the output light-field mode, and $\psi_v(x)$ is the mode field distribution of the v-order mode.

Paired-Interferometric MMI Coupler

The paired-interferometric MMI coupler can only excite the light-field mode when the pilot-mode order is divisible by three. Its excitation coefficients are zero for all other excitation modes. Therefore, the position of the input light field will affect the light field excitation. The self-map of the input port can be obtained at the output port. At this time, the length of N-fold self-influence is

$$L = \frac{p}{N} L_\pi, \tag{29.17}$$

where L is the length of the mode field and N is the multiplicity of the map. There is no greatest common divisor between P and N; $P = 1$. When the width of the MMI coupler is the same, the length of the paired interferometric coupler is only half that of the interferometric coupler. Therefore, this principle can be used to reduce the length of the MMI coupler [149].

Symmetrical Interferometric MMI Coupler

In the multi-channel waveguide of a symmetric-interferometric MMI coupler, only even-order modes can be excited; the excitation coefficient of the odd-order modes is 0. Therefore, the position of the input light field must be located in the center of the waveguide. When the length of the multimode waveguide $L = P(3L\pi/4)$, the output port obtains the reproduction or mirror of the input square. At this time, the length of the N-fold mirror is

$$L = \frac{P}{N} \frac{3L_\pi}{4}, \tag{29.18}$$

where L is the length of the mode field and N is the multiplicity of the image. There is no common divisor between P and N; $P = 1$. When the width of the MMI coupler is the same, the length of the symmetrical interferometric MMI coupler is only one-fourth that of the interferometric MMI coupler. The phase relationship of the output port of the MMI coupler is

$$\varphi_{\mathrm{rs}} = \frac{\pi}{4N}(S-1)(N-S). \tag{29.19}$$

Through the above analysis, we can summarize the imaging rules of MMI couplers of different interference types, as shown in Table 29.3 [149].

Table 29.3 Summary of MMI couplers with different interference mechanisms

Interference mechanism	General interference	Pairing interference	Symmetric interference
Input waveguide × output waveguide	$N \times N$	$2 \times N$	$1 \times N$
Input location	Any location	$y = \pm \frac{w_e}{6}$	$y = 0$
First image location	$3L_\pi$	L_π	$(3L_\pi)/4$
First N remapping position	$3L_\pi/N$	L_π/N	$(3L_\pi)/4N$
Mode-incentive condition	None	$C_v = 0$, $v = 2, 5, 8, \ldots$	$C_v = 0$, $v = 1, 3, 5, \ldots$
Multimode-zone length	$L = \frac{p}{N} 3L_\pi$	$L = \frac{p}{N} L_\pi$	$L = \frac{p}{N} \frac{3L_\pi}{4}$

Arrayed Waveguide Grating Structured Optical Mixer

An arrayed waveguide grating (AWG) is a planar optical mixing device based on the interference and diffraction effects of spatial light. It is fabricated using planar lightwave circuit (PLC) technology, and the process is compatible with the complementary metal oxide semiconductor (CMOS) process [150].

Compared with other wavelength division multiplexing devices, the AWG fabrication process is simple, the number of channels is large, the insertion loss is low, the device size is small, and it can easily be coupled with optical fiber. In addition, an AWG can be integrated on-chip with other integrated photonic devices. AWGs are not only used in the communication field [151], but are also widely used in optical-fiber sensing [152].

Basic Principle of the Arrayed Waveguide Grating

The basic structure of an arrayed waveguide grating (AWG) includes an input/output waveguide, two focusing-plate regions, and a multi-channel waveguide phased array. ΔL is the constant physical path length difference between adjacent waveguides of the phased array. The working process of the AWG can be briefly described as follows. When the signal light carrying information enters the input star coupler flat-plate waveguide through the central input waveguide, it disperses and diffracts and then reaches the end face of the arrayed waveguide with the same phase and is coupled to the arrayed waveguide region. This region is collected by each individual waveguide and propagates independently. Because the end faces of the arrayed waveguides are located on the circumference of the grating circle, the diffracted light is coupled to arrayed waveguides with the same phase.

Since the adjacent waveguides in the arrayed waveguide have the same length difference ΔL, the diffracted light will have an equal phase difference after passing through the arrayed waveguide. A mirror image of the light field in the input star coupler flat waveguide is generated at the output star coupler flat waveguide. Because the optical paths of different wavelengths propagating through the arrayed waveguide cause different phase differences, different light wavelengths will be output to and from different channel positions, respectively [153].

Research Progress on Arrayed Waveguide Gratings

Donald et al. [154] proposed the concept of combining planar waveguides and planar gratings in 1987, and Smith proposed the structure of arrayed waveguide gratings in 1988; it is regarded as the prototype of the AWG structure [155].

In 2010, Vellekoop and Smith [156] realized the first arrayed waveguide grating (AWG) element for use at multiple wavelengths. In 2012, Zirngibl et al. first proposed an InP-based element, which used a smaller waveguide size and bending radius in the design, and could be well integrated with other components [157].

In 2000, McLaughlin et al. proposed a design for machining the input and output ends of the AWG flat waveguide part into a tapered port. This design made the transmission spectrum more planar, reduced the coupling loss of the device, and effectively controlled the temperature and polarization [149]. In the same year, an AWG was officially commercialized in a dense wavelength division multiplexing system and played a relatively good role [158].

In 2005, Hill et al. designed a 4 × 4 AWG with a 1550 nm center wavelength and 2 nm channel spacing [159]. In 2009, Heck et al. achieved eight channels, channel spacing of 0.84 nm, and a 3 dB bandwidth of 0.8 nm [152].

In 2017, Stanton et al. [160] proposed and prepared an arrayed waveguide grating with an eight-channel silicon-on-insulator, with a 3.7 mm^2 device size, a 0.08 dB–0.81 dB channel loss, and a −30.2 dB channel crosstalk, which had better performance.

In 2017, Fang et al. designed and prepared a 1 × 4 cascaded AWG, which used a cascaded method to suppress crosstalk between channels. Compared with a single AWG, the cascaded AWG crosstalk increased to −33.2 dB, and the device size was 1.0 mm × 1.4 mm [161]. In 2017, Song and He et al. designed and fabricated a 3.2 nm channel spaced, 16-channel silicon-based AWG with a 0.58 mm × 0.77 mm device size and an insertion loss of 4.9 dB [162]. Cascading the devices is one solution to give the AWG a greater bandwidth and higher resolution.

In 2018, Stanton et al. [163] achieved a low-loss arrayed waveguide grating at a 2 μm wavelength, with a channel loss of 2.4 dB, and −31 dB crosstalk per channel. In the same year, Elke et al. [164] fabricated an AWG with an 850 nm center wavelength using a low-cost, rapid prototyping, maskless laser direct writing method.

In 2021, Park et al. fabricated an eight-channel AWG with an 838-nm center wavelength based on a silicon nitride platform. After testing, the insertion loss of this device was 0.43 dB and the inter-channel crosstalk was −29.6 dB [165].

Owing to the relatively low refractive index of SOI using silicon nitride materials, the device requires a larger area. For this reason, in 2020, Menard et al. proposed the concept of a waveguide superlattice, which reduced the size of AWGs prepared based on silicon nitride materials more than twice, while achieving an insertion loss of 3.4 dB and a channel crosstalk of −18 dB [159].

In 2021, Liu et al. designed a four-way silicon-based AWG device with an insertion loss of 2.5 dB [160]. In 2020, Hon et al. of the City University of Hong Kong successfully fabricated an AWG device with an 860-nm center wavelength and

40 channels on a silicon nitride platform. The device had a bandwidth of more than 60 nm and a center-channel insertion loss of 1.3 dB [166]. This work proved the feasibility of using large-scale programmable logic controller (PLC) technology to fabricate arrayed waveguide gratings, which further improved the degree of integration.

In 2021, Chen successfully fabricated 15 channels using silicon nitride on an SOI wafer and reduced the device size by combining it with a silicon photonic-loop reflector. The actual measured insertion loss was 5.46 dB, and the channel crosstalk was 19.2 dB [167]. In 2021, Taha et al. successfully developed a compact four-channel AWG device on a silicon photonic platform based on MMI, with a device size of 367 × 67 square microns and an insertion loss of 9.6 dB [168].

Comparison of the Material Properties of Optoelectronic Devices

Common Materials for Optical Mixers

In the optical communication field, the integration and flattening of coherent optical communication systems has promoted the integrated development of optoelectronic devices. Optical receiving and detector devices, including optical mixers, are oriented towards a tunable, focused response and narrow linewidth. The transmission linearity of the optical waveguide in the dielectric layer laid the foundation for integrated optics, after which optical waveguide–based optical mixer structures have been continuously produced.

Many materials with good optical properties can be used to make optical waveguides, among which five are the most widely used and more mature technologies [169]: optical waveguides based on lithium niobate crystals, silicon dioxide waveguides, semiconductor optical waveguides, optical glass waveguides, and polymer waveguides.

In the integrated optic field, the lithium niobate crystal ($LiNbO_3$) has excellent physical properties, such as electro-optics, acousto-optics, nonlinearity, photorefractivity, photoelasticity, and laser activity [170]. The lithium niobate crystal has a cubic crystal structure. One of its advantages is that it has a large electro-optical coefficient, and its optical-switching voltage is relatively low. Its outstanding electro-optic properties make it widely used for electro-optic devices, such as optical phase or intensity modulators, optical phase retarders, optical mixers, and optical scanners [171].

The silicon dioxide optical waveguide has the advantages of matching the production process of other electronic circuit fabrication processes, stable physical and chemical properties, good compatibility with optical fibers (high coupling efficiency), and extremely small loss in the strip-shaped single-mode waveguide. The upper and lower cladding layers of the silicon dioxide optical waveguide are both silicon dioxide, and the core layer is Ge-doped silicon dioxide. The preparation usually adopts lithography, reactive ion etching (RIE), and annealing processes.

Ion exchange is the most commonly used glass-manufacturing process. During the manufacturing process, cations (usually Na+ ions) in the glass material are replaced by ions with larger sizes or higher polarizability, making the refractive index of the ion-replacement region higher than that of other regions to form a waveguide structure. The ion exchange process is simple and low cost [172].

Polymer optical waveguides have been a research hotspot in recent years. They have the advantages of a simple fabrication process, low cost, wide bandwidth, and high photoelectric-coupling efficiency. They are suitable for fabricating passive waveguide devices. However, they have poor thermal stability and poor mechanical properties.

Comparison of Material Properties

The phase deviation of waveguide-type optical mixers is relatively large, so higher-order optical mode interference is used to reduce the phase deviation. The high-order mode of generated light places high fabrication requirements on the substrate material, and the fabrication technology is complicated. In addition, there are unavoidable additional signal losses in multiple input and output MMI couplers, as well as problems, such as signal crosstalk between multiple outputs. In addition, the performance of waveguide mixers of different materials is very different, so we compare different waveguide materials, as shown in Table 29.4.

Mixing-Error Analysis

The use of discrete optical elements, such as waveplates, polarization splitting prisms, and collimating lens groups, in the optical mixer, as well as the refractive

Table 29.4 Performance comparison of different waveguide materials

Material	Transmission loss (1550 nm, dB/cm)	Coupling loss (dB/ end face)	Core /core relative refractive index difference	Advantages and disadvantages
Lithium niobate	0.5	1	0–0.5%	Large size and small refractive index difference; belongs to weak refractive index optical waveguides
Silica	0.05	0.25	0–4%	Low transmission loss, good refractive index matching, low coupling loss
Polymer	0.1	0.1	0–35%	Devices are susceptible to contamination; aging leads to unstable performance
Silicon	0.05	0.1	0–0.5%	Low-loss, complex fabrication process, uneven refractive index distribution, unstable device performance

index distribution and assembly accuracy of the optical-fiber structured optical mixer will have a greater impact on the performance of the optical mixer. In addition, the vibration, temperature will also have a great impact on the stability of the device; thus, various optical mixer errors are theoretically analyzed [173].

Phase Error

A large number of optical elements are used in an optical mixer. The thermal expansion of an element caused by temperature, assembly errors, and aberrations in the optical element itself will cause the optical path difference of the passing light to not be strictly equal. It will increase with the increase of the laser wavelength and gradually expand [174].

The phase difference, the most important performance index of an optical mixer, is affected by many factors, such as the deviation of the optical axis of the waveplate, the phase delay deviation of the waveplate, and the phase delay deviation of the polarization splitter. According to the definition and calculation formula of the optical path difference, the additional phase difference is proportional to the frequency difference between the signal light and the local oscillator and the difference between the lengths of the two arms. When the frequency difference is 30 GHz and the difference between the lengths of the two arms is 1 mm, the additional phase difference is 0.628 mrad. When the frequency difference is below GHz, the additional phase difference can be ignored.

Polarizing-spectroscopic film is a multilayer film that alternately stacks high and low refractive index films on the spectroscopic surface so that the incident ray meets the Brewster angle, the P light transmittance is close to 100%, and the S light reflectivity is close to 100%. In practice, the phase effect of the polarizing spectroscopic film cannot reach the ideal state, so the corresponding differences of 90° or 180° cannot be accurately satisfied, which is also one of the important factors affecting the relative phase difference.

Insertion Loss

Each optical element in the optical mixer is a discrete element. When the laser is incident on and off the element surface, there will inevitably be insertion loss, which will reduce the sensitivity of the optical receiver where the optical mixer is located. The following types of optical components in the optical mixer are the main factors causing insertion loss.

Fiber Collimating Lens

As shown in Fig. 29.19, the signal light and the local oscillator light are respectively input to the optical element at the rear end, after being output from the pigtail of the laser by a fiber collimating lens to collimate the light beam. The four-way output light at 0°, 90°, 180°, and 270° is also coupled into the fiber through the collimating lens, and the light intensity of the output light is detected by the PIN. Because the lens focus in the collimating mirror is located at the fiber core with the highest coupling efficiency, and the diameter of the single-mode polarization-maintaining

fiber core is less than 10 mm, the coupling efficiency of the spatial light beam and fiber-collimating lens is low. Thus, the collimating lens at 90° is the primary factor for optical mixer insertion loss.

Polarization Beam-Splitting Prism (PBS) and Waveplate

Multiple polarization-splitting prisms are used in optical mixers. Their basic function is to separate the polarization components of the transmitted P ray and the reflected S ray. For the P and S lights, the transmittance of the prism is $(1 - R)^2$. The thickness of the waveplate is only about 1 mm, and the loss of optical power can be ignored. In addition, the surface is coated with the same anti-reflection film as the polarization splitting prism. Therefore, in theory, the transmittance of the waveplate is $(1 - R)^2$.

Splitting Ratio Error

The splitting ratio error refers to the power ratio between two adjacent channels. Theoretically, their ratio should be 1:1. However, since $T_P \neq R_S$ of the polarization-splitting prism, and the direction of the fast (slow) axis of the $\lambda/2$ waveplate is not strictly equal to 29.5°, the powers of the P light and S light of the outgoing polarizing-splitting prism are unequal. This means that the DC components of the adjacent two optical currents with a 180° difference are also not strictly equal, resulting in the corresponding noise.

Although the direction of the fast (slow) axis of the $\lambda/2$ waveplate cannot be accurately adjusted to 29.5° by the scale on the adjustment rack, the corresponding angular error can actually be compensated by rotating the $\lambda/2$ waveplate.

The polarization splitting prism introduces an inherent splitting ratio error. In the two adjacent channels obtained from the polarization-splitting prism data, the ratio of the reflected light to projected light power should be $R_S : T_P \approx 1.041$.

Analysis of the Mixing Efficiency of an Optical mixer in a Coherent Optical Communication System

Light Field Pattern Matching

In coherent optical communication, matching the light-field modes refers to matching the amplitude distribution of the light field between the signal light and the local oscillator light. This determines the energy distribution of the light spot received by the mixed light on the detector target surface, and the coincidence and uniformity of the light spot will inevitably affect the mixing efficiency of the coherent detection system [170]. Therefore, amplitude distribution matching is an important coherence premise and is very important for whether the signal and local oscillator lights can achieve high-efficiency mixing.

Optical Field Distribution

In coherent optical communication systems, the signal light and local oscillator light usually have several types of light-field distributions. The laser light-field distribution can be divided into Airy, uniform, and Gaussian distributions [170]. The different light-field distribution types affect the mixing efficiency of the mixer [171]. Several types of light-field distributions are as follows:

Gaussian distribution (Gauss):

$$U(r) = \exp\left(\frac{-r^2}{\omega_0^2}\right). \tag{29.20}$$

Airy distribution (Airy):

$$U(r) = \frac{2J_1\left(\frac{\pi r}{F\lambda}\right)}{\frac{\pi r}{F\lambda}}. \tag{29.21}$$

Uniform distribution:

$$U(r) = 1. \tag{29.22}$$

J_1 is a first-order Bessel function, F is the transmission parameter of the optical system, which usually determines the size of the light spot of the Airy spot; λ is the wavelength of the laser, and ω_0 represents the waist radius of the Gaussian light beam. The optical signal can have a Gaussian distribution after transmission, and an approximately uniform distribution after a long-distance transmission. Therefore, we describe the optical mixer efficiency when the signal light-field distribution is Gaussian and uniform, and the local oscillator light is three cases.

Mixing Efficiency

According to the coherent detection principle and limited by the bandwidth of the photodetector, a beat signal is obtained by mixing the wavefronts of the signal and the local oscillator light. The DC component is removed after subsequent processing to obtain an intermediate frequency signal with modulation information. The signal can be described in the following form:

$$i_{\mathrm{AC}} = \frac{R}{2Z}\iint_D A_{\mathrm{S}}(r,\varphi)A_{\mathrm{LO}}(r,\varphi)\cos(\omega_{\mathrm{d}}t,\Delta\varphi)ds, \tag{29.23}$$

where R represents the photodetector response, Z represents the impedance characteristics of the photodetector, and D represents the receiving photosensitive area of the photodetector. $A_{\mathrm{s}}(r, \varphi)$ and $A_{\mathrm{LO}}(r, \varphi)$ represent the amplitude distribution functions of the signal light and local oscillator light on the receiving plane, respectively, where r represents the off-axis distance. In the coherent detection process, the shot noise caused by the local oscillator light is the main source of the mixer noise.

The DC signal corresponding to the local oscillator light is used to represent the DC signal output in the detector, and the photocurrent can be written as shown in Eq. (29.24).The signal-to-noise ratio of the receiving system is the intermediate frequency signal photocurrent and the DC component mean-square ratio generated by the shot noise of the local oscillator light as Eq. (29.25). p_s indicates the power of the signal light, B indicates the bandwidth of the shot noise caused by the local oscillator, and η indicates the mixing efficiency of two beams of light.

$$i_{\mathrm{DC}} = \frac{R}{2Z}\iint_D U_{\mathrm{LO}}^2(r,\varphi)dS \tag{29.24}$$

In the formula, R represents the photodetector response, Z represents the impedance characteristics of the photodetector, and D represents the receiving photosensitive area of the photodetector:

$$\mathrm{SNR} = \frac{\langle i^2\mathrm{AC}\rangle}{2qBi_{\mathrm{DC}}} = \eta\frac{RP_{\mathrm{S}}}{qB}. \tag{29.25}$$

The mixing-efficiency formula can be established as follows:

$$\eta = \frac{\left|\int_0^{2\pi}\int_0^{r_0} U_{\mathrm{S}}(r,\varphi)U_{\mathrm{LO}}(r,\varphi)\exp[i\Delta\psi(r,\varphi)rdrd\varphi]\right|^2}{\int_0^{2\pi}\int_0^{r_0}[U_{\mathrm{LO}}(r,\varphi)]^2 rdrd\varphi\int_0^{2\pi}\int_0^{\infty}[U_{\mathrm{S}}(r,\varphi)]^2 rdrd\varphi}, \tag{29.26}$$

where $U_{\mathrm{S}}(r, \varphi)$ and $U_{\mathrm{LO}}(r, \varphi)$ are the normalized amplitude distributions of the signal light and local oscillator light, respectively, and the integral interval is the area of the entire photosensitive surface.

When the local oscillator light is uniformly distributed, its amplitude distribution is $U_{\mathrm{LO}}(r) = 1$, and the light field distribution function of the signal light and the local oscillator light is substituted into the above mixing-efficiency formula, and the common value of the mixing efficiency changing with the detector is obtained:

$$\eta(r_0) = 4\frac{\left[1 - J_0\left(\frac{\pi r_0}{F\lambda}\right)\right]}{\left(\frac{\pi r_0}{F\lambda}\right)^2}. \tag{29.27}$$

The above formula is the mixing efficiency formula when the local oscillator light is uniformly distributed. In the formula, J_1 is the first-order Bessel function, F is the transmission parameter of the optical system, and λ is the wavelength of the laser.

When the intrinsic light has an Airy distribution, the light-field distribution of the signal light and the local oscillator light is substituted into the mixing-efficiency

formula to obtain the mixing-efficiency formula when the local oscillator light has an Airy distribution:

$$\eta_{\mathrm{AA}}(r_0) = 1 - J_0^2\left(\frac{\pi r_0}{F\lambda}\right) - J_1^2\left(\frac{\pi r_0}{F\lambda}\right). \tag{29.28}$$

When the local oscillator light has a Gaussian distribution, the optical field amplitude distribution function of the two lights is also substituted into the mixing efficiency Eq. (29.26), sorted out as above, and the set parameters are substituted. When the local oscillator light has a Gaussian distribution, the mixing efficiency formula changes with the detector radius r_0:

$$\eta_{\mathrm{AG}}(r_0) = \frac{8\left|\int_0^{r_0} J_1\left(\frac{\pi r}{F\lambda}\right).\exp\left(-\frac{r^2}{\omega_0^2}\right)dr\right|^2}{\omega_0^2\left[1 - \exp\left(-2\frac{r_0^2}{\omega_0^2}\right)\right]}. \tag{29.29}$$

Light-Spot Size Mismatch

In a coherent laser communication system, when the amplitude and phase of the signal light and the local oscillator light completely match, the coherence is the best and the detection sensitivity is the highest. In this case, the ratio between the size of the signal light and the local oscillator light spot and the half-pass of the detector is smaller. Usually, the receiving target surface of the optical mixer is placed at the waist of the laser beam, which is more conducive to concentrating the available energy, which, in turn, helps to achieve higher efficiency mixing.

In this case, the mixing efficiency formula of the optical mixer under different light spot sizes can be obtained:

$$\eta = 2\frac{\left[\frac{2}{k}\int_0^{X_0} J_1(X)J_0(2F\theta X)\exp\left(-\frac{X^2}{k^2}\right)dX\right]}{1 - \exp\left(-2\frac{X_0^2}{k^2}\right)}, \tag{29.30}$$

where $k = \frac{X}{Z} = \frac{\pi\omega}{F\lambda}$. $X = \frac{\pi r}{F\lambda}$, $Z = \frac{r}{\omega}$, and the integral area is the area where the signal light and the local oscillator spot coincide. When the signal light beam has a great influence on the mixing efficiency of the mixer, assuming that the entire local oscillator light is received at this time, the optical mixer efficiency formula can be expressed as

$$\eta = \frac{8}{k^2}\left[1 - \exp\left(-\frac{k^2}{4}\right)\right]^2. \tag{29.31}$$

Good light-spot size matching can increase the signal on the target surface of the detector, the effective coherent area of the local oscillator light, and the energy concentration, resulting in a higher mixing efficiency. By optimizing the detector size and the relative light beam size, the communication light beam and the system can be designed to improve the mixing efficiency, thereby improving the communication performance of the coherent laser communication system.

Wavefront Mass

The mixer adds gain to the detection sensitivity of the receiving system by coherently mixing the signal light with the wavefront of the local oscillator light. Phase matching, as a key coherence condition, is very important for achieving high-efficiency mixing. The wavefront quality of the light beam directly affects the phase change of the two lights in the coherence process, and the phase distortion of the optical wavefront has a non-negligible impact on the mixing efficiency. Two main elements affect the wavefront quality [175]:

1. Internal optical system: Atmospheric channels, temperature changes, shock-vibration stress, other natural factors, and platform vibration will affect the imaging quality of the optical system in the transmission orbit. For example, large temperature changes lead to changes in the refractive index and lens-surface curvature. Thickness changes, lens-spacing changes, etc., cause a phase distortion of the light wavefront.
2. Incident ray channel: The random variation of the atmospheric refractive index will produce atmospheric turbulence, which has a huge impact on the wavefront phase of the light beam. It not only causes a light intensity fluctuation of the light field on the detector target surface, but can also distort the light wavefront. This can cause a laser speckle effect, resulting in a decrease in the Strehl ratio of the light spot, and even a serious deformation in the amplitude distribution of the light field received by the light spot on the target-detector surface.

Zernike polynomials are typically used to describe the wavefront distortion phase of the signal light. The Zernike polynomial of the main quintuple primary phase can be written in the following form:

$$\begin{cases} \varphi_{\text{tilt}}(\rho,\theta) = a_{111}\rho\cos\theta \\ \varphi_{\text{defocussing}}(\rho,\theta) = a_{020}\rho^2 \\ \varphi_{\text{spherical aberration}}(\rho,\theta) = a_{040}\rho^4 \\ \varphi_{\text{coma}}(\rho,\theta) = a_{131}\rho^3\cos\theta \\ \varphi_{\text{astigmatism}}(\rho,\theta) = a_{222}\rho^2\cos^2\theta \end{cases} . \tag{29.32}$$

where ρ is used as the normalized radius, and a is used as the aberration coefficient to represent the size of the wavefront aberration. An equation for studying the effect of

wavefront distortion on the mixing efficiency of spatial light is established, and the mixing-efficiency formula is obtained as follows [177]:

$$\eta = \frac{\left| \int_0^{2\pi} \int_0^{r_0} E_S(r,\varphi) E_{LO}(r,\varphi) \exp[i\Delta\psi(r,\varphi) r dr d\varphi] \right|^2}{\int_0^{2\pi} \int_0^{r_0} [E_{LO}(r,\varphi)]^2 r dr d\varphi \int_0^{2\pi} \int_0^{\infty} [E_s(r,\varphi)]^2 r dr d\varphi}. \tag{29.33}$$

The above formula is the mixing-efficiency formula under the influence of different aberrations. Both the local oscillator light and the signal light have Gaussian distributions. The influence of the wavefront distortions caused by the five primary phase differences on the mixing efficiency of the optical mixer is analyzed. The Zernike polynomial expression of each aberration is added to the mixing-efficiency expression to obtain the mixing-efficiency expressions of five basic aberrations, including tilt, defocusing, spherical, coma, and astigmatism.

Equation (29.34) shows the mixing-efficiency expression under the influence of a tilt aberration:

$$\eta_{\text{Tilt}} = \frac{8\left| \int_0^{r_0} \exp\left(-\frac{r^2}{\omega_0^2}\right) J_0(k a_{111} \rho) r dr \right|^2}{r_0^2 \omega_0^2 \left[1 - \exp\left(-\frac{2r_0^2}{\omega_0^2}\right)\right]}, \tag{29.34}$$

where the integral area is the entire receiving photosensitive surface area, ρ is a normalized half, a is the Zernike aberration coefficient, ω_0 is the waist radius of the light beam, and r_0 is the detector radius.

Equation (29.35) is the expression of the mixing efficiency under the influence of a defocus aberration:

$$\eta_{\text{Defocus}} = \frac{8\left| \int_0^{r_0} \exp\left(-\frac{r^2}{\omega_0^2}\right) \exp(-ik a_{020} \rho^2) r dr \right|^2}{r_0^2 \omega_0^2 \left[1 - \exp\left(-\frac{2r_0^2}{\omega_0^2}\right)\right]} \tag{29.35}$$

Equation (29.36) is the expression of the mixing efficiency under the influence of a spherical aberration:

$$\eta_{\text{Spherical aberration}} = \frac{8\left| \int_0^{r_0} \exp\left(-\frac{r^2}{\omega_0^2}\right) \exp(-ik a_{040} \rho^4) r dr \right|^2}{r_0^2 \omega_0^2 \left[1 - \exp\left(-\frac{2r_0^2}{\omega_0^2}\right)\right]}. \tag{29.36}$$

Equation (29.37) is the expression of the mixing efficiency under the influence of a coma:

$$\eta_{\text{Coma aberration}} = \frac{8\left|\int_0^{r_0} \exp\left(-\frac{r^2}{\omega_0^2}\right) J_0(ka_{131}\rho^3) r dr\right|^2}{r_0^2\omega_0^2\left[1 - \exp\left(-\frac{2r_0^2}{\omega_0^2}\right)\right]} \tag{29.37}$$

Equation (29.38) is the expression of the mixing efficiency under the influence of astigmatism:

$$\eta_{\text{Astigmatism}} = \frac{8\left|\int_0^{r_0} \exp\left(-\frac{r^2}{\omega_0^2}\right) \exp\left(-ika_{222}\frac{\rho^2}{2}\right) J_0\left(ka_{222}\frac{\rho^2}{2}\right) r dr\right|^2}{r_0^2\omega_0^2\left[1 - \exp\left(-\frac{2r_0^2}{\omega_0^2}\right)\right]}. \tag{29.38}$$

A tilt aberration has the greatest impact on the mixing efficiency. It is mainly caused by the shaking of the sight axis, which needs to be compensated by improving the tracking and aiming accuracy. The influence of astigmatism is minimal; a 0.1 λ astigmatism reduces the mixing efficiency by 3%. Spherical and defocusing aberrations of 0.1 λ reduce the mixing efficiency by 5% and by 14% at 0.2 λ. The mixing efficiency can be maintained above 65% when the size of each aberration is within 0.2 [176].

Vibration and Tracking Errors

The optical axis direction of the signal light and local oscillator light in the actual transmission process is affected by angular deviation. For example, a larger-scale atmospheric turbulence causes the light beam to drift, so that the center position of the signal-beam propagation plane is offset.

The vibration of the external platform and the shaking of the optical axis caused by the loop noise of the acquisition, pointing, and tracking (APT) subsystem directly affect the coaxiality between the received two beams of light. It moves the focal plane of the light spot, which, in turn, affects the effective coherence area of the light beam and loses useful light information energy. The signal caused by the shaking of the optical axis and the offset of the local oscillator light field and the focal plane of the light spot can be represented as shown in Fig. 29.21.

The influence of the center distance between the signal light and the local oscillator light spot on the mixing efficiency is analyzed, and the effective coherent light-spot area and the mixing efficiency are written as

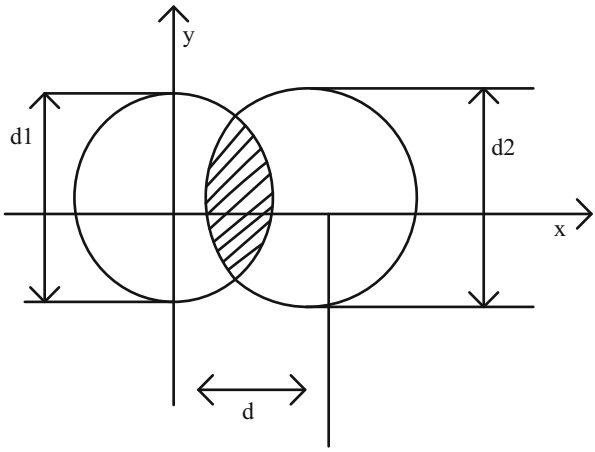

Fig. 29.21 Schematic diagram of the optical axis offset

$$s = \frac{\pi \bar{d}^2}{4} - \frac{\bar{d}^2}{2} \arcsin\left(\frac{d}{\bar{d}}\right) - \frac{\bar{d}^2}{4} \sin\left[2\arcsin\left(\frac{d}{\bar{d}}\right)\right] \tag{29.39}$$

$$\eta = \frac{S}{\pi(\bar{d}/2)^2} = 1 - \frac{2}{\pi} \arcsin\left(\frac{d}{\bar{d}}\right) - \frac{1}{\pi} \sin\left[2\arcsin\left(\frac{d}{\bar{d}}\right)\right]. \tag{29.40}$$

The above formula shows the effect of the off-axis light spot on the mixing efficiency, and the integral area is the overlapping area of the two light spots. In the formula, s is the area of the part where the signal light and the local oscillator light spot overlap, $\overline{d}$ is the radius of the overlapping area of the light spot, and d_1 and d_2 are the signal light and the light spot size of the local oscillator, respectively.

The mixing efficiency is attenuated by an increase in the angular deviation of the optical axis of the two light beams caused by the shaking of the visual axis. Compared with several other factors, the influence of the focal plane offset of the light spot caused by the shaking of the visual axis on the mixing efficiency is greatly improved. Good coaxiality of the optical axes of the two laser beams at the receiving end is very important. It can be compensated by improving the dynamic tracking of the optical signal and the aiming accuracy between the signal transmission and the receiving system.

Polarization Characteristics

The optical mixer can be regarded as a fixed-purpose polarization interferometer composed of a polarization-splitting prism and a waveplate. It mixes the signal with a constant phase difference, polarization matching, and close frequency with the local optical wavefront on the detector surface. The signal light gains by interfering with the local oscillator light, thereby improving the sensitivity of coherent

detection. Therefore, polarization matching is an important light beam coherence condition [178].

In a coherent optical communication system, before the laser beam is incident on the mixer, the polarization-maintaining fiber can ensure the stability of the polarization state of the local oscillator; however, the polarization state of the signal light is easily affected after passing through the complex spatial-transmission channel and optical transmission system. Therefore, the influence of the polarization characteristics of the signal light on the performance of the mixer is studied [179].

Influence of the Optical Vector Direction of the Linear Polarization Signal on the Mixing Efficiency

After the linearly polarized signal light and the local oscillator light are incident on the optical mixer, the DC branch photocurrent, used to restore the modulation information, and the quadrature branch photocurrent, used to control the loop, are output as follows:

$$I_{\mathrm{I}} = 2k_2k_3|E_{\mathrm{S}}E_{\mathrm{LO}}|\cos\phi(t) \tag{29.41}$$

$$I_{\mathrm{Q}} = 2k_1k_4|E_{\mathrm{S}}E_{\mathrm{LO}}|\cos\left(\phi(t) + 2\left(\tau_{//} - \rho_{\perp}\right) + \frac{\pi}{2}\right). \tag{29.42}$$

In the formula, k_1, k_2, k_3, and k_4 are the polarization vectors of the signal light and the polarized light, I_{I} is the modulation information reduction photocurrent, and I_{Q} is the photocurrent that controls the quadrature branch. Considering its impact on the performance of the mixer from the perspective of output power, the mixing-efficiency formula is written as [180]

$$\eta(\theta) = \frac{P_{\mathrm{Actual}}}{P_{\mathrm{Ideal}}} \propto \frac{I^2_{\mathrm{Actual}}}{I^2_{\mathrm{Ideal}}} = \frac{\left(\sqrt{2}\sin\theta + \sqrt{2}\cos\theta\right)^2}{4} = \frac{|1 + \sin 2\theta|}{2}. \tag{29.43}$$

Influence of Circular Polarization and Elliptical-Polarization Signal Lights on the Mixing Efficiency

Considering that circularly polarized and elliptically polarized light have better stability than the linearly polarized light used in traditional schemes, they have stronger adaptability to the atmosphere and have good polarization retention, especially in satellite-to-ground links. It is beneficial to improve the certainty of the polarization state of the communication light [181]. The situation when signal lights with different polarization states is incident can be simulated.

Therefore, in the case of ideal phase difference, as above, from the perspective of output power, considering its impact on the performance of the mixer, the mixing-efficiency formula is written in the form of an output power ratio:

$$\eta(\phi(t)-\psi,\theta)=\frac{I_{\text{Actual}}^2}{I_{\text{Ideal}}^2}=\frac{[\cos(\phi(t)-\psi)+\sin(\phi(t)-\psi)\sin(2\theta)]^2}{2} \tag{29.44}$$

$$\eta_c=\frac{\left[\int_0^{r_0}E_{\text{S}}(r)E_{\text{LO}}(r)\exp(i\Delta\varphi)rdr\right]^2}{\int_0^{r_0}[E_{\text{LO}}(r)]^2rdr\int_0^{\infty}[E_{\text{S}}(r)]^2rdr}\xrightarrow{\text{Energy changes and phase matches}}\frac{\left[\int_0^{r_0}\eta(\phi(t)-\psi,\theta)E_{\text{S}}(r)E_{\text{LO}}(r)rdr\right]^2}{\int_0^{r_0}[E_{\text{LO}}(r)]^2rdr\int_0^{\infty}[E_{\text{S}}(r)]^2rdr}. \tag{29.45}$$

When the angle between the fast axis of the quarter waveplate and the horizontal direction is 45°, the signal light entering the mixer is in a circular polarization state. At this time, the output signal power is the largest, which can be regarded as the relative mixing efficiency reaching its peak. When the fast axis of the quarter waveplate is located at other positions, the signal light is elliptically polarized, and the mixing efficiency decreases with the change of the angle θ of its fast axis.

Research on Optical Mixers at Xi'an University of Technology

Since 2000, Xi'an University of Technology has conducted in-depth theoretical research and experimental verification in complex environments and systems, and achieved good results in key areas of optical communication technologies, such as the following:

1. Transmission characteristics in laser atmospheric turbulence
2. Codecs in wireless laser communication systems
3. Optical wireless subcarrier modulation
4. Laser modulation and demodulation
5. Channel estimation and equalization
6. Design of optical transceiver systems
7. Acquisition-alignment tracking technology
8. Optical orthogonal frequency division multiplexing modulation and optical multiple input multiple output system research and
9. Optical wireless transmission theory and technology [182].

The Optoelectronic Technology Laboratory of Xi'an University of Technology conducts systematic research on many key elements of spatial coherent optical communications systems including the modulation mode, balanced detection module, adaptive-optics module, etc. A self-designed double-balanced detection receiver module is used in the self-designed and developed spatial coherent optical

communication system, and the performance of the detection system is theoretically analyzed and experimentally verified.

According to the crystal birefringence effect and comprehensively considering the function of the optical mixer, the Optoelectronic Technology Research Laboratory of Xi'an University of Technology designed a 2 × 4 90° crystal spatial optical mixer; analyzed its basic working principle, and produced its parameter design scheme. Finally, by establishing an error analysis model of the mixer, the phase error of the mixer, the uniformity of the branch energy, and the mathematical relationship between the I/Q splitting ratio of the mixer and the influencing factors were obtained.

Structural Design of an Optical mixer

Considering the function of the optical mixer and the optical properties of the uniaxial crystal, the schematic diagram of a crystal 2 × 4 90° spatial optical mixer is designed, as shown in Fig. 29.22. In Fig. 29.22, E_S and E_L represent the signal light beam and the local oscillator beam, respectively; all propagate along the z-axis. Along the light propagation direction are a quarter waveplate, birefringent crystal 1, first half waveplate, second half waveplate, birefringent crystal 2, and birefringent crystal 3.

In this structure, the main cross sections of crystals 1 and 2 are perpendicular to each other, the main cross sections of crystals 2 and 3 are at 45°, and the structures of crystals 1, 2, and 3 are the same. The optical axis x_3 is in the XOZ plane and forms an angle θ with the z-axis; x_2 is parallel to the y-axis. The surface of the quarter waveplate of the local oscillator optical path is parallel to the incident surface of crystal 1, and the fast axis of the waveplate is parallel to the x-axis. The surfaces of the first and second half waveplates are parallel to the incident surface of crystal 2, and the fast axis of the two waveplates is 45° with the x-axis.

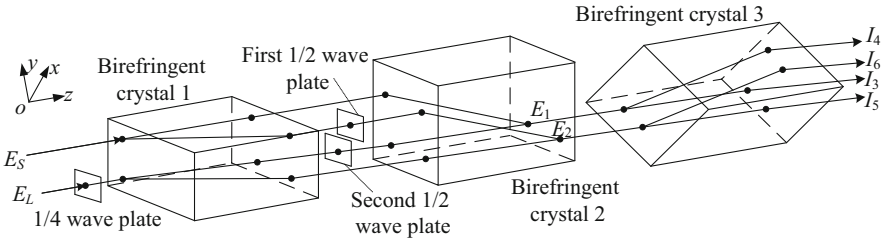

Fig. 29.22 Principle structure diagram of a crystal type 2 × 4 90° spatial light mixer (E_S: signal light beam; E_L: Local light beam; I_3, I_4, I_5, and I_6: four mixed output light beams)

Structural Optimization

The phase difference and splitting ratio are the most important factors to measure the performance of an optical mixer. Ideally, the phase difference of the I/Q of the mixer is 90° and the splitting ratio is 1. However, in practice, owing to the influence of various factors, errors will occur in the phase and splitting ratio of the mixer, which will affect its performance.

During the principle analysis of the mixer, it was found that the phase shift required by the mixer was provided by the quarter waveplate. Rotating the optical axis of the quarter waveplate can compensate the phase of the mixer; however, the resulting side effect is that the splitting ratio between the I/Q channels is changed.

As long as the Q branch can be properly locked, more energy can be distributed to the I branch for demodulating the signal, thereby improving the coherent detection sensitivity; hence, a method is needed to adjust the splitting ratio. A half waveplate is added to the signal optical path of the prism-type spatial optical mixer, and the splitting ratio can be adjusted by rotating this waveplate. It was applied to the optical mixer designed in this study.

The experimental results of the adjusted optical mixer show that when the laser frequency difference is greater than 400 MHz, it has a severe impact on the phase accuracy of the mixer; the quarter waveplate has a severe impact on the phase and splitting ratio of the optical mixer; and the crystal transmittance has a severe impact on the branch energy uniformity and splitting ratio. The phase compensation and splitting ratio adjustment scheme is simple and effective and has little impact on the mixing efficiency of the mixer.

Experimental Verification

The experimental system with the structure shown in Fig. 29.23 was built, and the designed crystal optical mixer was tested.

Through testing, it was found that two sine waves appeared on the oscilloscope. As shown in Figs. 29.24 and 29.25, the quarter waveplate is rotated for debugging, so that the amplitude between the two electrical signals is about 1:1. This verifies that

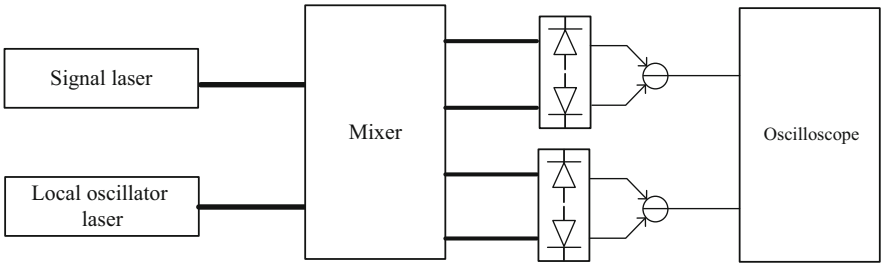

Fig. 29.23 Test-system structure diagram

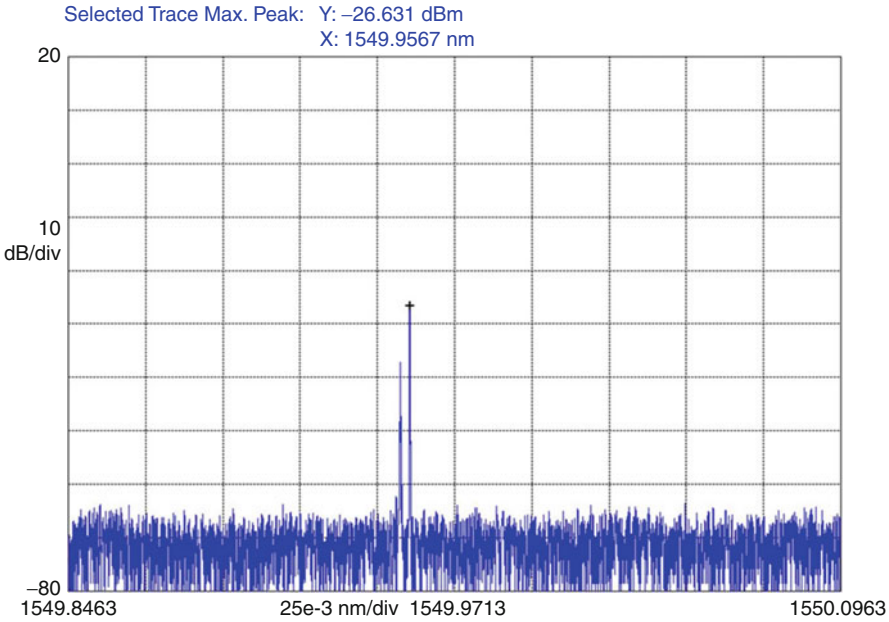

Fig. 29.24 Spectrum of the output intermediate frequency signal

the mixer can mix the signal light and local oscillator light. At this time, the intermediate frequency voltage of the two signals reaches between 130 mV and 145 mV. Because the voltage value detected by the detector is proportional to the received optical power, the insertion loss of the designed optical mixer is small.

Finally, the designed optical mixer is applied to the BPSK coherent optical communication system. The camera loads the collected signal into the optical signal through the phase modulator and transmits it to the optical mixer through the single-mode optical fiber. After the received signal light is mixed with the local oscillator light, the obtained quadrature branch controls the frequency of the local oscillator light through the frequency control system.

After a photoelectric conversion and differential processing are carried out by the balanced detector, the digital signal processing unit demodulates the signal, and the source is displayed on the computer as a video. After testing, the mixer can be used in coherent optical communication systems normally and can carry out long-term stable communication, which further verifies the function of the mixer.

Summary

This chapter systematically introduced the research status and progress of optical mixers and research results and compared the characteristics, advantages, and disadvantages of different structures and types. A high signal-to-noise ratio and

Fig. 29.25 Crystal optical mixer intermediate frequency signal test results

miniaturized, integrated, and high-stability optical mixers are still the goals pursued by researchers. They are also the future development trends of optoelectronic detector devices.

1. Coherent optical communication must continuously meet the rapid and normal communication needs of an information society, and continuously expand its own communication capacity and bandwidth. As a key component of a coherent optical communication system, the performance of the optical mixer is a key issue that must be solved.

   At present, coherent optical communication is concentrated in the C band and L band; thus, finding more communication bands has become a research hotspot for the next generation. The corresponding optical mixer should also be compatible with more bands, expand its bandwidth, and improve spectrum utilization, which are inevitable trends in the development of coherent optical communication.
2. Traditional optical mixers are mostly block and optical element structures, which are inconvenient for integration development. Therefore, the integrated development of optical mixers is an inevitable trend. Although the development of materials has promoted the integrated development of optoelectronic devices, there are still many challenges. The high capacity of new wave bands and the applicability of various high-order modulation formats should be adapted. Therefore, the integrated development of optical mixers is of great significance for developing new wave bands and realizing compact coherent light receivers.

   Existing optical modules are mainly based on silicon optical coupling technology, including optical mixers, and various transmit and receive optical devices. However, many problems in its development limit the communication capacity. The large waveguide loss and high insertion loss are problems to be solved. Therefore, improving the performance of silicon-based optical mixers is an effective way to further improve the communication capacity and solve current problems.

In the future, with the increasing integration of photons and the development of basic disciplines, such as material science and electronic science, both optical mixers and balanced detectors will eventually be integrated, through integrated technologies and more complex manufacturing processes, to establish high-performance photoelectric detection platforms.

Mixer research mainly focuses on two aspects. It improves the performance and reduces the signal-to-noise ratio by continuously designing new mixer structures, and it investigates the theoretical relationship between the various mixer parameters. With the continuous improvement of theoretical research work and the continuous emergence of new structures, mixer performance has made a huge leap and has been applied in many fields. As a key device in coherent optical communication, the mixer has received extensive attention and research. In the future, the exploration of new structures and improving the common mode rejection ratio and signal-to-noise ratio are still the goals of researchers.

The continuous optimization and improvement of photodetector devices will further promote the application and development of the coherent optical communication, photoelectric detection, and lidar fields. Coherent optical communication technology will further improve its communication capacity and communication quality, owing to the development of coherent optoelectronic devices, and better provide high-quality communication services for information societies.

Abstract

The working performance of an optical communication system is not only related to the light source, but also to its transmission medium. With the development of fiber optic technology and the pursuit of long-distance transmission in the field of optical communication, optical amplifiers have emerged. Optical amplifiers can directly amplify optical signals and have great application value in the field of communication. The basic principle and development of optical amplifier are reviewed in this paper. Firstly, the concept, classification types of optical amplifiers are introduced, including their working principles and performance. Then, the current situation of various types of optical amplifiers at home and abroad are analyzed. Finally,

Introduction

Optical amplifiers play an important role in optical communications by amplifying the signal light so that it can be adapted to various applications. In the field of fiber-optic communication, the continuous advancement in fiber-optic fabrication technology has led to a very low level of intrinsic loss in fiber-optic transmissions. However, the insertion loss of fiber-optic connectors and the intrinsic loss of long-distance transmissions lead to the attenuation of optical signals, which seriously restricts the transmission distance of fiber-optic communication systems. Therefore, it is important to study methods for amplifying optical signals without electrical relays.

Channel attenuation causes the optical signal to attenuate to an undetectable level after a certain transmission distance. Before optical amplifiers were invented, photoelectric and electro-optical conversions were typically used to amplify the optical signal. That is, after the attenuation of the optical signal was detected, it was converted to an electrical signal, shaped and amplified, reloaded to the optical wave, and allowed to continue to propagate.

The photoelectric conversion often decreases the signal-to-noise ratio. Optical amplifiers can directly amplify the attenuated signal light without the optical-electrical-optical conversion [1]. As fiber-optic communication technologies have developed towards long distances, high speeds, and large capacities, optical amplifiers have become an important development direction for future fiber-optic communication technologies.

Optical-Amplifier Classification

There are two types of optical amplifiers: fiber and semiconductor. Fiber amplifiers can be classified into various types, including erbium-doped, praseodymium-doped, and Raman amplifiers. In the 1550 nm wavelength range, the gain of the erbium-doped optical amplifier is the best, whereas in the 1310 nm wavelength range, the gain of the praseodymium-doped optical amplifier is the best. Raman amplifiers are typically used for distributed amplification.

Semiconductor optical amplifiers have received considerable attention because of their small size and easy integration; however, the polarization effect limits their commercial application.

Principle of Optical Amplifiers

An optical amplifier amplifies optical signals using the effects of excited radiation and optical amplification. The operating principle of an optical amplifier is similar to that of a semiconductor laser, in that both use a constant carrier leap to produce excited emissions to achieve a gain effect. Hence, the optical amplifier can be considered as a laser without an optical resonant cavity or an amplifier with feedback suppression from the resonant cavity [2].

In an optical amplifier, the optical signal is transmitted to the amplifier through an optical fiber or other transmission medium, processed by a series of optical components, and then enters the amplification medium. The amplifying medium is typically an optical fiber or semiconductor material doped with rare-earth ions (such as erbium, europium, neodymium, or terbium).

When the optical signal passes through the amplifying medium, the excited-radiation effect gives the photons emitted by the rare-earth ions in the amplifying medium the same frequency as the optical signal. As the emitted photons interact with the photons of the original signal, they amplify the optical signal and produce a gain effect [3]. In addition, the photons in the amplifying medium are affected by the light-amplification effect, thus increasing the photon energy and amplifying the light signal.

Specifically, optical amplification can be divided into three steps: first, the input optical signal is guided into a working medium doped with an exciter, such as an optical fiber or semiconductor. Next, the exciter converts the input optical signal into a set of photons with a photon energy greater than that of the input photons. Finally, these newly generated photons interact with the original photons, thus amplifying the input optical signal. The amplification effect of the optical amplifier is related to the dopant concentration, length of the fiber or semiconductor, wavelength, and other factors.

In summary, the principle of an optical amplifier is to amplify an optical signal using excited radiation and the light-amplification effect. Optical amplifiers are widely used in the fields of optical communications and sensing.

Erbium-Doped Optical-Fiber Amplifiers (EDFA)

Erbium-doped fiber amplifiers were the first commercially available optical amplifiers [4]. They are widely used and simple to construct [5]. They use a wavelength-selective coupler to mix a higher-power beam with an input signal that is significantly different in wavelength from the excitation light, and direct the mixed light into an erbium-containing fiber [6]. This high-energy beam stream is used to excite Er^{3+} to higher energy levels. When a signal with a wavelength different from that of the pump light collides with an excited Er atom, the Er atom loses energy and returns to a lower energy state [7]. An erbium-doped amplifier is a high-gain amplifier [8] that has the advantages of a high gain, wide bandwidth, low noise, and high output power.

Principle of the Erbium-Doped Fiber Amplifier

Erbium-doped fiber is formed by doping the core of a quartz fiber with the trivalent rare-earth metal erbium; Er^{3+} ions leap to higher energy levels under the action of a pump light. The radiation excited by the action of the signal light drops to the ground state and emits photons corresponding to the signal light as it does so [9]. This increases the number of photons, thus amplifying the signal [10]. The erbium-doped fiber-amplifier pumping process uses a three-energy-stage structure, the principle of which is shown in Fig. 30.1.

By injecting an extremely strong pumping light into the Er-doped fiber, more Er^{3+} can be transported from the ground state to the excited state, thus efficiently pumping the Er^{3+}. On this basis, electrons are rapidly transported from the excited state to the substable state. Because the erbium ion has a longer lifetime at a substable energy level, particle inversion can easily occur in this case.

In this process, the signal photon interacts with the doped rare-earth ions after passing through the doped fiber, resulting in excited radiation. This creates photons corresponding to the signal light on its surface, which leads to a sharp increase in the number of signal photons propagating through the fiber, thereby acting as a signal amplifier. When the signal light is amplified, the particles in the substable state enter the ground state via amplified spontaneous emission (ASE) [11]. This ASE is also amplified, which reduces the pump light and introduces noise [12].

When the power of the signal light and amplified spontaneous emission is low, the number of particles accumulated in the substable state is sufficient, and the gain can be maintained at a high level. When the pump-light supplement of substable particles

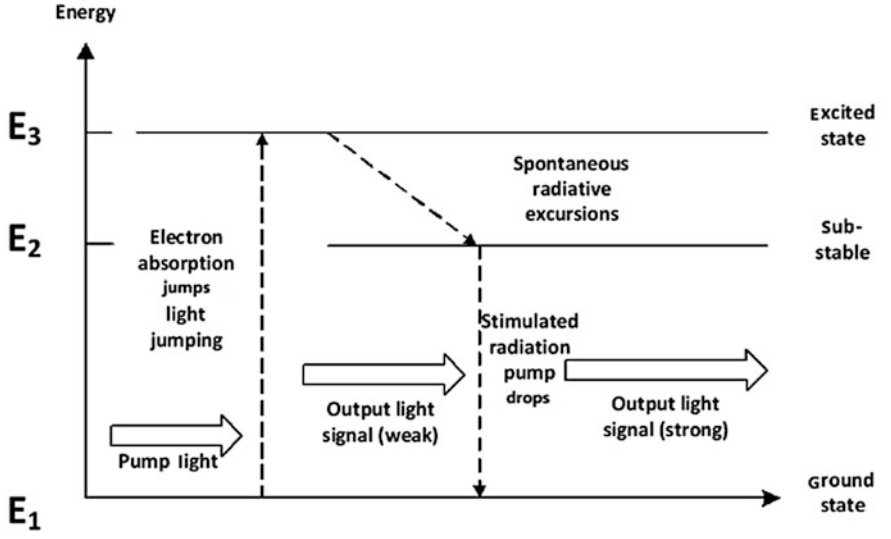

Fig. 30.1 Pumping process of an erbium-doped fiber amplifier

is insufficient to support the consumption of signal light and amplified spontaneous emission, the gain of the erbium-doped fiber amplifier drops and enters the amplification saturation state. Therefore, the suppression of ASE noise is an important direction in research on erbium-doped fiber amplifiers.

To amplify optical power, certain passive optical devices, pump sources, and erbium-doped fibers are combined into a specific optical structure to form an erbium-doped fiber amplifier. Figure 30.2 shows the optical structure of a typical erbium-doped optical fiber amplifier with a dual-pump source [12].

As shown in Fig. 30.2, the input-signal light is divided into two optical signals by the optical splitter. One goes to the photodiode (PD) light detector; the other passes through the fiber-optic isolator (ISO). It is then combined with the pump light emitted by the pump laser by the optical coupling element, and then passes into the erbium-doped fiber amplifier, which consists of two pump lights and two secondary pumps. Under the excitation of the pump light, the erbium-doped fiber amplifier amplifies the signal light, which then passes through the optical isolator and optical splitter and is output.

Features of Erbium-Doped Fiber Amplifiers

For erbium-doped fiber amplifiers, the amplifier gain is an important factor affecting the output performance; the amplification effect depends on the gain characteristics. The gain G of the erbium-doped fiber amplifier is $G = 10\ lg(P_o/P_i)$, which is the ratio of the output-signal optical power P_o to the input-signal optical power P_i.

The erbium-doping concentration in the fiber also significantly influences the gain. At an erbium-ion concentration greater than a certain value, the gain significantly decreases because too many erbium ions will polymerize and lead to concentration extinction; therefore, the concentration of doped erbium ions must be strictly controlled when preparing an erbium-doped optical fiber.

In addition to the concentration of erbium ions, the signal gain is closely related to the optical power of the pump. The relationship between the two is shown in Fig. 30.3. The gain coefficient of the system is greater for a smaller

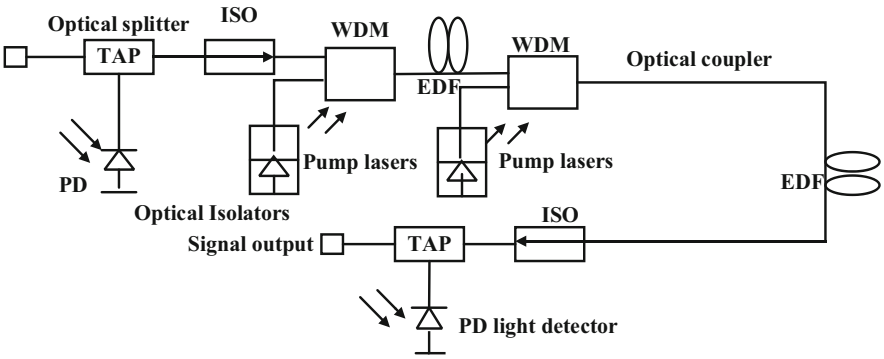

Fig. 30.2 Optical structure of an erbium-doped optical fiber amplifier [13]

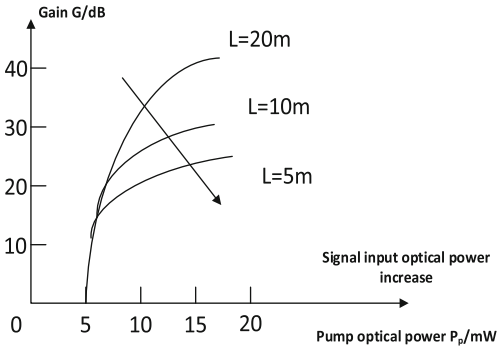

Fig. 30.3 Gain versus pump optical power [14]

input signal than for a larger input signal. Generally, when the gain is equal to 0, the optical power of the pump is called the threshold power P_{th}, whose expression is $P_{\text{th}} = AhP_p/BT$, where A is the effective area of action, h is Planck's constant, P_p is the pump optical power; B is the pump-absorption cross section; and T is the fluorescence lifetime (10^{-14} ms).

P_{th} is usually 5 mW. If $P_p = P_{\text{th}}$, the net gain is zero. When P_p continues to increase, G increases. The results show that in the initial stage, G increases rapidly and linearly with P_p. As P_p changes, G gradually decreases and eventually reaches the saturation region. When the pump optical power P_p has a ratio P_p/P_{th} greater than three, the gain of the amplifier tends to saturate [14]; that is, despite the increase in the pump optical power, the gain of the amplifier remains almost unchanged.

The gain of an erbium-doped fiber amplifier is also related to the length of the fiber. As the length of the Er-doped fiber increases, the gain tends to increase during the initial stage but decreases as the fiber length increases [15]. However, it should be noted that this length is only the length required to obtain the maximum gain, owing to other performance factors (e.g., noise performance).

Research Progress on Erbium-Doped Fiber Amplifiers

Research on doped fiber amplifiers began in 1962; however, owing to technological limitations, they were never implemented. In 1985, Mearas et al. introduced erbium-doped fiber-amplification technology, which began to develop rapidly and became a new research hotspot [16].

In 2012, Kang et al. from the University of Southampton, UK, theoretically demonstrated the characteristics of a step-refractive multimode erbium-doped fiber amplifier and simulated its single-mode gain of 20 dB and an intermodal-gain difference of 2 dB [17].

In 2013, Mahad et al. investigated gain flattening and obtained a gain flatness of 24 ± 0.29 dB in the range of 1546 nm–1558 nm [18].

In 2013, Jung et al. conducted an experimental study on the characteristics of a ring erbium-doped fiber. A two-signal mode gain was achieved in the experiment, and an average gain of 22 dB was obtained for a 3 dB intermodal-gain difference [19].

In 2014, Herbster et al. from the University of São Paulo, Brazil, chose a 180 mW LP11 pump light as the pump source and developed a new dual-ring Er-doped fiber. It obtained an average gain of 24.3 dB for four signal modes and a 0.6 dB intermodal-gain difference [20].

In 2015, Lecocq et al. proposed a novel fiber-design method based on a decreasing optimization method. They proposed a gain-equalization design method for microstructure-based erbium-doped fibers with few modes [21].

In 2015, Zhang studied the gain and noise of erbium-doped fiber amplifiers, based on the fiber mode-field theory, and reconfigured the spatial distribution of Er by adjusting the optical pumping structure to achieve a gain balance [22].

In 2016, Liu et al. conducted an experimental study on laser-amplification technology based on flat-plate waveguide lasers using flat-plate waveguide theory and laser-theory rate-dependent equations for flat-plate waveguide lasers [23].

In 2016, Yao et al. developed a novel erbium–ytterbium co-doped fiber amplifier using an auxiliary-cavity pumping technique and experimentally analyzed its spectrum, gain, and other performance metrics. A 17 W pump power was obtained in the 976 nm band, and 7.25 W was achieved in the 1550 nm band with a gain flatness of 0.12 dB for 100 mW of operation [24].

In 2017, Varona et al. constructed an erbium-ytterbium co-doped optical amplifier with continuous characteristics without amplified spontaneous emission, based on a main oscillating power-amplification structure. They replaced a 976 nm semiconductor laser with a 940 nm semiconductor laser, and obtained the highest laser-output power of 111 W at the central wavelength of the 1556 nm band with a 46.2% conversion efficiency [25].

In 2017, Savelii et al. of the *centre national de la recherche scientifique* (CNRS) optimized the glass composition of Er-doped alumina fibers, with Er ions in the fiber core layer, to incorporate a glass modifier [26].

In 2017, Liu proposed a novel low-noise and high-gain dual-way erbium-doped fiber amplifier, based on the theory of Er-ion excited amplification, and optimized its performance by numerical simulation [27].

In 2018, Zhang theoretically modelled a multiwavelength erbium-doped fiber amplifier based on the laser velocity equation and investigated its amplification performance and gain-balance performance [28].

In 2020, Lei et al. used values from a C-band light source to pump quartz fibers, with improved pumping efficiency compared to the conventional 1480 nm or 980 nm pumping modes, thus increasing the gain value in the L-band [29].

In 2021, Chen et al. from the Huazhong University of Science and Technology developed a Yb/Er co-doped fiber to improve its pumping efficiency by increasing the phosphorus content in the core to increase its maximum soliton energy. The core diameter of this fiber was 10 mm, the cladding diameter was 130 mm, and cladding absorption coefficient at 940 nm was 3.58 dB/m. The core absorption coefficient at

1535 nm was 34.5 dB/m. The laser slope efficiency at a 1.5 mm wavelength reached a maximum of 35.5%, with an output power of 2.5 W [30].

In 2021, Khudyakov et al. developed and tested a tapered erbium-doped fiber amplifier to achieve pulsed amplification with a high peak power. The core diameter was changed from 15.8 μm to 93 μm with a pump-to-signal conversion efficiency of 15.6% with a 1555 nm single-mode performance slope maintained along 3.7 m [31].

In 2021, Chen et al. developed a bidirectional erbium-doped fiber amplifier with low gain and low noise characteristics, based on a linear cavity structure, and obtained a gain factor of 15.52 dB and a noise factor of 3.25 dB [32].

In 2022, He et al. from the Huazhong University of Science and Technology successfully developed a new L-band quartz-based doped fiber using a modified chemical-vapor deposition method. They studied the effect of co-doped ions on the excited-state absorption characteristics of the material at the 4I13/2–4I9/2 energy level to establish single-stage forward-pumped and multi-stage optical-amplifier devices to study the broadband-amplification characteristics of the material.

Based on the forward 980 nm single-stage pumping structure, the gain reached 10.5 dB and the noise index reached 5.9 dB at a 9 dBm input signal power and a 530 mW pumping power at a 1629.3 nm wavelength. Using a multi-stage amplification structure, the gain of the fiber reached 27.4 dB at a 1629.3 nm wavelength [33].

Raman Fiber Amplifiers (RFA)

The structure of the Raman amplifier is similar to that of the erbium-doped fiber amplifier; however, because of the difference in the amplification medium, the output signal is amplified using the principle of Raman amplification. In contrast to other devices, such as erbium-doped fiber amplifiers and semiconductor optical amplifiers, the amplification of this device is based on a nonlinear interaction between the signal light and pump light. Raman fiber amplifiers use optical fibers, which have a simple structure, for nonlinear amplification [34].

A Raman amplifier is a fiber-optic amplifier that amplifies optical signals using the excited Raman-scattering effect [35]. In a nonlinear optical medium, the signal light at low frequencies interacts with the pump light at high frequencies to form a new signal light, and the excess energy is absorbed by the material in the form of molecular vibrations (i.e., photo-phonons), resulting in a jump between the two vibrational states. This process allows for the amplification of all-optical signals in the 1260–1675 nm range [36].

The pumped light can enter the transmission fiber along the same direction (isotropic pumping), in the opposite direction (reverse pumping), or be coupled in both directions (bidirectional pumping) [37], which yields an increased gain bandwidth of up to 6 THz [38]. Among these methods, reverse pumping is most common because of the reduced noise-transmission from the pump to the signal. These characteristics allow Raman amplifiers to be used in high-speed all-optical optical-communication systems.

Principle of the Raman Amplifier

A Raman fiber amplifier is an optical-signal amplification device based on excited Raman scattering in quartz fibers. It is achieved by simultaneously transmitting a weak signal and a strong pump light in the fiber in the Raman gain range of the pump light and amplifying the weak signal using the field of the excited Raman scattering effect.

Figure 30.4 illustrates the working principle of the Raman amplifier. The pump light is used to excite the electrons in the fiber so that they jump from low- to high-energy levels. On this basis, when the signal light is irradiated to its imaginary energy level, the electrons in its imaginary energy level emit Stokes photons to the higher-energy level of vibration. The rest of the energy is absorbed by the matter in the form of photo-phonons, causing the two vibrational dynamics to jump.

According to the law of conservation of energy, the internal energy of the molecules increases. This energy-transfer process is known as the Raman light-amplification process. A high-frequency pump light produces nonlinear scattering in the transmission medium, such that its incident light produces a Stokes frequency shift. The size of the shift depends on the vibrational energy level of the molecule, the amplitude of which determines the frequency range of the excited Raman scattering.

The Raman amplifier has a wide gain bandwidth, and with an increase in pump power, the amplifier's Raman gain also increases. However, the pump power cannot be increased indefinitely; if the pump power is transferred to the signal light, the resulting loss is large and will result in a gain saturation [39].

Features of the Raman Amplifier

The Raman amplifier has the following characteristics:

1. The gain wavelength is related to the pump wavelength. Theoretically, the signal can be amplified in any wavelength range when an appropriate pump source is selected. Using this method, a gain bandwidth can be obtained from multiple

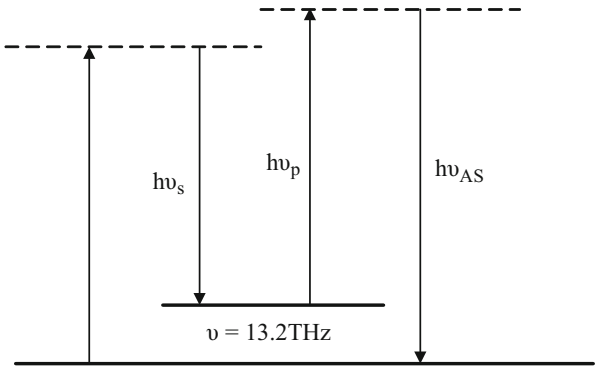

Fig. 30.4 Raman energy-level diagram of fiber-optic molecules

pump-light sources that is much larger than that of an erbium-doped fiber amplifier.
2. No other amplification medium is required because the gain medium is the transmission fiber itself. Thus, for those who find setting up repeaters inconvenient, fiber-optic communication systems have good application prospects.
3. Good noise performance. The signal power in the fiber is relatively small, regardless of the location. For ultralong-distance transmissions, Raman amplifiers are typically used in high-digit systems over kilometers to ensure a good signal-to-noise ratio.

Research Progress on Raman Amplifiers

In 1928, Raman experimentally discovered Raman scattering, where light waves changed their frequency when subjected to Raman scattering. Since this discovery, scientists have been studying Raman scattering [40].

In the 1960s, Koester of the United States suggested that rubidium-doped optical fibers could be used as optical-amplifier materials.

In 1972, Stolen et al. observed excited Raman scattering and the excited Raman effect in optical fibers and provided experimental results. Since then, scientists worldwide have studied optical-fiber communications based on excited Raman scattering [41]. However, erbium-doped fiber amplifiers received widespread attention because they accelerated the practical application of wavelength-division multiplexing (WDM) technology and adapted to the social needs of the time. After the 1990s, with the development of multichannel optical-amplification technology, erbium-doped fiber amplifiers were gradually restricted, and Raman fiber amplifiers reemerged.

In 1985, Aoki et al. first applied Raman amplifiers to fiber-optic communication systems to enable the transmission and amplification of light signals [42].

In 2002, Perlin et al. proposed an effective amplifier design scheme to optimize the gain and gain bandwidth of a multi-wavelength pumped Raman fiber amplifier. Compared with unoptimized Raman amplifiers of milliwatt magnitude, the gain flatness of this scheme was greatly improved. A gain spectrum with an 83 nm bandwidth and 0.05 dB flatness was obtained [43].

In 2003, Mori et al. used a 250 m tellurium-based fiber with a high Raman-gain coefficient and a four-wavelength channel laser as the pump source to achieve a Raman-gain spectrum with a 160 nm bandwidth, and a gain of more than 10 dB via bidirectional pumping [44].

In 2004, Wang et al. of Southeast University, China, used a 60 km-long general-purpose single-mode fiber as the gain medium in an experiment, and obtained a 18.5 dB average switching gain and 1.5 dB flatness for each channel by controlling the pump light from five reverse-pump sources [45].

In 2005, Varshney et al. used a multi-clad photonic-crystal fiber (PCF) with a 5.2 km length and a single 1450 nm pump source with a 520 mW power to obtain a

Raman-gain spectrum with an average net gain of 19 dB and a gain flatness of ±1.2 dB in a 30-nm bandwidth [46].

In 2006, Yan et al. used a genetic algorithm to optimize the wavelength and power of a Raman amplifier in backward pumping mode and obtained five optimal pumping wavelengths and powers. A distributed Raman-amplification system used a dispersion-shifted fiber with a 100.8 km gain medium and seven lasers in five wavelength ranges as pump sources. It obtained Raman amplification with an average gain of 15.55 dB and 0.87 dB over a bandwidth of 1520–1610 nm [47].

In 2008, Sperti et al. used a three-wavelength backward-pumping structure to optimize the pumping power using a hybrid genetic algorithm (combining a genetic algorithm and a simplex method). They found that the maximum difference between the experiment and simulation for the three channels was only 0.15 dB, when the preset signal optical gain was 7 dB in the test [48].

In 2009, Castellani et al. developed a low-flatness, high-gain, and low-loss photonic-crystal fiber Raman amplifier. This amplifier obtained Raman amplification in the C-band with an average gain of 8.5 dB and an average gain of 0.71 dB, using only two low-power pumped lasers [49].

In 2014, Singh et al. used a genetic algorithm to optimize the Raman-amplifier pump power in a wavelength-division multiplexing system with 320 channels spaced at 25 GHz intervals, and showed that the gain flatness of the Raman amplifier was less than 0.5 dB [50].

In 2017, Zhang et al. of the Harbin Institute of Technology used a new photonic-crystal optical fiber, optimized its structure, and reduced the Raman-gain flatness to less than 1 dB using one pump source [51].

In 2020, Tan et al. used a field-programmable gate array (FPGA) to control an eight-bit digital-to-analog converter (DAC) chip to provide the drive signal for a Fabry-Perot fiber tunable filter. It scanned in the 1532 nm–1567 nm band, and fed the detection results to the control terminal, thus achieving a tunable laser output [52].

In 2021, Song et al. developed a Raman optical amplifier based on the Yb band using a random fiber laser. By optimizing the random-fiber laser linewidth, a 3-dB output with a spectral linewidth of only 0.23 nm at a 100-W output power was achieved [53].

In 2022, Yao et al. of the National University of Defense Technology (NUDT), China, obtained the highest-power Raman-laser output of 373 W using spectral-synthesis techniques to enhance the pump-source brightness through laser-diode (LD) direct-pump Raman-amplifier research. The output-signal optical power was 373 W at a pump power of 544 W. The remaining pump light was 157 W, corresponding to an efficiency of 67.2% for light–light conversion [54].

In 2022, Gong of the Xi'an University of Posts and Telecommunications used a tellurium-based fiber as the transmission medium. Based on this, a second-order Raman-fiber amplifier consisting of two second-order pumps and four first-order pumps was proposed, which could be used to amplify the signal light in the C + L band. The second-order tellurium-based Raman fiber amplifier had an average

output gain of 31.3601 dB and a gain flatness of 0.6601 dB at an ultrahigh bandwidth of 1530–1630 nm [55].

Semiconductor Optical Amplifiers (SOAs)

A semiconductor optical amplifier generates gain through a semiconductor medium. The structure of the semiconductor optical amplifier is illustrated in Fig. 30.5. This amplifier is similar in structure to a Fabry-Perot excitation diode but with an anti-reflection element at its end. Because this causes the cavity to consume more power than its gain, it does not allow the amplifier to function as a laser. Another type of semiconductor optical amplifier consists of two parts. One is a Fabry-Perot semiconductor laser, and the other is a cone-type laser for reducing the power density of the output surface.

Currently, semiconductor optical amplifiers are primarily manufactured from Group II-VI GaAs/AlGaAs, InP/InGaAs, InP/InGaAsP, InP/InAlGaAs, and other semiconductors with Group II-VI structures. The amplifiers are generally used in communication systems, which operate at a wavelength of 0.85–1.6 μm, and their gain can reach 30 dB.

Semiconductor optical amplifiers have the advantages of miniaturization, electrical pumping, lower cost, and integration with other devices. They have high noise, small gain, low polarization correlation, high nonlinearity, and a fast transient response. The biggest advantage of semiconductor optical amplifiers is that they have four types of nonlinear effects (cross-gain modulation, cross-phase modulation, four-wave mixing, and polarization rotation). Their nanosecond state life gives their gain a fast response to changes in pump-light or signal-light intensity and also produces phase changes.

In addition, SOAs can operate at low laser power. Although the nonlinear effect is currently the biggest challenge in the field of fiber-optic communication, it also

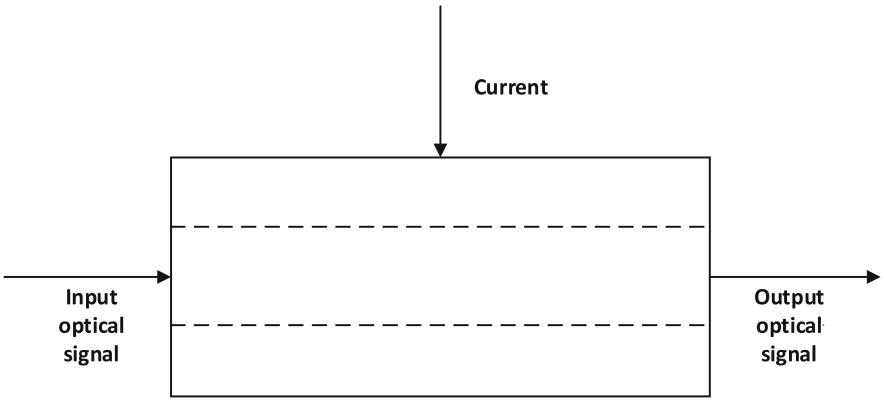

Fig. 30.5 Semiconductor optical-amplifier structure diagram [56]

offers the possibility of realizing wavelength bands different from those of erbium-doped fiber amplifiers. In recent years, some scholars have developed "linear optical amplifiers" using gain-clamping techniques.

Owing to their highly nonlinear characteristics, SOAs have great potential for applications in all-optical switching and wavelength conversion. Semiconductor optical amplifiers are core devices for optical signal processing, wavelength conversion, and other functions, and have a wide range of application prospects.

SOAs have a small size, high gain, and wide bandwidth, and can realize ultra-high-speed optical-pulse amplification at the picosecond level and output-signal amplification. SOAs have a variety of nonlinear characteristics that can convert signals between multiple wavelength bands in all-optical communication systems and can add multiple converters to optical networks. They are closely related to the development of wavelength-division multiplexing technology.

Principle of Semiconductor Optical Amplifiers

The difference between a semiconductor optical amplifier and a rare-earth-doped fiber amplifier is that the former's light-emitting medium is not a rare element but electron–hole pairs. The SOA is a new type of optical amplifier based on the mechanism of light amplification by excited radiation.

On this basis, a current simultaneously injects electrons and holes into the excitation region so that the electron–hole pairs in the excitation region produce a particle inversion, which results in a stronger light from the electron–hole pairs in the excitation region. When a semiconductor amplifier with light input power is considered, as shown in Fig. 30.6, the light input power is set to P_{in} and its output power to P_{out}; the output can be expressed as follows [57]:

$$P_{\text{out}} = P_{\text{in}} \times xp(agL), \tag{30.1}$$

where a denotes the proportion factor by which the light energy transmitted in the activation zone is suppressed [58].

Classification of Semiconductor Optical Amplifiers

Semiconductor optical amplifiers can be classified into two types. One is a normal semiconductor laser. The second uses an antireflection film on the two end faces of a Fabry–Perot (F-P) laser, which achieves broadband, high output, and low noise [59].

The multiple reflections generated by the semiconductor laser at the Fabry–Perot resonant-cavity junction are referred to as the F-P resonant cavity. As can be seen in Fig. 30.7, the incident light enters from the left end and passes through the active layer before reaching the right end. Some of the light is reflected back through the active layer, reaches the left end face, is amplified, and part of it exits from the left

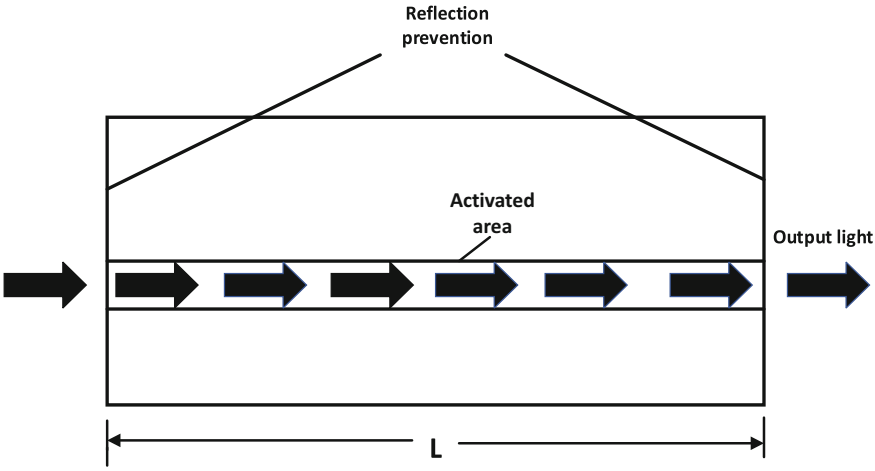

Fig. 30.6 Semiconductor optical amplifier

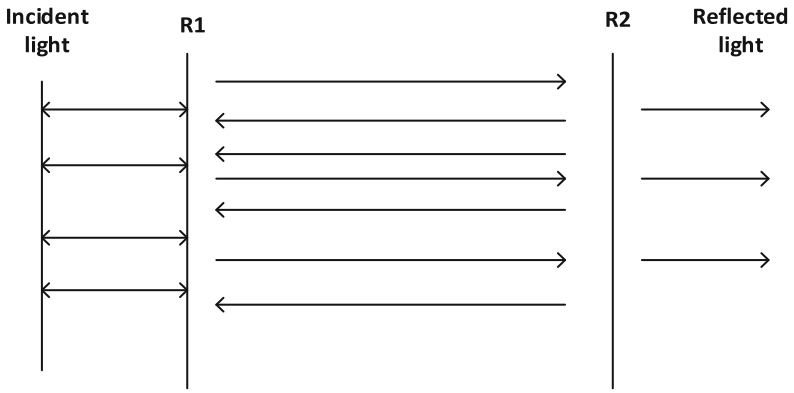

Fig. 30.7 Operating principle of an F-P semiconductor optical amplifier

end face. The remaining part is reflected from the left end face and passes through the active layer again, thus obtaining the amplification effect [60].

The device uses a Fabry–Perot resonant cavity to effectively modulate the optical signal. However, unlike semiconductor lasers, the light wave passing through a semiconductor optical amplifier is a traveling wave. This is because semiconductor optical amplifiers do not have resonant cavities or produce reflections. The operating principle of a traveling-wave semiconductor optical amplifier is shown in Fig. 30.8 [61].

In a semiconductor optical amplifier, the forward-injected current supplies carriers to the active region; when the injected current reaches a certain value, a particle-

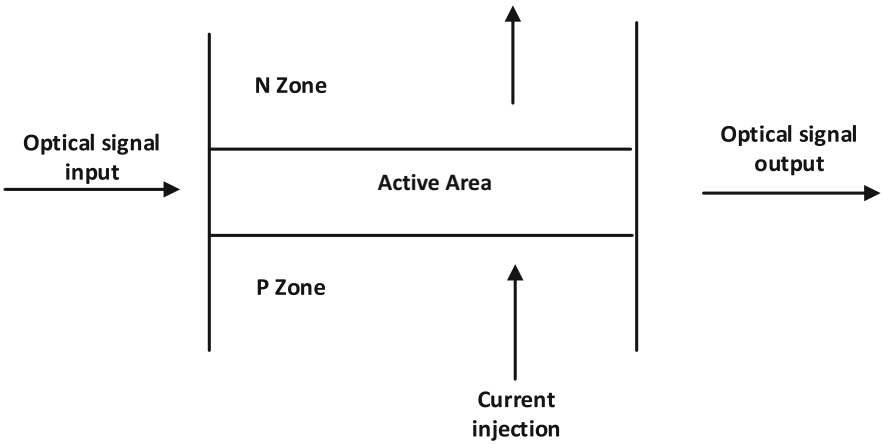

Fig. 30.8 Schematic diagram of a traveling-wave semiconductor optical amplifier

number flip occurs in the active region. If an optical signal is injected, the carriers in the semiconductor optical amplifier will be excited to produce photons. Because the light emitted by its excitation is the same as the surrounding light—that is, it has the same phase, polarization, and other information—the light can be amplified. The essence of semiconductor optical amplifiers is the interaction between photons and electrons in semiconductor materials. The higher the injected current, the higher the number of photons produced [62].

Characteristics of Semiconductor Optical Amplifiers

When the input signal is weak, the gain of a semiconductor optical amplifier is mainly manifested as amplified spontaneous emission; the power gain at this time is very low. When the input signal is sufficiently weak, its gain will rise sharply with the increase in current. At this time, the semiconductor optical amplifier works in the linear zone; i.e., its gain and the input signal are in a linear relationship. As the input signal increases, the gain flatness of the SOA gradually increases; however, the gain changes more slowly and approaches saturation.

In addition, the gain-saturation problem in semiconductor optical amplifiers has not attracted sufficient attention. When the input signal is constant, the gain of the semiconductor optical amplifier increases with the injection current; however, within a certain range, the gain decreases instead of increasing. This saturation is caused by the limitation of the carrier gain-recovery time [63].

The polarization characteristics of a semiconductor optical amplifier are primarily reflected in its sensitivity to the polarization state of the input signal light, and the gain of the signal light differs for different polarization states.

Research Progress on Semiconductor Optical Amplifiers

Semiconductor optical amplifiers have been investigated since the invention of semiconductor lasers in 1960 and the development of double-heterojunction devices in 1970 [64].

In 1970, Panish et al. prepared by solution epitaxy a double-heterostructure AlxGa1xAs–GaAs–AlxGa1xAs injected semiconductor laser with a room-temperature threshold as low as 2300 A/cm^2 [65].

In 1973, Zeidler et al. investigated the application of optical amplifiers in fiber-optic communication systems, where they could act as analog repeaters between regenerative repeaters in hybrid digital–optical communication systems [66].

In 1986, researchers began investigating InGaAsP semiconductor optical amplifiers because of the low loss of optical fibers at 1310 and 1550 nm. Broadband traveling-wave semiconductor optical amplifiers at 1500 nm were studied, analyzed, and further developed by Saitoh et al. [67].

In the 1990s, Mork et al. proposed a model for semiconductor optical amplifiers that included the local-carrier concentration and incorporated the temperature characteristics of carriers. This allowed better simulation of in-band effects, such as spectral hole-burning and free-carrier absorbance [68].

Since the 1990s, along with the continuous improvement of the semiconductor-technology level, research on semiconductor optical amplifiers has increasingly improved, especially with the progress of strain quantum wells and superlattice technology. Their application scope and performance were developed, especially in terms of the minimum signal gain, maximum output power, and signal-to-noise ratio index [69].

In 1990, Eisenstein et al. prepared a multi-quantum-well optical amplifier in the 1550 nm band and analyzed its size signal-gain characteristics [70].

In 2001, Connelly et al. established a steady-state model for semiconductor optical amplifiers, providing a broadband model of SOA gain. It was characterized by considering the relationship between the wavelength variation and gain [71].

In 2007, Liu et al. proposed the Hakki–Paoli direct-detection (HP-DD) algorithm, based on wavelet noise reduction and deconvolution. The results of this project helped to improve the measurement accuracy of the gain-coefficient spectrum of SOAs and reduce the influence of factors, such as instrument resolution and system noise, on the measurement accuracy. The simulated real spectra were obtained using a numerical-simulation process at resolutions of 0.05 nm, 0.1 nm, and 0.5 nm [72].

In 2011, Yu et al. conducted a study on all-optical logic devices based on cross-gain modulation for quantum-dot SOAs. Since quantum-dot semiconductor optical amplifiers have a fast gain-effect extraction property, their repair process can be accelerated by reducing the minority-carrier repair time, either by increasing the injected voltage or by decreasing the chirality period between the carriers from the wetted layer to the excited state [73].

In 2013, Ehsan et al. investigated the relationship between a tapered waveguide quantum-dot semiconductor optical amplifier and gain and cross-gain modulation;

the active region of a quantum-dot semiconductor optical amplifier has a tapered structure; therefore, the carrier-concentration distribution in the active region increases gradually with the direction of light propagation. Therefore, the gain and cross-gain modulation efficiency are improved [74].

In 2015, Matsumoto et al. used a strain-compensation method to prepare a 155 nm-band multilayer quantum-dot SOA to study the fundamental gain and femtosecond optical impulse response of this SOA. They laid the foundation for applying this semiconductor optical amplifier to ultrafast all-optical logic devices [75].

In 2016, Kotb et al. enabled all-optical logic with heterodyne gates, based on quantum-dot semiconductor optical amplifiers, to achieve an operating rate of 1 Tbit/s with a high output performance [76].

Recent Advances in Quantum-Dot Semiconductor Optical Amplifiers (QDSOA)

In 2017, Yang et al. conducted a theoretical and experimental study of cross-gain modulated/cross-phase modulated quantum-dot all-optical wavelength conversion, based on quantum-dot semiconductor amplifiers. They systematically investigated the photoelectric-conversion efficiency of cross-gain modulated/cross-phase modulated photonic-crystal wavelength-conversion devices by combining theory and experiments. Simulation results showed that reducing the input pulse width, decreasing the loss coefficient, shortening the leap time, increasing the length of the active region, and increasing the gain could improve the conversion efficiency of the wavelength converter [77].

In 2020, Mi et al. studied the cross-gain-modulated wavelength conversion and cross-phase-modulated wavelength conversion of quantum-dot semiconductor optical amplifiers. They conducted an in-depth study on the extinction ratio, Q-factor, and conversion efficiency of the method, and compared the method with existing cross-gain modulation and cross-phase modulation [78].

In 2022, Li et al. conducted a systematic study of the wavelength-conversion characteristics of photonic crystal-based quantum-dot SOAs under different external-field conditions using theoretical calculations, experimental tests, and numerical simulations. The results showed that the performance of photonic crystal-based quantum-dot SOAs was superior to that of quantum-dot SOAs [79].

Recent Advances in Reflective Semiconductor Optical Amplifiers (SOA)

In 2017, a new design idea for a gain-saturated reflective quantum-dot semiconductor optical amplifier was proposed by Yin et al. With appropriate parameter settings, the 3 dB cut-off frequency of the reflective quantum-dot semiconductor optical amplifier was expected to exceed 10 GHz [80].

In 2020, Deng et al. modelled and simulated a reflective semiconductor optical amplifier; when the bias current exceeded 130 mA, the gain of the reflective SOA remained above 26 dB and the noise figure remained at 11 dB. When the bias current was constant, the reflective SOA could still reach the optimal operating range at a low input power of −30 dBm [81].

In 2020, Rizou et al. experimentally demonstrated the feasibility of using birefringent fiber rings to enhance the efficiency of semiconductor optical amplification. A birefringent fiber ring is an optical filter that inverts the electro-optical characteristics of a reflective semiconductor optical amplifier. It can effectively eliminate the modulation bandwidth of a reflective SOA, limiting it in practical applications. By suitably adjusting its detuning, the birefringent fiber circuit can modulate the physical spectral composition, owing to the fiber detuning [82].

In 2021, Mukherjee et al. first used gain dynamics based on a reflective semiconductor optical amplifier to design and analyze a logical gate using Arcon pulses. The simulation results showed that the gate had efficient performance ($Q > 80$ dB) with low hardware complexity. The logic gate had an extinction ratio of approximately 14 dB, contrast of approximately 15 dB, and Q of approximately 90 dB. The effect of amplified spontaneous emission noise was also investigated. The logic gate used a single reflective semiconductor optical amplifier and can be used in the future design of any optical logic processor [83].

Summary and Outlook

Summary

Optical amplifiers have evolved rapidly over the past few decades and have become major components in today's communication networks. Optical amplifiers have attracted considerable attention in both academia and industry. They will become important components of future all-optical communication systems. With the continuous progress of optical wavelength-division multiplexing technology, the amount of data transmitted in optical fibers will become increasingly large, which means that the future development direction of optical-fiber communication is to achieve all-optical communication.

The invention of optical amplifiers, on this basis, has promoted the development of optical-fiber communication technology and organically combined it with the future development of new equipment and technology. It is expected to gradually develop in an all-optical direction.

Outlook

As one of the most important technologies in optical communication, optical amplifiers have a promising future development. Future development of erbium-doped fiber amplifiers will likely start from the following points.

1. Research on new highly doped fibers compatible with silicon-based fibers is important for high-power erbium-doped fiber amplifiers.
2. Research on new co-band high-power pump lasers is expected to be a key technical means of reducing the power output of erbium-doped fiber amplifiers.

3. Investigating new gain-flattening treatments is expected to broaden the range of bands amplified by erbium-doped fiber amplifiers in photoacoustic-spectroscopy detection systems.

Further developments in Raman fiber amplifiers could include the following:

1. Researchers should investigate the output gain characteristics of Raman fiber amplifiers with a high-order pumping structure.
2. Higher pumping-power mechanisms should be investigated to obtain higher-power pumping for Raman fiber amplifiers.

The future development of semiconductor optical amplifiers could start from the following points:

1. Research on the effects of the polarizability, end-face reflectivity, and carrier temperature of semiconductor optical amplifiers on wavelength conversion.
2. Research on monolithic integration technology for semiconductor optical amplifiers and other devices.
3. Research on reducing the optical-signal gain saturation.

Abstract

Due to the advantages of high speed, low latency, and high confidentiality, underwater optical wireless communication (UOWC) has become the main means of underwater wireless communication. In recent years, this technology has developed rapidly, and the technical requirements for UOWC systems have also become increasingly high. This article provides a brief summary of the models and research status of the UOWC system, focusing on the key technologies used in the UOWC system, including the selection of light sources, modulation and coding, detection, channel modeling, and other key technologies. It also elaborates on the influencing factors and modeling of the theoretical channel model of UOWC. Finally, it summarizes the future development trends and challenges faced by UOWC for achieving long-distance underwater

Introduction

Underwater optical wireless communication uses light as a carrier to transmit information. Its advantages include a high communication speed, small time delay, good security, and low cost. In recent years, researchers have conducted extensive research on key technologies in underwater optical wireless communication systems, including modulation and coding, detection, light source selection, and channel model establishment.

With the development of the Internet and the arrival of the 6G era, optical wireless communication combined with the Internet for ocean exploration is bound to be a future development trend. The study of key technologies in underwater communication will provide methods and technologies for future ocean exploration.

Underwater Wireless Communication

Ocean exploration requires real-time high-speed communication to transmit audio, image, and video information. Traditional communication uses wired technology, such as optical fibers and cables, to transmit information. However, cable communication is significantly affected by the underwater environment, and its construction difficulty and mobility are particularly poor. Moreover, it is very difficult to maintain and its cost is high.

Therefore, in recent years, wireless communication has been used in underwater communication systems to overcome the shortcomings of cable communication. Underwater wireless communication enables ocean exploration and is attracting increasing attention from researchers. Underwater wireless communication includes acoustic, radio frequency (RF), and optical communication [1].

Acoustic Communication

Sound waves are mechanical waves, and their attenuation in water is very small. Therefore, the transmission distance of sound waves in water is relatively long. Currently, acoustic wave technology for underwater wireless communication is more mature and also the most widely used.

Acoustic communication was first used in the military. In 1945, after the Second World War, the United States used sound waves to communicate in submarine systems; therefore, underwater acoustic communication rapidly developed [2]. Russia attached great importance to the development of aircraft carriers and invested considerable energy and financial resources in underwater submarine communication. The "God of the North Wind" submarine was Russia's military support [3].

With the continuous progress and development of science and technology, acoustic communication has been widely used in civil areas, such as monitoring underwater environmental pollution and underwater information collection. Digital signal processing technology has also been applied to underwater acoustic communication. Underwater acoustic communication uses sound waves as the communication carriers. After decades of development, the performance of underwater acoustic communication has stabilized [4].

Because the transmission speed of sound waves in seawater is related to the depth, temperature, salinity, etc., with increasing depth, the change in seawater temperature bends the sound waves. At a certain depth, upward divergent sound waves bend downward and the downward divergent sound waves bend upward. Therefore, sound waves oscillate back and forth near a certain depth, which is called the deep sea acoustic channel [4]. At this depth, acoustic energy transmissions are similar to laser transmissions in optical fiber, with minimal loss; therefore, they can be detected by sonar at a very long range. This is where the 550-km transmission distance was achieved by the United States.

The US Sound Surveillance System (SOSUS) sonar array on the seabed used the deep sea acoustic channel to detect enemy submarines thousands of kilometers away [5]. However, the depth in the South China Sea is approximately 1100 m, whereas in the Mediterranean and temperate Pacific, the depth of the acoustic axis is within the range of 100–300 m. In the Arctic Ocean, the acoustic axis is close to the sea [6]. However, the submarine is less than 1000 m deep; thus, its utilization value is very small [7].

Another underwater acoustic effect is that of the underwater acoustic convergence zone. Because sound waves bend underwater, waves emitted from shallow waters will focus at a distance of 35 km, which is called the first convergence area. They will focus again at 70 km, after being reflected by the sea surface; this is called the second convergence area. The third convergence area is at 105 km. Sound waves are very confused at this point, so there is generally no fourth convergence area [8].

The main problems of long-distance underwater acoustic communication are that the channel is complex and changeable, the noise interference is high, and the signal bandwidth is limited. Therefore, the communication rate is low [9]. In 2005, Northwest Polytechnical University conducted an underwater acoustic communication experiment with a 20-bit/s signal communication rate, 80 km from the coast [10]. In 2013, the joint research team of the US Navy and Marine Corps conducted an underwater acoustic communication experiment with a received signal communication rate of 6.5 bit/s at a distance of 550 km from the coast [9].

In addition, a team from the University of California, San Diego, United States, used orthogonal frequency-division multiplexing technology to achieve underwater

acoustic communication with a signal communication rate of 15 bit/s, 550 km from the coast, and 7.5 bit/s, 700 km from the coast [11]. Later, after improving the underwater communication system, the team finally conducted an underwater acoustic communication experiment with a signal communication rate of 50 bit/s at a location 550 km from the coast [12].

Acoustic communication is affected by underwater noise, salinity, and water pressure, among other factors. Most communication systems only use acoustic waves to transmit voice signals, which cannot adapt to complex battlefield conditions and are easily detected by enemy sonar detectors. Therefore, at present, underwater acoustic communication can only be used as an auxiliary communication means [13].

The underwater transmission time delay of acoustic waves is relatively large, and the communication rate can only reach the order of kbit/s [14]. In short-distance transmissions, the frequency of the acoustic wave is 50 Hz, and the communication rate can reach 100 kbit/s. In medium- and long-distance transmissions, the communication rate can reach 50 kbit/s when the acoustic frequency range is 50–100 Hz. For long-distance transmission, the communication rate can only reach 10 kbit/s [15] when the acoustic frequency range is 100–1000 Hz.

Underwater acoustic communication also has a large time delay, which is harmful to marine organisms [16]. Acoustic communication can easily be overheard and has poor confidentiality. The system equipment is bulky and consumes considerable power. Thus, it cannot meet the small size and low-power consumption requirements for underwater communication [17].

Radio Frequency Communication

The penetration ability of an RF signal in water is related to the RF signal frequency. The transmission distance of a 30–300-kHz signal in water is several meters, that of a 3 Hz–30 kHz signal in water is 10–20 m, and that of a 30–300-Hz signal in water is 100–200 m [17]. Currently, extremely low-frequency (ELF) and very-low-frequency (VLF) long-wave radio stations use RF signals for underwater communication. Relevant radio communication equipment has been established mainly in the United States, Russia, the United Kingdom, France, and other countries.

The US Navy built a number of long-wave radio stations for one-way underwater communication. In 1953, the Jim Creek VLF long-wave radio station was used for one-way underwater communication by Pacific Navy submarines. The radio call sign was NLK, the frequency was 28.8 kHz, and the output power was 1.2 MW [18]. In 1960, the Cutler VLF long-wave radio station in Maine was used for one-way communication between Atlantic submarines. The radio station call sign was NAA, the frequency was 24 kHz, and the output power was 1.8 MW [19].

In 1997, the LaMoure VLF long-wave radio station built in North Dakota was transferred to the US Navy for submarine communication. The radio station call sign was NML, and the frequency was 29.2 kHz [20]. In 1972, the Lualualei VLF long-wave radio station built in Hawaii served the US military in the Pacific theater, with

the call sign of NPM and frequencies of 24.4 kHz and 31.4 kHz [19]. The Harold E. Holt VLF long-wave radio station, located on the northwest coast of Australia, was used for surface and underwater ship–submarine communications in the Western Pacific Ocean and East Indian Ocean. The radio station was jointly used by the United States and Australia. Its call sign was NWC, and the frequency was 21.8 kHz [21].

The call sign of the Aguada, Puerto Rico, low-frequency long-wave radio station built by the US Navy was NAU, and the frequency was 40.75 kHz [22]. The call sign of the Keflavik, Iceland, low-frequency long-wave radio station was NRK, and the frequency was 37.5 kHz. The call sign of the Sigonella, Italy, low-frequency long-wave radio station was NSY, and the frequency was 45.9 kHz [23].

The VLF long-wave radio stations in Russia were mostly alpha navigation-base stations and beta time service stations. The call signs of the VLF long-wave radio stations used in the Russian navy were RSDN, RDL, and RJH, and the corresponding frequency parameters were 11.91 kHz, 31.2/24.1 kHz, and 25 kHz, respectively [23].

The British Anthorn long-wave radio communication station was located in Cumbria, England. Anthorn's VLF long-wave radio call sign was GQD, and the communication frequency to submarines was 21.6 kHz. Anthorn was one of the four VLF long-wave radio stations in the North Atlantic Treaty Organization (NATO). Anthorn's low-frequency long-wave radio is part of the British National Physical Laboratory. Its main function is to provide time service. The call sign of the radio is MSF with a 60-kHz frequency and 17-kW power [18]. In 2001, Skelton, England's very-low-frequency long-wave radio station was mainly used to send coding instructions to submarines. Its call sign was GBZ, and its frequency was 21.58 kHz [22].

France's very-low-frequency long-wave radio transmitter in Rosnay is an antenna system composed of 13 antenna poles. The central antenna pole is the highest at 357 m. The inner circle is composed of six 310-m-high antenna poles, and the outer circle is composed of six 270-m-high antenna poles. The call sign of the radio station is HWU, with frequencies of 15.1 kHz, 31.9 kHz, and 24.7 kHz [22].

The Norwegian Noviken VLF long-wave radio has a call sign of JXN and a frequency of 19.4 kHz. The Rhauderfehn VLF long-wave radio station in Germany has a call sign of DHO38 and a frequency of 31.4 kHz. These two types of long-wave radio stations are part of a submarine broadcasting system operated by NATO [24]. The Grimeton VLF long-wave radio in Sweden provides encrypted communication services for the Swedish Navy. The call sign of the radio station is SRC, and the frequency is 40.4 kHz. The radio station also has a channel with a call sign of SAQ and frequency of 19.2 kHz [25]. In 1976, Iceland's Grindavik VLF long-wave radio station was successfully built. In addition to VLF radio communication, stations can also achieve short-wave radio communication. The call sign of the station is TFK, and the frequency is 37.6 kHz [26].

The call sign of the Ebino VLF long-wave radio station in Miyazaki, Japan, is JJI, and the frequency is 31.2 kHz. The call sign of the Awase low-frequency long-wave radio station in Okinawa, Japan, is NDI with a 54-kHz frequency [26]. The call sign

of the Mokpo VLF long-wave radio station located in southwest South Korea is UNID25, with a frequency of 25 kHz [26].

India built VLF long-wave radio stations in Mumbai and south Tamil Nadu. The VLF long-wave radio station in Mumbai has been closed, whereas the VLF long-wave radio station in south Tamil Nadu is still in operation. The call sign of the radio station is VTX3, and the frequency is 18.2 kHz [25]. The Karachi VLF long-wave radio in Pakistan is used for submarine communication in the Pakistani Navy. The radio call sign is PNSH, and its frequency is 14–29.2 kHz [22]. Argentina's Monte Grande VLF long-wave radio is used for Argentine naval communications. The radio is composed of eight 210-m-high and two 219-m-high antenna poles. The call sign of the VLF long-wave radio is LPZ, and the frequency is 19.33 kHz [27].

In 1968, the Sanguine project, an extremely low-frequency long-wave radio station in the United States, was planned. However, the project needed to occupy nearly two-fifths of the area of Wisconsin, and it would be difficult for the huge antenna array planned by the project to survive under a nuclear attack. Finally, this project was not implemented [28].

The SHELF project was a deeply buried ELF communication system. It was closely followed by the SEAFARER project, which was a shallow-buried ELF antenna surface communication system. The two schemes were ultimately not implemented for various reasons [29]. The final implementation was Project ELF, which consisted of two sites located 148 miles apart in Wisconsin and Michigan, with an antenna array on the ground. The project was implemented in 1989, with a working frequency of 76 Hz and a standby frequency of 45 Hz. Because it was too large, vulnerable to fatal attacks, and local residents protested, the US Navy closed the only extremely low-frequency long-wave radio communication station in the United States in 2004 [28].

The frequency of the Russian ZEVS ELF long-wave radio is 82 Hz, and the output power of the entire ELF long-wave radio communication facility was approximately 10–14 MW [18]. India's ELF long-wave radio station was successfully built in 2012. At present, owing to military confidentiality and other reasons, little information is known about the call sign or frequency of this ELF long-wave radio station [30].

Unfortunately, it is difficult for underwater submarines to receive external signals. To communicate with submarines, countries spared no expenses in establishing long-wave radio stations. However, this communication mode had several limitations. The communication rate was extremely low. Therefore, under normal circumstances, long-wave communication was only used as a telephone to inform the submarine to surface quickly and then send out a communication buoy for rapid communication. However, such a situation is extremely easy to detect using radio positioning [31]. During World War II, Britain used radio positioning technology to carry out targeted attacks on German wolf-pack submarines [32].

Submarines and other underwater equipment typically use ultra-low and very low frequencies for limited communication, and the communication rate is only approximately 300 bit/s [33]. However, the generation of low-frequency, very-low-frequency, and extremely low-frequency signals requires extremely powerful

transmitting antennas, which are very expensive [34] and vulnerable to repeated damage in the communication process.

Because the conductivity of seawater is very good, it stimulates the induced current to consume the energy of electromagnetic waves, which seriously attenuates the RF signal during underwater transmissions. This limits the underwater communication distance of the RF signal; thus, it is only suitable for short-distance underwater communication, and cannot do the long-distance and high-speed underwater information transmissions needed in the future [35].

Optical Communication

The communication rates of underwater acoustic and radio frequency communication in water cannot reach Mbit/s and cannot transmit large-capacity high-definition videos. Owing to these limitations, optical communication has become a hot topic in underwater communication research because of its higher spectral efficiency.

Optical wireless communication has a high spectrum (400–800 THz) and is advantageous for high-speed communication. The communication distance can reach 100 m and the communication rate can reach the Gbit/s level [36]. Moreover, its volume is much smaller than the first two, its bandwidth utilization is high, its energy consumption is low, its beam directivity is good, its divergence angle is small, and its security is high, all of which are conducive to long-distance transmission [37]. Because the frequency of light waves is relatively high, their ability to carry information is strong, and a high-capacity wireless communication system can be built [38].

However, underwater optical communication has certain limitations. Because of the influence of underwater-channel scattering, absorption, turbulence, and other factors, the transmission distance is limited. Table 31.1 compares the advantages and disadvantages of different underwater wireless technologies.

This chapter briefly introduces the transmission characteristics of underwater optical wireless communication, summarizes and discusses the key technologies and progress in underwater optical wireless communication, including channel modeling, light source selection, coding modulation technology, and detection technology, and summarizes the difficulties and future development directions of underwater optical wireless communication.

Model and Research Status of Underwater Optical Wireless Communication Systems

System Model

An underwater optical wireless communication system includes transmitting equipment, an underwater channel, and receiving equipment. Figure 31.1 shows the underwater optical communication system model. The transmitting end is composed

Table 31.1 Advantages and disadvantages of different underwater wireless technologies

Underwater wireless technology	Advantages	Disadvantages
Acoustic	Relatively mature, with small attenuation and long transmission distance	Low communication rate, time delay, high-power consumption, poor confidentiality, and harmful to marine organisms
Radio frequency	Less affected by turbulence	Short communication distance, low communication frequency, severe attenuation, and high transmission power
Optical	High communication rate, small size, high-bandwidth utilization, and low-power consumption	Affected by absorption and scattering

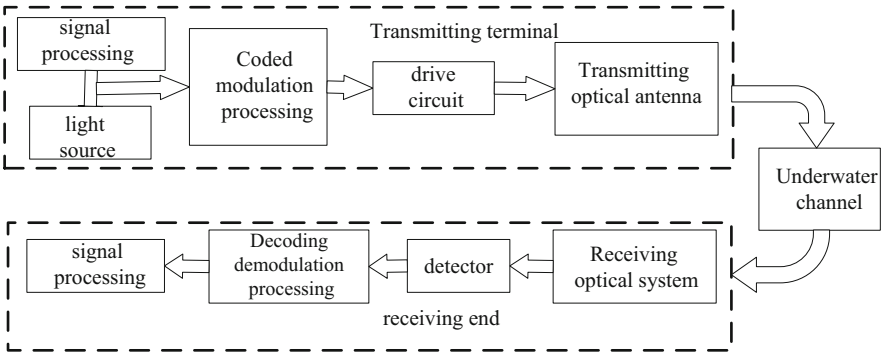

Fig. 31.1 Underwater optical wireless communication system

of a light source, coding–modulation processing circuit, driving circuit, and transmitting antenna. The receiver is composed of a detector, decoding–demodulation processing, filter, and output signal unit.

The underwater channel is relatively complex. In theory, an underwater channel includes turbulence, absorption and scattering factors, noise, and other factors affecting the communication.

The working process of the underwater optical communication system is as follows. At the transmitting end, the signal is encoded by an encoder, converted into a current that changes with the signal by a modulator, loaded onto the light source through a driving circuit, and finally transmitted through the transmitting antenna. At the receiving end, the receiving antenna gathers the received beam onto the detector surface. The detector converts the optical signal into an electrical signal, demodulates the signal, and finally recovers the original information.

Foreign Research Status

Since the 1960s, researchers have been exploring underwater optical communication systems [1]. In 1963, Duntley et al. [39] found that 470–570-nm blue-green light had the smallest attenuation in water, compared with other wavebands; that is, there was a low energy consumption "window." This discovery provided a reference for the selection of light sources for underwater optical communication systems.

In 1968, Gordon [40] used a laser as an emission light source underwater and experimentally proved the feasibility of using a laser to measure the depth of seawater. Moreover, he established the world's first system to measure the depth of seawater using a laser.

In 1972, Phillips et al. [41] introduced a technology to independently measure the absorption and scattering coefficients of seawater. This technology used an airborne system that transmitted laser pulses down to the water and recorded the upward scattering signals of particles in the water. The feasibility and effectiveness of the system were verified by comparing the experimental results with field measurement results.

In 1976, Karp [42] established optical wireless communication models for underwater and above-water terminals using multiple scattering models and experimentally proved their feasibility. The results showed that the radiation function was related to the transformation of the spatial covariance function (mutual interference function).

In 1977, Doherty et al. [43] used a focused blue-green laser diode as the light source to realize a one-way underwater optical wireless communication system from shore to submarine. This confirmed that it was feasible to establish an underwater optical wireless communication system, with a laser diode as the transmitter, to communicate at greater depths and higher cruising speeds.

In 1980, Wiener et al. [44] introduced a method for communicating underwater with a marine missile submarine. In the underwater submarine experiment, a blue-green LED was used as the light source of the transmitter to verify the feasibility of the system. This method was used in national defense and military affairs.

In 1983, the Soviet Union's Black Sea Fleet [45] realized underwater submarine communication near Sevastopol. The emission light source of this system was a blue-green laser. Finally, the system was used to implement a scheme for space-based and ground-based submarine communication.

In 1986, Billard et al. [46] studied an algorithm for airborne bathymeters. This algorithm could detect and locate reflections from the sea surface and seabed within 256 consecutive 2-ns received green light waveforms. The algorithm was flexible and simple and met the data processing requirements of an airborne bathymeter.

In 1992, Snow et al. [47] used an optical receiver to detect a green laser beam and measured the functional relationship between the propagation distance, data rate, and bit error rate. The maximum data rate was 50 kbit/s, and the error rate was 10^{-9} in a 50-m water tank.

In 1995, Bales et al. [48] designed an underwater optical communication system that used an LED as the emission light source. The experiment proved that the

underwater optical communication system had a communication rate of 1–10 kbit/s and a communication distance of 20–30 m in clear water.

In 2000, Tivey et al. [49] developed underwater short-distance communication equipment for submarine communication with a blue LED as the emission light source and a silicon photodiode as the detector at the receiving end. Error-free reception was realized in a 2.7-m water tank, and errors occurred when the communication distance exceeded 3 m. Finally, an underwater experiment with a communication distance of 5 m, communication rate of 115.2 kbit/s, and 70% accuracy rate was realized in the pool.

In 2003, Schill et al. [50] established a small, real-time optical communication transceiver using a group of small autonomous submersibles. The transceiver used a 3-W high-power blue-green laser diode and a 520-nm photodiode. An underwater experiment with a 2-m communication distance, 57.6-kbit/s data transmission rate, and no error codes was successfully implemented.

In 2004, Akyildi et al. [51] used a high-power blue-green LED as a light source in an underwater optical communication system. The experimental results showed that the system could complete underwater experiments with a 1.7-m communication distance, 57.6-kbit/s data transmission rate, and almost no error codes.

In 2005, Farr et al. [52] proposed a preliminary design for an optical modem system based on omnidirectional sources and receivers. First, the functional requirements and system constraints of the system driver were reviewed. The optical transmission characteristics of seawater and the factors affecting high-speed communication were discussed. The relationship between the link budget, data rate, and distance was established. In the experiment, a blue light-emitting diode was used as the light source, the detector was a photomultiplier tube, and the switch keying modulation mode was used. A vertical ocean test experiment of nearly 100 m was conducted, and the communication rate was close to 10 Mbit/s.

In 2007, Cochenour et al. [53] introduced the influence of scattering on underwater light transmissions. Using binary phase shift keying, quadrature phase shift keying, 8-phase shift keying, 16 quadrature amplitude modulation, and 32 quadrature amplitude modulation, an underwater experiment were conducted in a turbid water environment. The data rate was up to 5 Mbit/s, communication distance was 3.6 m, and bit error rate was 10^{-3}.

In 2008, Hanson et al. [54] simulated an underwater signal transmission system with a 532-nm laser diode in a 2-m water pipe in a laboratory. The 532-nm light source originated from a 1064-nm continuous-wave (CW) laser diode. Using intensity modulation and Monte Carlo simulations, the extinction ratio was 36 dB. An underwater experiment with a communication rate of 1 Gbit/s, communication distance of 2 m, and almost no error codes was conducted.

In 2008, Cox et al. [55] used a 405-nm laser diode as the emission light source and used switch keying modulation and a Reed–Solomon (RS) (255, 129) coding mode to successfully conduct underwater transmission experiments with a communication rate of 500 kbit/s, communication distance of 3.66 m, and a bit error rate lower than 10^{-4}. The experimental results showed that the signal-to-noise ratio of the coded system was improved by 8 dB, compared to that of the uncoded system.

In 2008, Jaruwatanadilok [56] used the vector radiative transfer theory to model an underwater optical communication system. A 532-nm laser diode was used as the emission light source, and the Monte Carlo simulation method was used to successfully realize an underwater communication experiment. It had a communication rate of 1 Gbit/s over 30 m, a communication rate of 500 Mbit/s over 50 m, and no error codes in the outbound communication.

In 2009, Doniec et al. [57] used an AquaOptical device for experiments with an underwater communication system. In clear water, the communication rate was 1.2 Mbit/s over a 30-m transmission distance, with a received data success rate of 100%. An underwater communication experiment with a 0.6-Mbit/s data rate and 9-m communication distance was realized in turbid water with a visibility of 3 m; however, the accuracy of the received data decreased.

In 2009, Cochenour et al. [58] studied an underwater communication system using a beam spread function. The system used a 520-nm light-emitting diode at the transmitter and a photomultiplier tube as the detector at the receiver. The Monte Carlo simulation method was used, and a small-angle approximation method was used to solve the radiative transfer equation. An underwater communication experiment with a transmission rate of 70 Mbit/s, communication distance of 107 m, and almost no error codes was realized.

In 2010, Simpson et al. [59] adopted digital signal processing and error correction technology. In the experiment, a 470-nm LED was used as the emission light source, and a photomultiplier tube was used as the detector. They were tested in 3-m and 7.7-m water tanks. The test speed was 5 Mbit/s. Under a 10^{-5} bit error rate, the signal-to-noise ratio was improved by 4 dB, compared with the uncoded data.

In 2010, Cox et al. [60] used a 532-nm blue-green laser diode as the emission light source and adopted orthogonal frequency shift keying modulation and an RS (255, 129) coding mode. They conducted a MATLAB simulation experiment in a 7.7-m underwater channel. When the transmission rate was 500 kbit/s, there were almost no errors. When the transmission rate was 1 Mbit/s, the error rate was 1.19×10^{-2}.

In 2011, Vucic et al. [61] used a high-power white LED as the emission light source and an avalanche photodiode with quadrature amplitude modulation as the detector in underwater experiments. The data transmission rate was 513 Mbit/s and the bit error rate of the received data was 2×10^{-3}.

In 2012, Gabriel et al. [62] used a 532-nm LED transmitter and a silicon PIN photodiode receiver, using a switch keying modulation method, and used the bit error rate as the standard for evaluating the system. An underwater experiment with a data transmission rate of 1 Gbit/s, communication distance of 20 m, and 10^{-6} bit error rate (BER) was realized.

In 2013, Cossu et al. [63] used two low-cost LED arrays as the emission light source and avalanche photodiodes as the detector. Using the Manchester coding method, they successfully conducted an underwater experiment with a 6.25 Mbit/s communication rate in a 3.3-m-diameter outdoor water tank. When the discrete multitone modulation mode was adopted in the experiment, a communication rate

of up to 58 Mbit/s was realized. The experimental results showed that error-free transmission could be realized under all experimental conditions.

In 2013, Doniec et al. [64] designed an end-to-end underwater communication system. The system used a 470-nm LED as the emission light source, an avalanche photodiode as the detector at the receiving end, and switch keying modulation and RS (255, 223) coding. They successfully conducted underwater communication experiments with a 10 Mbit/s communication rate, 36-m communication distance, and 10^{-6} error rate.

In 2014, Han et al. [65] designed an acousto-optic hybrid underwater communication system and estimated its performance through the QualNet simulator. The system used an AquaOptical II optical modem, which could communicate underwater with a maximum communication distance of 50 m, maximum communication rate of 2.28 Mbit/s, and almost no error codes. The system also used a S2CR18/34 acoustic modem, which realized underwater communication experiments with a maximum communication distance of 3.5 km, maximum communication rate of 13.9 kbit/s, and almost no error codes.

In 2014, Hiskett et al. [66] designed an underwater communication system with a 450-nm laser diode as the light source at the transmitter and a silicon avalanche photodiode at the receiver. The experimental results showed that the data transmission rate was up to 45.32 Mbit/s and the bit error rate was 1.8×10^{-4} in a 1-m-long water tank.

In 2015, Oubei et al. [67] adopted a TO-9 packaged 450-nm braided laser diode and the 16 orthogonal-amplitude modulation orthogonal frequency-division multiplexing (16 OAM-OFDM) modulation mode to achieve a transmission distance of 5.4 m, communication rate of 4.8 Gbit/s, bit error rate of 2.6×10^{-3}, and signal-to-noise ratio of 15.63 dB.

In 2015, Nakamura et al. [68] used the intensity modulation/direct detection orthogonal frequency-division multiplexing method with avalanche photodiodes as detectors. An experiment with a 405-nm blue laser diode transmission in a 4.8-m underwater channel was completed, with a communication rate of up to 1.45 Gbit/s and a bit error rate of 9.4×10^{-4}.

In 2016, Oubei et al. [69] used commercially available TO-9 packaged 520-nm braided laser diodes and avalanche photodiodes with switch keying modulation in underwater experiments. The transmission distance was more than 7 m, the communication rate was up to 2.3 Gbit/s, and the bit error rate was 2.23×10^{-4}.

In 2016, Stephen et al. [70] adopted a 420-nm laser diode doped with AlGaInN, and the maximum optical power of the laser diode was 100 mW. In the laboratory water tank, an underwater experiment was conducted with a data transmission rate of up to 2.5 Gbit/s, 10-m transmission distance, and almost no error codes. GaN laser diodes have been proven to be suitable for underwater communication systems.

In 2017, Abdullah et al. [71] used commercially available TO-9 packaged 520-nm laser diodes as emission light sources and avalanche photodiodes as detectors. An underwater video-image transmission experiment was successfully conducted with a communication rate of 4 Gbit/s and a 5-m communication distance in clear and port seawater. When the modulation modes of quadrature phase shift

keying (QPSK), quadrature amplitude modulation (QAM), and 8-quadrature amplitude modulation (8-QAM) were adopted, the bit error rate was 10^{-9}. When the 8-PSK modulation mode was adopted, the bit error rate was 9.9×10^{-9}.

In 2017, Tsai et al. [72] used a 450-nm blue GaN laser diode as the emission light source and a PIN photodiode as the detector and adopted the 16 OAM-OFDM mode in an underwater communication experiment. The communication rates were 12.4, 9.2, and 5.2 Gbit/s, respectively; the communication distances were 1.7, 6.8, and 10.2 m, respectively, and the bit error rates were 2.7×10^{-3}, 2.9×10^{-3}, and 3.2×10^{-3}, respectively.

In 2017, Oubei et al. [73] modeled an underwater channel with a temperature gradient and adopted an experimental method with a generalized gamma distribution. The experimental results showed that the measured data for all underwater channel conditions had a good fit. In addition, it was observed that a thermally homogeneous channel can be well described by a simple gamma distribution. This was the first model to comprehensively describe thermal homogeneous and gradient-based underwater optical channels.

In 2017, Jamali et al. [74] used multiple-input multiple-output (MIMO) spatial diversity technology on an underwater optical wireless communication link to mitigate the fading caused by turbulence. In the experiment, a 450-nm LED was used as the emission light source, the switch keying modulation mode was adopted, and the Monte Carlo simulation method was used to realize an underwater experiment in a 25-m pool in the laboratory. The bit error rate was lower than 10^{-9}. Finally, considering the effects of absorption and scattering, the exact expressions of the optimal gain, equal gain combination, and upper bound of the BER were obtained using an analytical solution method.

In 2018, Halafi et al. [75] designed an underwater video transmission system that could realize two-way underwater communication. The uplink and downlink emission light sources of the system were a commercial TO-9 packaged 450-nm blue laser diode and 520-nm green laser diode, respectively, with a bandwidth of 1.2 GHz. The uplink and downlink receiver detectors used avalanche photodiodes. When the communication distance was 4.5 m, the communication rate reached 15 Mbit/s when using the quadrature phase shift keying (QPSK) modulation mode. When 16-QAM and 64-QAM were adopted, the communication rate reached 30 Mbit/s, and the peak signal-to-noise ratio in the harbor seawater reached 16 dB.

In 2018, Illi et al. [76] used an improved radiative transfer equation to predict the optical path loss in an underwater channel and calculated the change in the BER performance of an underwater optical wireless communication system with the transmission time and distance. In the experiment, an LED was used as the emission light source, and the intensity modulation/direct detection (IM/DD) method was adopted. An underwater experiment with a communication distance of 3.5 m and a BER of less than 10^{-4} was successfully realized.

In 2019, Illi et al. [77] further improved the method for calculating the radiative transfer equation in an underwater communication system. The system used an LED as the emission light source and realized an underwater experiment with a communication distance of 6 m and a BER of 10^{-6}. The experimental results showed that

the improved method of the radiative transfer equation obtained the same results by calculating the BER of an underwater optical wireless communication system. It was consistent with the Monte Carlo simulation results, thereby reducing the system complexity.

In 2019, Tsai et al. [78] proposed and demonstrated an underwater wireless laser transmission system using four-level pulse amplitude modulation (4-PAM). The system was equipped with a beam constrictor/expander on a 12.5-m pipeline underwater channel and 2.5-m high-turbidity port underwater channel, respectively, in an underwater experiment. It achieved data transmission rates of 15 Gbit/s and 30 Gbit/s and BERs of 2.4×10^{-7} and 10^{-6}, respectively. In the highly turbid underwater link of the harbor, the large amount of scattered light received by the optical receiver of the 4-PAM system improved with the beam-shrinking/expanding device.

In 2020, Ramavath et al. [79] used the switch keying modulation method and the hyperbolic tangent distribution method to specify the probability density function of a lognormal distribution. The new closed-form analytical BER expressions for single-input single-output (SISO), single-input multiple-output (SIMO), multiple-input single-output (MISO), and MIMO links in the noncoding and RS coding cases were calculated and verified using Monte Carlo simulation results. The underwater data transmission rate was 500 Mbit/s, the communication distance was 30 m, and the BER of the received data was 10^{-5}. It realized underwater Internet of things applications, such as communication between submarines, between submarines and docks, between sensors collecting ocean parameters, and aggregation equipment.

In 2020, Arvanitakis et al. [80] used six 450-nm LED arrays as emission light sources, PIN photodiodes as detectors at the receiving end, and the switch keying modulation mode in an underwater communication experiment. They successfully achieved communication rates of 4.92, 3.22, and 3.4 Gbit/s; communication distances of 1.5, 3, and 4.5 m; and bit error rates of 1.5×10^{-3}, 1.1×10^{-3}, and 3.1×10^{-3}, respectively.

In 2022, Kong et al. [81] proposed a prototype for a real-time digital video dynamic underwater monitoring system. The system used a 458-nm LED as the light source, and the video stream was processed by a transmitter circuit composed of video coding and switch keying modulation. In a 1.5-m pure water channel, 1.53 mL/s bubble-induced turbulent pure water channel, and other channels, the communication rate was 2.5 Mbit/s and the bit error rate of the received data was 5.31×10^{-4}.

The foreign research status of underwater optical communication system models is summarized in Table 31.2.

The foreign research progress on underwater optical communication rates (kbit/s, Mbit/s, and Gbit/s) is summarized in Table 31.3.

It can be seen from the foreign research status of underwater optical wireless communication systems that, to improve the communication performance, researchers have attempted to improve the communication rates and increase the transmission distances through optimizing the modulation modes and light sources of underwater optical communication systems. They have also analyzed underwater optical wireless communication systems through various simulation models,

Table 31.2 Foreign research progress on underwater optical communication system models

Year	Researcher	Research content	Research results
1963	Duntley	Attenuation of light of different wavebands in water	Blue-green light with a 470–570 nm wavelength has the weakest attenuation in water
1968	Gordon et al.	Characteristics of laser propagation under water	Established the world's first system for measuring the depth of seawater using a laser
1972	Phillips et al.	Technique for independently measuring the absorption and scattering coefficients of seawater	The experimental results were compared with the field measurement results to prove the feasibility and effectiveness of the system
1976	Karp et al.	Established an underwater optical wireless communication model above the water surface	The feasibility of the system was proved using multiple scattering models
1977	Doherty et al.	Established an underwater communication system using blue-green laser diodes	Realized a one-way underwater optical wireless communication system from shore to submarine
1980	Wiener	Research on the communication modes of marine missile submarines	The feasibility was verified by using blue-green light communication in an underwater submarine experiment
1983	Soviet Black Sea Fleet	Research on submarine communication using blue-green lasers	Scheme design of space-based to submarine communication and ground-based to submarine communication was carried out
1986	Billard et al.	Algorithm was studied for the WRELADS airborne bathymeter	The bathymeter could detect and locate the reflections of the sea surface and sea bottom in 256 consecutive 2-ns received green light waveforms

compared the simulation data of communication rates and distances with engineering tests, and verified the derivation of theoretical data through experiments.

Domestic Research Status

China began to study underwater optical communication technology for use against submarines in the 1980s. In 1987, Jiang et al. [82] designed a special codec image compression scheme. The experimental results showed that the image transmission rate reached 640 kbit/s and the bit error rate was 5.2×10^{-2} after using the codec image compression scheme. A complete image could be transmitted in about 10 s.

In 1989, Ao [83] used pulse position modulation in an experiment and RS coding in a laser submarine communication channel. He analyzed the error correction ability of RS (7, 3), (15, 7), (31, 15), (63, 31), and (255, 223) codes in the channel. The results showed that the RS error correction coding method could be applied to a laser

Table 31.3 Foreign research progress on communication rates (kbit/s, Mbit/s, and Gbit/s)

Classification	Year	Communication rate	Researcher	Communication distance	Error rate
Kbit/s	1992	50 kbit/s	Snow et al.	50 m	10^{-9}
	1995	1/10 kbit/s	Bales et al.	30/20 m	–
	2000	115 kbit/s	Tivey et al.	5 m	–
	2003	57.6 kbit/s	Schill et al.	2 m	Accuracy: 70%
	2004	57.6 kbit/s	Akyildi et al.	1.7 m	No error codes
	2008	500 kbit/s	Cox et al.	3.66 m	$< 10^{-4}$
	2010	500 kbit/s	Cox et al.	7.7 m	Almost no error codes
	2014	13.9 kbit/s	Han et al.	3.5 m	Almost no error codes
Mbit/s	2005	10 Mbit/s	Farr et al.	100 m	Almost no error codes
	2007	5 Mbit/s	Cochenour et al.	3.6 m	10^{-3}
	2008	500 Mbit/s	Jaruwatanadilok	50 m	No error codes
	2009	1.2/0.6 Mbit/s	Doniec et al.	30/9 m	Almost no error codes
	2009	70 Mbit/s	Cochenour et al.	107 m	Almost no error codes
	2010	1 Mbit/s	Cox et al.	7.7 m	1.19×10^{-2}
	2010	5 Mbit/s	Simpson et al.	7.7 m	10^{-5}
	2011	513 Mbit/s	Vucic et al.	–	$< 2 \times 10^{-3}$
	2013	58 Mbit/s	Cossu et al.	3.3 m	Almost no error codes

	2013	10 Mbit/s	Doniec et al.	36 m	10^{-6}
	2014	45.32 Mbit/s	Hiskett et al.	1 m	1.8×10^{-4}
	2014	2.28 Mbit/s	Han et al.	50 m	Almost no error codes
	2018	30 Mbit/s	Halafi et al.	4.5 m	–
	2020	500 Mbit/s	Ramavath et al.	30 m	10^{-5}
	2022	2.5 Mbit/s	Kong et al.	1.5 m	5.31×10^{-4}
Gbit/s	2008	1 Gbit/s	Hanson et al.	2 m	Almost no error codes
	2008	1 Gbit/s	Jaruwatanadilok	50 m	No error codes
	2012	1 Gbit/s	Gabriel et al.	20 m	10^{-6}
	2015	1.45 Gbit/s	Nakamura et al.	4.8 m	9.4×10^{-4}
	2016	2.3 Gbit/s	Oubei et al.	7 m	2.23×10^{-4}
	2016	2.5 Gbit/s	Stephen et al.	10 m	Almost no error codes
	2017	4 Gbit/s	Abdullah et al.	5 m	10^{-9}
	2017	12.4/9.2/5.2 Gbit/s	Tsai et al.	1.7/6.8/10.2 m	$2.7 \times 10^{-3}/2.9 \times 10^{-3}/3.2 \times 10^{-3}$
	2017	4.8	Oubei et al.	5.4 m	2.6×10^{-3}
	2019	15/30 Gbit/s	Tsai et al.	12.5/2.5 m	$2.4 \times 10^{-7}/10^{-6}$
	2020	4.92/3.22/3.4 Gbit/s	Arvanitakis et al.	1.5/3/4.5 m	$1.5 \times 10^{-3}/1.1 \times 10^{-3}/3.1 \times 10^{-3}$

submarine communication system to correct errors and greatly improve the channel error rate.

In 1992, Sui et al. [84] established a method for analyzing underwater optical communication systems and conducted experimental simulations using different modulation methods. With a signal-to-noise ratio of 30 dB, when using the switch keying modulation mode, the bit error rate was 10^{-2}. When the four-pulse position modulation (4-PPM) mode was used, the bit error rate was 10^{-3}. When the 8-PPM mode was used, the bit error rate was 10^{-5}. When the relative phase shift keying (RPSK) modulation mode was used, the bit error rate was 10^{-8}. However, when the SNR was less than 10 dB, the bit error rates of the several modulation modes were essentially the same.

In 1995, Wang et al. [85] studied a time slot synchronizer. An analysis of its performance showed that the synchronizer had a fast signal acquisition speed, strong noise resistance, etc., and could improve the performance of underwater communication systems.

In 1997, Yang et al. [86] introduced an underwater laser communication system using error correction code methods. The detector at the receiving end of the system used a photomultiplier tube, RS coding, and PPM to compare different error correction code methods based on an error rate analysis. The experimental results showed that when the input bit error rate was 2×10^{-2}, using the RS (255, 223) error correction code reduced the bit error rate, after decoding, to less than 10^{-6}, and the coding gain exceeded 1 dB.

In 1998, Huang et al. [87] studied a full-duplex underwater laser communication experimental device controlled by an 89C51 single-chip microcomputer in a 3-m-long water tank. The experiment showed that the maximum data transmission rate of the system could reach 21.2 kbit/s, and the received data bit error rate was 2.8×10^{-3}.

In 1999, Ao et al. [88] developed an underwater laser communication model using an adaptive array signal intensifier and diversity reception. The experimental results showed that the output signal-to-noise ratio of the adaptive array signal intensifier was proportional to the number of array input signals, which meant that the underwater adaptive array signal was less affected by the noise in the channel.

In 2002, He et al. [89] designed an underwater communication system using PPM with a 532-nm light wavelength, multiple diversity reception at the receiving end, and a PIN photodiode detector. The communication distance of the system was 50 m, and the bit error rate was 1.76×10^{-3} in a water tank in the laboratory. Underwater experiments were conducted in three different sea areas in Hainan Province, China, which further verified the feasibility of the system.

In 2003, Wang et al. [90] studied an underwater communication system using fiber-grating filters. The fiber wavelength used in the experiment was 532 nm; it achieved 100% reflectivity and a reflection bandwidth lower than 0.01 nm. This method expanded the application field of fiber gratings and was a new research method in underwater optical communication.

In 2004, Pang [91] successfully conducted an experiment with a 1 Mbit/s communication rate in a 10-m water tank in the laboratory using a blue LED. An

underwater experiment with a 13-m communication distance and 3 Mbit/s communication rate was successfully realized using an ultra-bright blue LED. The experimental results showed that the received file had an error rate of 8×10^{-9} with almost no bit errors.

In 2006, Ao et al. [92] designed a highly sensitive digital optical receiver for an underwater communication system based on digital PPM and digital signal processing technology. Experiments and tests showed that the receiver reduced the system's signal-to-noise ratio requirements and achieved good performance.

In 2008, Cui [93] used a 532-nm green laser diode as the transmitting light source in an underwater communication system. Polarized light was used as the carrier, and the frequency of the signal pulse was 128 Hz. In the laboratory water tank, he performed an experiment with a 5-m communication distance, which proved that using polarized light as the carrier could reduce the bit error rate and improve the communication rate of the underwater optical communication system.

In 2008, Luo et al. [94] used a blue-green LED as the emission light source and designed an underwater optical communication system based on the Infrared Data Association (IrDA) physical-layer communication protocol. The system used a curve-fitting method to establish the relationship between the light intensity and distance. The experimental results showed that an underwater communication experiment with a data transmission rate of 125 kbit/s and error-free code could be realized without any influence of the light source within 2 m. This verified that the system could meet the high-speed communication requirements of underwater mobile wireless sensor network nodes.

In 2009, He et al. [95] designed a heterodyne laser Doppler vibrometer with an optical fiber structure to analyze the impact of water waves on an acousto-optic communication system. The experiment showed that the acousto-optic communication system could achieve a communication rate of 5 kbit/s without waves on the water surface, and there were almost no error codes in the experiment. With small waves on the water surface, the system could complete the experiment with a communication rate of 30 kbit/s and almost no error codes.

In 2010, Liu et al. [96] simulated the performance of the laser uplink of an underwater platform received by a satellite using the Monte Carlo simulation method. Using the PPM and maximum-likelihood estimation methods, they calculated that the bit error rate of the communication system was less than 10^{-4} and proposed a laser uplink communication scheme between 60-m underwater and a satellite.

In 2011, Cong [97] introduced the structure of an adaptive underwater optical communication network framework and studied an adaptive decoding scheme applied to underwater optical communication systems based on different coding schemes. The data transmission rate was 3 Mbit/s, the communication distance was 20 m, and the bit error rate was 4×10^{-4} in the underwater experiments.

In 2012, Wang et al. [98] studied an underwater optical communication system that could compress the dynamic range of the signal and used a variable gain amplifier to vary the dynamic range of the compressed signal, so that the signal eventually stabilized. This method not only reduced the dynamic range of the signal

but also effectively improved the accuracy of the digital-to-analog converter, which could be well applied to underwater optical communication systems.

In 2012, Ao et al. [99] designed a control system that used an electronic compass to adjust the angle of an underwater optical transmitter. Through the electronic compass, the depression and elevation angles of the system at the current time were obtained so that the transmitter could be adjusted to an appropriate angle, according to the actual situation. The system realized a transmission experiment with a communication distance of approximately 10 m and no error codes.

In 2013, Tian et al. [100] designed and implemented an underwater optical communication system based on LEDs. In the experiment, the RS232 serial communication protocol was used to encode and decode information. By adjusting the communication baud rates at different speeds, the final experimental results showed that the data transmission rate was 38.4 kbit/s and the communication distance was 30 m.

In 2013, Xu et al. [101] introduced an underwater optical communication system with IM/DD orthogonal frequency-division multiplexing (OFDM). The system used a blue light-emitting diode as the emission light source and a PIN photodiode as the receiving detector. In the 2-m underwater channel, 16-QAM, 32-QAM, and 64 QAM modes were used to achieve communication rates of 161.36 Mbit/s, 156.31 Mbit/s, and 131.07 Mbit/s, respectively. The bit error rates were, respectively, 2.5×10^{-3}, 7.42×10^{-4}, and 3.17×10^{-3} in underwater experiments.

In 2013, Hu et al. [102] designed a high-speed underwater communication system using digital signal processing. The light source at the transmitting end of the system used a 532-nm laser diode, and the detector at the receiving end used a photomultiplier tube. Using PPM and RS coding, an error-free full-duplex underwater communication experiment with a 73-kbit/s communication rate was realized in a 100-m pool.

In 2014, Xi et al. [103] produced a frequency response model of an underwater optical wireless communication channel using the discrete coordinate method based on the vector radiative transmission theory. They used this model to evaluate the performance of an underwater optical communication system using m-ary PPM. The experimental results showed that the communication rate was 1 Gbit/s, and the bit error rate performance decreased with an increase in transmission distance. The BER performance of quaternary pulse position modulation was almost the same as that of switch keying modulation. Octal pulse position modulation or 16 PPM could be used to further improve the bit error rate performance.

In 2015, Cai et al. [104] used blue-green light-emitting diodes as the emission light source and photodiodes as the receiver detector in an underwater communication system. In a 10-m water tank in the laboratory, they conducted an experiment with a data transmission rate of 115.2 kbit/s and almost no bit errors.

In 2016, Shen et al. [105] realized a small, low-power underwater communication system using a single-mode 450-nm laser diode, a silicon avalanche photodetector, and a simple non-return-to-zero switch keying modulation mode. In a 12-m underwater channel, the received data had a bit error rate of 2.8×10^{-5} and a

communication rate of up to 2 Gbit/s. In a 20-m underwater channel, the received data had a bit error rate of 3.0×10^{-3} and a communication rate of up to 1.5 Gbit/s.

In 2016, Hu et al. [106] studied an underwater two-way communication system using a blue LED. The system used a photodiode as the receiver detector and realized an error-free full-duplex underwater communication experiment with a communication distance of 5 m and communication frequency of up to 60 MHz.

In 2016, Zhou et al. [107] used a blue-green laser diode as the emission light source of an underwater system. The detector used an avalanche photodiode to combine low-density parity check codes and PPM to form a simplified soft demodulation method. MATLAB simulation verified that the bit error rate performance of the simplified soft demodulation method was better than that of the RS code, proving the effectiveness of the method in an underwater optical communication system.

In 2016, Lu et al. [108] used a 405-nm blue laser diode as the emission light source, an avalanche photodiode as the detector at the receiving end, and adopted the 16 OAM-OFDM mode to successfully conduct an underwater experiment with a data transmission rate of 9.6 Gbit/s, communication distance of 8 m, and bit error rate of 10^{-4}.

In 2016, Xu et al. [109] studied the transmission characteristics of red light in water from the perspective of the extinction coefficient and channel bandwidth using the Monte Carlo simulation method. In the laboratory, a simple low-cost top 5 red laser diode was used as the emission light source and an avalanche photodiode was used as the detector. They used 128- and 32-OAM-OFDM modes in underwater experiments. In a 6-m-long water tank, the data transmission rates were 1.324 Gbit/s and 4.883 Gbit/s, respectively, and the bit error rates were 2.02×10^{-3} and 3.20×10^{-3}, respectively.

In 2017, Liu et al. [110] used a 520-nm green laser diode and the switch keying modulation mode in an underwater experiment. The communication distance was 34.5 m, the communication rate was up to 2.7 Gbit/s, and the received data bit error rate was less than 3.8×10^{-3}. In the experiment, the maximum data rate reached 4.60, 4.20, 3.93, 3.88, and 3.48 Gbit/s, when the underwater distances were 2.3, 6.9, 11.5, 19.1, and 31.7 m, respectively.

In 2017, Chen et al. [111] used a single-mode braided green laser diode as the light source, and the modulation technology employed 32 OAM-OFDM. They successfully completed a 5.3 Gbit/s uplink transmission with no power load in a 21-m underwater channel and the received data bit error rate was 2.47×10^{-3}. They also completed a 5.5 Gbit/s downlink transmission with a power load, and the received data bit error rate was 2.92×10^{-3}.

In 2017, Ao et al. [112] used a blue-green LED as the emission light source with pulse position modulation. The receiver detector used photodiodes. They successfully completed an underwater experiment with multiple inputs and outputs with a data transmission rate of 10 Mbit/s, a communication distance of 2.3 m, and error-free codes.

In 2017, Lin [113] used a green laser diode as the emission light source and a PIN photodiode as the detector at the receiving end, adopted OFDM, and used a field

programmable gate array. They achieved a communication distance of 2 m, a communication rate of 80 Mbit/s, and a bit error rate of 2.24×10^{-3}.

In 2017, Song Aerospace [114] used a blue light-emitting diode as the emission light source and a photodiode as the detector at the receiving end and adopted the MIMO OFDM mode. They realized underwater communication experiments using MATLAB programming with a 2-m communication distance, a communication rate of 31.082 Mbit/s, a signal-to-noise ratio of 20 dB, and a bit error rate lower than 10^{-4}.

In 2018, Huang et al. [115] adopted the 16-OAM frequency-division multiplexing modulation mode and used a blue laser diode as the emission light source. They achieved a communication distance of 1.7 m, and a received data bit error rate of 1.9×10^{-5}; the data transmission rate was 14.8 Gbit/s. When the communication distance was 10.2 m, the bit error rate of the received data was 1.5×10^{-4}, and the data transmission rate was 10.8 Gbit/s.

In 2018, Wang et al. [116] designed an underwater optical communication system using PPM. The system used a 450-nm blue light-emitting diode as the emission light source and an avalanche photodiode as the detector at the receiving end. An undistorted transmission experiment with a 6-m communication distance and 0.98 Mbit/s communication rate was realized in the laboratory.

In 2018, Han [117] used a 472-nm blue LED as the emission light source, a photomultiplier tube as the receiver detector, switch keying modulation, and RS coding. Using the Monte Carlo simulation method, he successfully realized an underwater two-way network video transmission experiment with the longest communication distance of 9.6 m, the largest communication rate of 20 Mbit/s, and a bit error rate of 10^{-9}.

In 2018, Yang et al. [118] used a high-power blue-green LED as the emission light source, a photomultiplier tube as the detector, and PPM in an underwater communication system. In the laboratory water tank, they successfully completed a 3-m communication distance, a data transmission rate of 6 Mbit/s, and a bit error rate of 7×10^{-4}.

In 2018, Wang et al. [119] used a low-cost 448-nm blue LED as the emission light source and an avalanche photodiode as the detector at the receiving end. An underwater communication experiment with a 25 Mbit/s communication rate, a 10 m communication distance, and a bit error rate of less than 10^{-4} was successfully realized using a non-return-to-zero modulation mode on the key control and an RS (255, 223) coding mode.

In 2018, Zhang [120] used a 520-nm laser diode as the emission light source, a photodiode as the detector at the receiving end, and PPM to successfully achieve underwater video and audio transmission experiments in the water tank of the laboratory. They achieved a communication rate of 9.6 kbit/s, a communication distance of 3 m, and an error rate of less than 10^{-5}.

In 2018, Li [121] used a 515-nm green LED as the emission light source and an avalanche photodiode as the detector at the receiving end. They designed an underwater optical wireless two-way communication system using an Ethernet conversion interface module. The system achieved a communication rate of

100 Mbit/s, communication distance of 16 m, and bit error rate of 2.4×10^{-6}, when transmitting voice, files, real-time video, and other services.

In 2019, Wang et al. [122] used a 520-nm green laser diode in an underwater communication system using switch keying modulation. In experiments using tap water, they successfully achieved a communication rate of up to 500 Mbit/s, a communication distance of 100 m, and a bit error rate as low as 2.5×10^{-3}. According to the measured minimum required power and power attenuation model in the underwater channel, the predicted transmission rates were 500 Mbit/s and 100 Mbit/s, and the communication distances were 146 m and 174 m, respectively.

In 2019, Hong et al. [123] used a 450-nm laser diode, discrete multitone modulation, and probabilistic constellation shaping (PCS) technology to approximate the channel capacity limit of a discrete multitone transmission. The available modulation bandwidth was 2.75 GHz. Underwater experiments with communication distances of 5 m, 25 m, and 35 m and net data transmission rates of 18.09 Gbit/s, 19.21 Gbit/s, and 12.62 Gbit/s, respectively, were realized. Compared with conventional QAM, the capacity increased by 32.22%, 30.03%, and 31.55%, respectively.

In 2019, Jiang et al. [124] carried out detection experiments in the South China Sea using dual-wavelength multi-channel lidar consisting of 486.1-nm and 532-nm blue-green bands. The experimental results showed that the laser radar could achieve a maximum communication distance of 160 m, and the communication rate was 30% higher than that of the traditional 532-nm blue-green laser diode.

In 2019, Wang et al. [125] used a 450-nm laser diode as the emission light source, a PIN photodiode as the detector at the receiving end, adopted 16 OAM and used a field programmable gate array to conduct an underwater high-speed communication experiment. They achieved a communication rate of 50 Mbit/s, a communication distance of 3 m, and a bit error rate of 7.11×10^{-4}.

In 2019, Zhou et al. [126] used a GaN-doped LED as the emission light source and PIN photodiode as the detector at the receiving end. A 64-QAM discrete multitone modulation mode was adopted, and an underwater communication experiment with a communication rate of 14.81 Gbit/s was successfully implemented in a 1.2-m-long water pipe in the laboratory. With bit-loaded discrete multitone modulation, an underwater communication experiment with a communication rate of 15.17 Gbit/s was also realized. The bit error rate under both modulation modes was lower than 3.8×10^{-3}.

In 2019, Meng [127] used a 532-nm laser diode as the emission light source, a PIN photodiode as the receiver detector, and the switch keying modulation mode. The longest underwater transmission distance was 12 m and the bit error rate was 9.028×10^{-4} for text transmissions and 5.031×10^{-4} for 640 × 480 resolution video and picture transmissions.

In 2019, Han [128] used a 450-nm laser diode as the emission light source and a photomultiplier tube as the detector at the receiving end. Using switch keying modulation and nonlinear compensation, he successfully realized an underwater high-speed communication experiment with a communication rate of 6.23 Gbit/s, a communication distance of 66 m, and a bit error rate lower than 10^{-4}.

In 2019, Shang [129] used a blue-green laser diode as the emission light source and a photodetector at the receiving end. Using switch keying modulation and RS coding, he built an underwater real-time optical wireless communication experimental system. The experimental results showed that the system had a communication rate of 75 Mbit/s, communication distance of 4 m, and no error codes.

In 2020, Li et al. [130] designed a communication system that could realize two-way underwater video transmissions. The system used a 445-nm light-emitting diode as the light source and an avalanche photodiode as the detector at the receiving end for a full-duplex underwater video transmission experiment in the water tank of the laboratory. It adopted binary frequency shift keying and RS (255, 239) coding. The communication rate was 1 Mbit/s, the communication distance was 10 m, and the bit error rate was 3.9×10^{-6}.

In 2020, Ji et al. [131] proposed a low-complexity two-level chaotic encryption scheme that could be used in underwater optical wireless communication and extended discrete multitone modulation technology using a discrete Fourier transform. The experimental results showed that encryption did not negatively impact the performance of the proposed underwater optical communication system. An underwater experiment with communication distances of 50 m and 55 m and communication rates of 5 and 4.5 Gbit/s, respectively, was successfully implemented.

In 2020, Ao et al. [132] introduced a method to restore distorted underwater images using a depth learning algorithm. The simulation results showed that this method could effectively restore images transmitted underwater. This algorithm increased the transmission rate of the image. The average running time was only 0.78 s, while the running time of the traditional iterative algorithm was more than 20 s.

In 2020, the Shanghai Institute of Optics and Mechanics [133] developed blue-green laser diode radar equipment equipped with 486-nm and 523-nm wavebands, which were compatible with the detection needs of nearshore and coastal seawater. The experimental results showed that the 486-nm blue-green laser diode radar equipment could complete the 100-m communication experiment, while the 532-nm blue-green laser diode radar equipment could only complete the 75-m communication experiment.

In 2020, Wu [134] studied the design of an underwater-positioning communication system based on a photoelectric array. The system used light-emitting diodes as the emission light source, and the receiving end used a curved array detector composed of 32 photodiodes. It used quaternary PPM. The bit error rate was analyzed under different receiving angles. When the receiving angle was less than 50°, the bit error rate was 1.248×10^{-6}. When the receiving angle was greater than 50°, the bit error rate was 6.234×10^{-3}, resulting in accurate positioning and communication.

In 2020, Tong [135] used a 470-nm blue-green LED as the emission light source and an avalanche photodiode as the detector at the receiving end. Using OFDM, he completed an underwater communication experiment with a communication rate of up to 10 Mbit/s and a bit error rate as low as 10^{-4} in a 1.5-m pool in the laboratory.

In 2021, Dong et al. [136] used four 470-nm blue light-emitting diodes to form a light source array. The receiving optical transceiver used Fresnel lens imaging to

achieve large field-of-view reception. The detector used avalanche photodiodes. An underwater communication experiment was completed in a 20-m pool with a communication rate as high as 5 Gbit/s and a bit error rate as low as 10^{-6}.

In 2021, Xu et al. [137] proposed the use of soft spread spectrum software with five times the spread spectrum gain to improve the receiving sensitivity of underwater optical communication systems. Simulations verified that spread spectrum technology could extend the communication distance. The experimental results showed that when the signal bandwidth was 200 MHz, the sensitivity of the system receiver increased by 4.8 dB to −32.5 dBm, which is equivalent to the communication distance being extended by 5.8 m.

In 2021, He et al. [138] studied an underwater optical communication system with an adaptive alignment. The system used a high-power blue laser diode as the emission light source, and the receiver used an avalanche photodiode as the detector. An error-free underwater experiment was conducted in a pool with a 30-m communication distance and achieved a 100 Mbit/s transmission.

In 2021, Ma et al. [139] designed a high-speed underwater video transmission system using a novel underwater image transmission method. The system used a blue-green LED as the emission light source and PPM mode to complete the high-definition video transmission experiment. The communication distance was 1.4 m and the bit error rate was less than 10^{-6}.

In 2021, Li et al. [140] studied a DC-biased optical OFDM underwater optical communication system using digital preequalization technology. The system used a blue-green LED as the emission light source and a photodiode as the detector. An underwater experiment with a communication distance of 1 m, a data transmission rate of 32 Mbit/s, and a bit error rate lower than 10^{-3} was successfully completed in clean water.

In 2021, Li et al. [141] studied a MIMO underwater optical communication system. The system used six blue-green LED arrays as the emission light source, and the receiver detector was composed of three photomultiplier tubes. The data transmission rate was 1 Mbit/s, and the bit error rate was 1.1×10^{-5} in a 10-m-deep water tank in a laboratory. The signal-to-noise ratio was 21.4 dB.

In 2021, Chai [142] used a 470-nm blue laser diode as the emission light source, the receiver used an avalanche photodiode as the detector, and the improved OFDM mode was adopted. In a laboratory water tank, the data transmission rate was up to 6.28 Mbit/s, the communication distance was up to 1.8 m, and the bit error rate was as low as 9.552×10^{-6}.

In 2021, Shen [143] used a 24-W high-power blue-green LED as the transmitting light source, and the receiving optical antenna used an aspheric lens with a 50-mm diameter, and the switch keying modulation mode was adopted. An underwater experiment was completed with a data transmission rate of up to 18 Mbit/s, communication distance of up to 16 m, and communication error rate of less than 10^{-7}. It completely transmitted pictures, files, text, and other data streams.

In 2022, Fei et al. [144] used 450-nm laser diode and switch keying modulation. In a laboratory water tank, the data transmission rate was up to 3 Gbit/s, the

communication distance was up to 100.6 m, and the bit error rate was as low as 4.2×10^{-5}.

In 2022, Ke et al. at Xi'an University of Technology [145] designed an underwater optical communication model with a receiving antenna consisting of a double compound eye lens using a blue-green LED light source and a switch keying modulation mode. The system was tested in the laboratory through different suspended particle turbidities and transmission distances, verifying its feasibility.

In 2022, Shi et al. [146] studied a method to directly detect the channel of an underwater optical communication system by means of end-to-end deep learning and used this method to study and compare the signal-to-noise ratio and bit error rate of the underwater communication system. The experimental results showed that the depth learning algorithm performed better than the traditional least mean-squares algorithm. When the communication distance was 15 m, the SNR was 67 dB, and the bit error rate was 7.02×10^{-4}.

In 2022, Li et al. [147] studied a high-power underwater laser emission system device. The light source of the system used a 532-nm green laser diode with an average power of up to 2 W in an underwater optical communication experiment. The experimental results showed that when using a high-power laser diode, the communication distance was up to 150 m, the communication rate was up to 1.2 Mbit/s, and the bit error rate was 3.5×10^{-4}.

In 2022, Zhang et al. [148] studied an underwater weak light signal detection method based on adaptive stochastic resonance. By analyzing the characteristics of underwater weak light signals and the stochastic resonance detection mechanism, a second sampling was introduced to make stochastic resonance applicable to optical signal detection at any frequency. To verify the effectiveness of this method, an underwater optical wireless communication (UOWC) experimental system based on an avalanche photodiode was built. The experimental results showed that when the SNR was −4.559 dB, the bit error rate was 5×10^{-4}. This further proved that underwater weak light signal detection based on adaptive stochastic resonance could significantly improve the bit error rate performance of the UOWC receiver.

In 2022, Wang [149] used a blue-green laser diode as the emission light source, an avalanche photodiode as the detector at the receiving end, and the RS (255, 233) coding method. In the laboratory's water tank, he completed an underwater full-duplex communication experiment with a data transmission rate of up to 50 Mbit/s, a communication distance of up to 30 m, and a bit error rate as low as 10^{-13}.

In 2022, Chen et al. [150] used an LED as the emission light source and an avalanche photodiode as the detector at the receiving end. They successfully implemented an underwater communication experiment with a 2.5-m communication distance and a data transmission rate of up to 50 Mbit/s using the OFDM QAM method. The measured channel signal-to-noise ratio was 6.62 dB on average, and the maximum was 33.55 dB.

Domestic research progress on underwater optical communication systems is summarized in Table 31.4.

Table 31.5 summarizes the domestic research progress in underwater optical communication systems, according to the communication rates (kbit/s, Mbit/s, and Gbit/s).

Table 31.4 Domestic research progress in underwater optical communication systems

Year	Researcher	Research contents	Research results
1989	Ao et al.	Laser submarine communication using error simulation, pulse position modulation, and RS coding	RS error correction coding can greatly improve the channel bit error rate
1995	Wang et al.	Design of a new time slot synchronizer for laser underwater communication	The synchronizer has good anti-noise performance and can meet the requirements of an underwater signal detection and demodulation unit
1992	Sui et al.	Different modulation methods were used in an underwater communication system	When the relative phase shift keying modulation mode is used, the bit error rate is the minimum at 10^{-8}
1997	Yang et al.	Laser underwater communication system using photomultiplier tubes and RS coding	If the bit error rate is controlled below 10^{-8}, more than 1 dB of coding gain can be obtained
1999	Ao et al.	Underwater laser communication model using an adaptive array intensifier and diversity reception	The output signal-to-noise ratio of the adaptive array signal intensifier is proportional to the number of array input signals
2006	Ao et al.	A highly sensitive digital optical receiver for underwater communication systems was designed	The receiver reduces the system requirements for the signal-to-noise ratio and achieves good performance
2012	Wang et al.	Variable gain amplifier was used to reduce the dynamic range of the received signal, and two controllable gain methods were proposed	This method can effectively compress the dynamic range of the signal and make it stable
2021	Xu et al.	Used soft spread spectrum software with five times the spread spectrum gain to improve the receiver sensitivity of underwater optical communication systems	The sensitivity of the receiving end of the system increased to −32.5 dBm, 4.8 dB higher, which is equivalent to extending the communication distance 5.8 m
2022	Ke et al.	Designed an underwater optical communication model with a blue-green LED light source, and a double compound eye lens composed of a receiving antenna and a compound eye lens	The communication distances are 1 m, 3 m, and 5 m. the received optical power of the double-layer compound eye system is, respectively, 72%, 65%, and 60% higher than that of the single-layered system

Table 31.5 Domestic progress in terms of kbit/s, Mbit/s, and Gbit/s communication rates

Classification	Year	Researcher	Communication rate	Communication distance	Error rate
Kbit/s	1987	Jiang et al.	640 kbit/s	–	5.2×10^{-2}
	1998	Huang et al.	21.2 kbit/s	3 m	2.8×10^{-3}
	2002	Huang et al.	20 kbit/s	50 m	1.76×10^{-3}
	2008	Luo et al.	125 kbit/s	2 m	Error free
	2009	He et al.	30 kbit/s	–	Error free
	2010	Liu et al.	–	60 m	$< 10^{-4}$
	2013	Zhu et al.	73 kbit/s	2 m	Error free
	2013	Tian et al.	38.4 kbit/s	30 m	–
	2015	Cai et al.	115.2 kbit/s	10 m	Almost error free
	2018	Zhang	9.6 kbit/s	3 m	$< 10^{-5}$
Mbit/s	2004	Pang	1/3 Mbit/s	10/13 m	8×10^{-9}/ 7.31×10^{-9}
	2008	Cui	2 Mbit/s	30 m	–
	2011	Cong	3 Mbit/s	20 m	4×10^{-4}
	2013	Xu et al.	161.36/156.31/ 131.07 Mbit/s	–	2.5×10^{-3}/7.42×10^{-4}/3.17×10^{-3}
	2016	Hu et al.	60 Mbit/s	5 m	Error free
	2017	Ao et al.	10 Mbit/s	2.3 m	Error free
	2017	Lin	80 Mbit/s	2 m	2.24×10^{-3}
	2017	Song	31.082 Mbit/s	2 m	$< 10^{-4}$
	2018	Wang et al.	0.98 Mbit/s	6 m	Error free
	2018	Han	20 Mbit/s	9.6 m	10^{-9}
	2018	Yang et al.	6 Mbit/s	3 m	7×10^{-4}
	2018	Li	100 Mbit/s	16 m	2.4×10^{-6}
	2018	Wang et al.	25 Mbit/s	10 m	$< 10^{-4}$
	2019	Wang et al.	500 Mbit/s	100 m	2.5×10^{-3}
	2019	Wang et al.	50 Mbit/s	3 m	7.11×10^{-4}
	2019	Shang	75 Mbit/s	4 m	Error free
	2020	Li et al.	1 Mbit/s	10 m	3.9×10^{-6}
	2020	Tong	100 Mbit/s	1.5 m	$< 10^{-4}$
	2021	Li et al.	32 Mbit/s	1 m	10^{-3}
	2021	Li et al.	1 Mbit/s	10 m	1.1×10^{-5}
	2021	He et al.	100 Mbit/s	30 m	Error free
	2021	Chai	6.28 Mbit/s	1.8 m	$< 9.552 \times 10^{-6}$
	2021	Shen	18 Mbit/s	16 m	$< 10^{-7}$
	2022	Wang	50 Mbit/s	30 m	$< 10^{-13}$
	2022	Chen et al.	50 Mbit/s	2.5 m	–
	2022	Li et al.	1.2 Mbit/s	150 m	3.5×10^{-4}
Gbit/s	2015	Liu et al.	2.7 Gbit/s	35 m	3.8×10^{-3}
	2016	Shen et al.	2/1.5 Gbit/s	12/20 m	2.8×10^{-5}/3.0×10^{-3}

(continued)

Table 31.5 (continued)

Classification	Year	Researcher	Communication rate	Communication distance	Error rate
	2016	Lu et al.	9.6 Gbit/s	8 m	10^{-4}
	2016	Xu et al.	1.324/4.883 Gbit/s	6 m	2.02×10^{-3}/3.20×10^{-3}
	2017	Chen et al.	5.3/5.5 Gbit/s	21 m	2.47×10^{-3}/2.92×10^{-3}
	2018	Huang et al.	14.8/10.8 Gbit/s	1.7/10.2 m	1.9×10^{-5}/1.5×10^{-4}
	2019	Hong et al.	18.09/19.21/ 12.62 Gbit/s	5/25/35 m	Capacity increased by 32.22%, 30.03%, and 31.55%, respectively
	2019	Zhou et al.	15.17 Gbit/s	1.2 m	3.8×10^{-3}
	2019	Han	6.23 Gbit/s	66 m	$< 10^{-4}$
	2020	Ji et al.	5/4.5 Gbit/s	50/55 m	–
	2021	Dong et al.	5 Gbit/s	20 m	10^{-6}
	2022	Fei et al.	3 Gbit/s	100.6 m	4.2×10^{-5}

With the improvement in channel coding and modulation, the communication rates of systems are increasing from kbit/s and Mbit/s to Gbit/s. However, in a real underwater environment, the channel is subject to the influences of temperature, salinity, and other parameters, and most of the above experiments were carried out in laboratories, not in real rivers and oceans. This may result in a significant difference between the experimental results and the actual application results. Therefore, actual ocean exploration needs further research.

Moreover, the communication distance of most underwater optical wireless communication system experiments can only reach a few meters to tens of meters, and only a few experiments reach 100 m. Therefore, increasing the communication distances of underwater optical wireless communication systems is a current challenge, and more experiments are required to address this in the future.

Key Technologies in Underwater Optical Wireless Communication

Channel Modeling of Underwater Optical Wireless Communication Systems

Optical Properties of Water

According to Mobley's theory, water has two types of optical properties: intrinsic and apparent [11]. The inherent optical properties of water mainly include absorption and scattering coefficients. Compared with the apparent optical properties, the

inherent optical properties have a greater impact on the performance of underwater optical wireless communication; therefore, research has mainly focused on inherent optical properties.

The underwater environment is complex, and absorption and scattering have a serious impact on beam propagation, resulting in attenuation [151]. The absorption characteristic shortens the communication distance, and the scattering characteristic affects the propagation direction of light. This results in a multipath effect that reduces the signal-to-noise ratio and increases the bit error rate. Figure 31.2 shows the geometric structure of the inherent optical properties of seawater.

According to the law of conservation of energy [37],

$$P_I(\lambda) = P_A(\lambda) + P_S(\lambda) + P_T(\lambda), \tag{31.1}$$

where λ is the wavelength, ΔD is the width of the water tank, $P_I(\lambda)$ is the incident light power, $P_A(\lambda)$ is the absorbed light power of the water, $P_S(\lambda)$ is the scattered light power, and $P_T(\lambda)$ is the output light power.

Using the absorbance definition formula, the absorption coefficient can be obtained as follows [37]:

$$a(\lambda) = \lim_{\Delta D \to 0} \frac{P_A}{P_I \Delta D}. \tag{31.2}$$

The underwater light absorption coefficient can be expressed as four parts: pure seawater absorption ($a_\omega(\lambda)$), detritus absorption ($a_{\text{det}}(\lambda)$), phytoplankton absorption ($a_{phy}(\lambda)$), and colored dissolved organic matter absorption ($a_{CDOM}(\lambda)$). Therefore [1],

$$a(\lambda) = a_\omega(\lambda) + a_{\text{det}}(\lambda) + a_{phy}(\lambda) + a_{CDOM}(\lambda). \tag{31.3}$$

Using the definition for the scattering degree, the scattering coefficient can be obtained as follows [37]:

$$b(\lambda) = \lim_{\Delta D \to 0} \frac{P_S}{P_I \Delta D}. \tag{31.4}$$

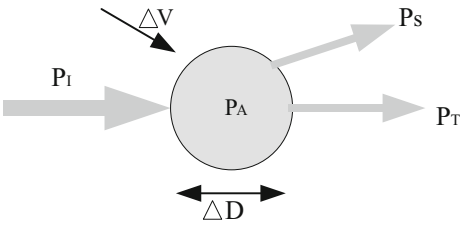

Fig. 31.2 Geometric structure of inherent optical properties of seawater

The underwater light scattering coefficient can be represented by three parts: pure seawater scattering ($b_\omega(\lambda)$), detritus scattering ($b_{\text{det}}(\lambda)$), and phytoplankton scattering ($b_{phy}(\lambda)$); hence [1],

$$b(\lambda) = b_\omega(\lambda) + b_{\text{det}}(\lambda) + b_{phy}(\lambda). \tag{31.5}$$

The attenuation coefficient of light $c(\lambda)$ can be expressed as [37].

$$c(\lambda) = a(\lambda) + b(\lambda), \tag{31.6}$$

where the attenuation coefficient is expressed in m^{-1}. The attenuation coefficient $c(\lambda)$ is related to many factors of the seawater environment, including the seawater salinity, turbidity, and even plankton.

The correlation coefficients for different seawater samples are listed in Table 31.6. It can be seen that the main substances in pure seawater are water and inorganic salts; thus, the attenuation is mainly caused by absorption. The scattering coefficient is relatively low and can be ignored. In clear seawater, the concentration of colored dissolved organic matter is relatively large, which mainly affects the light scattering. In coastal seawater, phytoplankton and debris cause light absorption and scattering. In turbid harbors, suspended particles and debris cause severe light beam attenuation.

The Beer–Lambert law can be used to describe the attenuation effect of light under water [152]; its expression is as follows:

$$I = I_0 e^{-c(\lambda)d}, \tag{31.7}$$

where I_0 is the transmitted light power, $c(\lambda)$ is the attenuation coefficient, d is the transmission distance, and I is the residual optical power after reaching the transmission distance, d. The value of $c(\lambda)$ changes with the difference in the water area type and water depth.

A model with two exponential functions that can more accurately describe the power loss of the underwater channel can also be obtained from the Beer–Lambert law; its expression is as follows [153]:

$$I = I_0 e^{-c_1(\lambda)d} + I_1 e^{-c_2(\lambda)d}. \tag{31.8}$$

In this formula, the first index indicates that the diffusion length is greater than the attenuation loss length, and the second index indicates that the diffusion length is less than the attenuation loss length. The specific parameters are listed in Table 31.7.

Table 31.6 Typical absorption ($a(\lambda)$), scattering ($b(\lambda)$), and attenuation ($c(\lambda)$) values for four different water qualities [58]

Water quality	a(λ)(m^{-1})	b(λ)(m^{-1})	c(λ)(m^{-1})
Pure seawater	0.041	0.003	0.044
Clear seawater	0.114	0.037	0.151
Coastal seawater	0.179	0.219	0.398
Turbid port water	0.366	1.824	2.190

Table 31.7 Parameters for the power loss model of a long-distance underwater channel [154]

Seawater conditions	$C(mg/m^3)$	$I_0(m^{-1})$	$c_1(\lambda)(m^{-1})$	$I_1(m^{-1})$	$c_2(\lambda)(m^{-1})$
Pure seawater	0.0050	0.2000	0.0657	0.0046	0.2634
Clear seawater	0.3100	0.1000	0.1508	0.1589	0.4937

Generally speaking, when light travels underwater, absorption and scattering cause three problems: First, absorption reduces the total energy of the light, which limits the communication distance. Second, scattering diffuses the beam, thereby reducing the total number of photons received. Third, scattering causes photons to arrive at the receiver at different times, resulting in a multipath phenomenon. Therefore, to solve these problems, extensive research and experiments should be conducted on the factors that affect underwater channels. Over the past few years, researchers have designed many reliable underwater optical wireless communication system models. The following are the three main underwater-channel modeling methods.

Model of an Underwater Turbulent Channel

When light propagates underwater, it is affected not only by absorption and scattering but also by underwater turbulence. Underwater turbulence refers to a change in the random refractive index when a light beam passes through a water body [155]. The refractive index of underwater turbulence is not only affected by temperature but also by the water quality, salinity, and other factors. Underwater turbulence also changes with a change in geographical location [156]. However, it still conforms to the hydrodynamic equation [157].

Nikishov [158] proposed a method to describe the complex underwater turbulence spectrum, considering the temperature, salinity, refractive index, and other factors, which well simulate the transmission of light in water. The underwater refractive index fluctuation spectrum can be expressed as [159]

$$\begin{aligned}\Phi(k) = {} & 0.388 \times 10^{-8}\varepsilon^{-1/3}(k)^{-11/3}\left[1 + 2.35(\eta k)^{2/3}\right] \\ & \times \frac{\chi_T}{w^2}\left(w^2 e^{-A_T\delta} + e^{-A_S\delta} - 2we^{-A_{TS}\delta}\right),\end{aligned} \tag{31.9}$$

where k is the spatial wave number, ε is the kinetic energy dissipation rate of the water medium, η is the Kolmogorov internal scale, and χ_T is the temperature dissipation rate. From the water surface to underwater, the range of χ_T is [10] K^2/s. w is the underwater turbulence ratio caused by salinity and temperature, $A_T = 1.863 \times 10^{-2}$, $\delta = 8.284(\eta k)^{4/3} + 12.987(\eta k)^2$, $A_S = 1.9 \times 10^{-4}$, and $A_{TS} = 9.41 \times 10^{-3}$.

Because the underwater environment is more complex than the atmospheric environment, multiple underwater parameters must be expressed together. The following are the four turbulence parameters of the underwater turbulence intensity.

1. Temperature Dissipation Rate χ_T: The temperature change is closely related to the turbulence state. The temperature dissipation rate can be used to express the influence of the temperature change on the underwater turbulence parameters; its expression is [160]

$$\chi_T = 2\kappa_T \left\langle \left(\frac{\partial T}{\partial x}\right)^2 + \left(\frac{\partial T}{\partial y}\right)^2 + \left(\frac{\partial T}{\partial z}\right)^2 \right\rangle, \tag{31.10}$$

where T represents the temperature value and κ_T is the temperature difference coefficient. Assuming that the water quality is uniform, $\frac{\partial T}{\partial x}$ represents the temperature gradient in the x direction, $\frac{\partial T}{\partial y}$ represents the temperature gradient in the y direction, and $\frac{\partial T}{\partial z}$ represents the temperature gradient in the z-direction. The temperature gradient at each location is the same. The above equation can be simplified as [161]

$$\chi_T = 6\kappa_T \left\langle \left(\frac{\partial T}{\partial z}\right)^2 \right\rangle, \tag{31.11}$$

where T represents the temperature, κ_T is the temperature difference coefficient, and $\frac{\partial T}{\partial z}$ represents the temperature gradient in the z-direction. The larger the temperature dissipation rate, the stronger the stratification of the water area, and the stronger the underwater turbulence.

2. Kinetic Energy Dissipation Rate ε: With isotropy and uniform water quality, the kinetic energy dissipation rate per unit of fluid mass can be expressed as [161]

$$\varepsilon = \frac{15v\left\langle (\partial u/\partial z)^2 \right\rangle}{2}, \tag{31.12}$$

where v is the viscosity of the molecular motion, and $\partial u/\partial z$ represents the derivative of the turbulent velocity.

3. Underwater Turbulence Ratio w Caused by Temperature and Salinity: When the temperature gradient is constant, w can be expressed as [161]

$$w = \frac{\alpha(\Delta T/\partial z)}{\beta(\Delta S/\partial z)}, \tag{31.13}$$

where α and β are constants, ΔT is the temperature difference between the water surface and underwater, and ΔS is the salinity difference between the water surface and underwater.

4. Kolmogorov Internal Scale η: The minimum underwater turbulence scale is the Kolmogorov internal scale, and its expression is [158]

$$\eta = \left(v^3/\varepsilon\right)^{1/4}, \tag{31.14}$$

where v is the kinematic viscosity variable, and $\varepsilon$is the turbulent flow energy dissipation rate. From Eq. 31.14, it can be seen that the Kolmogorov internal scale increases with an increase in the kinematic viscosity and decreases with an increase in the turbulent flow energy dissipation rate.

In recent years, many researchers have investigated the effects of turbulence on underwater optical wireless communication systems and also proposed models to suppress the turbulence effects. Marine turbulence channel models include the generalized gamma turbulence model, logarithmic normal turbulence model [159], and the MIMO channel turbulence model [162].

In 2014, Hamza et al. [163] established a fading model of a Gaussian lognormal distribution in weak ocean turbulence using the Rytov method. A formula for the on-axis scintillation index of focused Gaussian beams in weak ocean turbulence was derived, and the average bit error rate was calculated using this formula. In the same year, Tang et al. [164] used a double-gamma function to model the impulse response of an underwater optical communication link in coastal and port waters. The model was consistent with the Monte Carlo simulation results, and the effective region of the model was further studied.

In 2017, Oubei et al. [73] modeled an underwater channel with a temperature gradient and adopted an experimental method with a generalized gamma distribution. The experimental results showed that the measured data under all underwater channel conditions fit the distribution. In addition, it was observed that a thermally homogeneous channel could be well described by a simple gamma distribution. This was the first model to comprehensively describe a thermally homogeneous and gradient-based underwater optical channel.

In 2020, Du [165] studied the bit error rate performance of optical wireless communication systems using pulse position modulation (PPM) in ocean anisotropic turbulence and calculated the bit error rate using the double-gamma distribution method. In 2021, He et al. [166] experimented with underwater optical communication systems using a marine turbulent channel transmission model with a double-gamma distribution. They analyzed and compared the average bit error rate of underwater optical communication systems with different wavelengths.

Jamali et al. [74] used MIMO spatial diversity technology on an underwater optical wireless communication link to mitigate the fading caused by turbulence. Considering the effects of absorption and scattering, the exact expressions of the optimal gain, equal gain combination, and upper bound of the BER were obtained using the analytical solution method.

In 2016, Li et al. [167] considered anisotropic turbulence using a Gaussian–Schell model of a seawater channel. It was concluded that the greater the temperature fluctuation was, the greater the depolarization effect. However, the depolarization effect of anisotropic turbulence was weaker than that of isotropic turbulence. In 2019, Zou et al. [168] used a partially coherent Gaussian beam SISO model to

analyze the average capacity of an underwater optical wireless communication system under weak ocean turbulence.

In 2021, Jiang [159] analyzed different ocean turbulence models, including the lognormal distribution, exponential logarithmic distribution, Weibull distribution, gamma–gamma distribution, and generalized gamma distribution, and provided their probability density functions. Finally, the Monte Carlo simulation method was used to verify the accuracy of asymmetric clipped optical OFDM and DC-biased optical OFDM spatial diversity systems under different turbulence environments.

At present, the characteristics of underwater channels in underwater optical communication systems are mainly studied in the laboratory through simulations. The simulated marine environment is somewhat different from actual seawater, which makes the experimental data insufficient and reliable. In the future, a comprehensive experimental study of the influence of turbulence on underwater channels should be conducted in a real marine environment.

Channel Attenuation Model

Because the underwater environment is much more complex than the air environment, underwater optical wireless communication research is challenging, owing to the absorption and scattering of light when it propagates underwater. The attenuation of light beams in water is approximately 100–1000 times higher than that in air [169]. Therefore, one of the main objectives of underwater optical communication channel modeling is to evaluate the overall path attenuation loss.

The optical path attenuation model of underwater optical communication mainly consists of direct and indirect view models, both of which can be obtained using the Monte Carlo method. These modeling methods are described in detail below.

Direct Viewing Model

Two methods are used for modeling the direct view model: the radiative transfer equation and the Beer–Lambert law. The light attenuation effect in a simple underwater environment can be expressed using the Beer–Lambert law [1]. The Beer–Lambert law is an exponential attenuation model that is typically used to calculate the optical path loss [170]. Smar [170] used the Beer–Lambert law to study and experiment with a direct viewing underwater optical communication system and obtained the performance of an underwater optical wireless communication system under different water qualities and communication distances.

However, in actual underwater communication, most researchers have chosen the radiative transfer equation model. The radiative transfer equation is a general theoretical model. Jaruwatanadilok expressed the radiative transfer equation as [56]

$$\vec{n}\cdot\nabla L\left(\lambda,\vec{r},\vec{n}\right)=-cL\left(\lambda,\vec{r},\vec{n}\right)+\int_{2\pi}\beta\left(\lambda,\vec{n},\vec{n}'\right)L\left(\lambda,\vec{r},\vec{n}'\right)d\vec{n}'+E\left(\lambda,\vec{r},\vec{n}\right). \tag{31.15}$$

All parameters in the formula are related to the wavelength. c is the attenuation coefficient, ∇is the divergence operator, $L\left(\lambda, \vec{r}, \vec{n}\right)$ is the optical radiance propagating in direction $\vec{n}$ at location $\vec{r}$, $E\left(\lambda, \vec{r}, \vec{n}\right)$ is the source radiance, and $\beta\left(\lambda, \vec{n}, \vec{n}'\right)$ is the volume scattering function.

The radiative transfer equation model includes two common solutions: analytical and numerical [171]. The radiative transfer equation considers the polarization and multiple scattering of light, which can more accurately simulate the attenuation of underwater beam propagation. However, the radiative transfer equation is a complex multivariable calculus equation, and it is very difficult to find a general analytical solution form. Therefore, researchers generally use the probability method to obtain a numerical solution to the radiative transfer equation.

Numerical solution methods include the Monte Carlo, discrete ordinate, random model, and invariant embedding methods [14]. Because the invariant embedding method can only solve a one-dimensional radiative transfer equation, it is unsuitable for underwater optical wireless communication systems. The discrete ordinate method is difficult to program and generally not selected [171]. The stochastic model, based on the probability property of the photon trajectory, is not yet mature and therefore rarely used. The Monte Carlo method is the most widely used. Therefore, only the application of the Monte Carlo method to underwater optical wireless communication systems is studied here.

In 2008, Jaruwatanadilok [56] used the vector radiative transfer theory to model an underwater optical communication system and quantized the relationship between the scattering, distance, and bit rate through a Monte Carlo simulation. In 2009, Cochenour et al. [58] proposed a beam spread function for an underwater optical communication system and used the small-angle approximation method to solve the radiative transfer equation.

In 2015, Li et al. [171] proposed a fast numerical solution for the radiative transfer equation to calculate the optical path loss of underwater channel attenuation. The results showed that this method was faster than the traditional Monte Carlo method. In 2018, Illi et al. [76] proposed an improved radiative transfer equation to predict the optical path loss in an underwater channel and calculated the change in the bit error rate performance of an underwater optical wireless communication system with the transmission time and distance.

In 2019, Illi et al. [77] further improved the radiative transfer equation calculation method. The experimental results showed that the improved radiative transfer equation could obtain the same results by calculating the bit error rate of the underwater optical wireless communication system. It was consistent with the Monte Carlo simulation results, thereby reducing the complexity of the system.

Because of the complexity of calculating the radiative transfer equation, it is difficult to obtain an accurate solution. The Monte Carlo method is simple to program, flexible, and calculates accurately; therefore, it is often used to solve the radiative transfer equation. Using Monte Carlo simulations, the US Naval Laboratory published a usage guide for underwater optical wireless communication. It was

proven effective by many researchers and adopted by many scholars studying underwater optical wireless communication [1].

Li et al. [172] used the Monte Carlo model to study the channel capacity of underwater optical communications. This model can flexibly represent various parameters of the transmitter, receiver, and channel and is applicable to the design of physical underwater optical communication links. Gabriel et al. [173] proposed the channel impulse response of underwater optical wireless communication systems for different water quality types by solving the radiative transfer equation through a Monte Carlo simulation. The above research methods are mainly aimed at the underwater optical communication channel model, and there is no requirement for the communication distance.

Hanson [54] conducted an experiment by simulating dozens of meters of seawater path using the Monte Carlo method; the results showed that the underwater optical communication rate reached 1 Gbit/s. Dalgleish et al. [174] used the Monte Carlo method to calculate a 500-ps laser pulse in a 12.5-m test box and obtained the pulse response under different environments.

In addition to using the Monte Carlo method, Ding et al. [175] introduced a multiple scattering channel model, in which the optical power at the receiver could be solved using Monte Carlo integration as the multiple integration of the probability density function.

In 2020, Yuan et al. [176] obtained the impact response function of the system through Monte Carlo integration in optical wireless multiscattering channel communication. The experimental results showed that for third-order scattering, compared with the original Monte Carlo integration based on uniform sampling, the computational efficiency of the Monte Carlo integration model based on partial importance sampling was improved by 12 times, which is 5.6 times that of the widely used Monte Carlo simulation model. For high-order scattering, the Monte Carlo integration model based on partial importance sampling has higher computational efficiency than the Monte Carlo simulation model.

Owing to the simplicity of modeling and implementing direct viewing channels, most underwater optical wireless communication experimental systems use direct viewing links. However, the direct view model must be a point-to-point transmission, and it is difficult to achieve point-to-point transmissions in underwater environments, owing to the scattering effect; therefore, the direct view model has certain limitations in underwater optical wireless communication systems.

Indirect Viewing Model

In traditional direct view links, signals are transmitted from point to point. Obstacles in the propagation path can attenuate or even hinder the propagation of optical signals. An indirect viewing model was proposed to solve this problem. The indirect viewing model uses a reflected beam of water molecules to overcome obstacles in the communication link [14]. Similar to the direct viewing channel model, the indirect viewing channel model is mostly simulated using the Monte Carlo method.

Arnon et al. [177] studied a new indirect viewing underwater optical wireless communication network using the Monte Carlo method and deduced the

mathematical model of the channel. Tang et al. [178] studied the path loss of an indirect viewing underwater optical wireless communication link, based on Monte Carlo simulation, and considered the influence of seawater scattering characteristics. The experimental results showed that with an increase in attenuation length, the scattered light could eliminate the influence of the random surface slope caused by wind on the received signal.

Jagadeesh et al. [179] proposed an indirect viewing underwater optical wireless communication model to evaluate channel characteristics using the Monte Carlo simulation method. The performance of the underwater system under different water types and receiving fields of view was characterized and simulated using the derived impulse response model. The results showed that this model provided a new method for characterizing indirect viewing underwater optical wireless communication channels.

Anous et al. [180] evaluated the system performance of direct and indirect view underwater optical wireless communication, based on the underwater optical communication vertical link model. Considering the heterogeneity of underwater environments, a simple two-layer model was established to accurately calculate the link budget. Doniec et al. [64] introduced a general model of an end-to-end underwater optical communication system, which provides a reference for later research on underwater communication models.

Modeling Cross-Media Transmissions

In an underwater optical communication system, the light beam must cross atmospheric, air, sea, and water channels. Different channels differently affect the optical transmission characteristics. The substances that affect the beam propagation in atmospheric channels include aerosols, atmospheric molecules, fog, and rain. Because the sea surface is affected by the sea wind, the light beam experiences serious refraction and reflection. The main factors affecting light beam transmission in water channels are biological particles and soluble organic matter.

At present, extensive research has been conducted on the transmission characteristics of light beams in different channels at home and abroad; however, most of them are for a single channel, which cannot meet the design requirements of cross-medium channel modeling.

The wave spectrum selected for wave modeling is the Pierson–Moskowitz (PM) spectrum. Its specific expression is [181]

$$S(\omega) = \frac{g^2\kappa}{\omega^5} \exp\left[-\vartheta\left(\frac{g}{U\omega}\right)^4\right], \tag{31.16}$$

where g is the acceleration of gravity, ω is the angular frequency, $\kappa = 8.1 \times 10^{-3}$ is the dimensionless quantity, $\vartheta = 0.74$, and U is the wind speed 21.5 m from the sea surface.

The wave spectrum is generally the product of the spectrum and direction function, and its expression is [181]

$$S(\omega, \theta) = S(\omega)\varphi(\theta), \tag{31.17}$$

where $S(\omega)$ is the frequency spectrum, $\varphi(\theta)$ is the direction function, and θ is the wind direction angle in the propagation direction.

The direction function is more specific than the frequency spectrum when describing the propagation direction of the sine wave, and its expression is [182]

$$\varphi(\theta) = \frac{2}{\pi}\cos^2(\theta). \tag{31.18}$$

When the laser is at the air–sea interface, the reflectivity and transmissivity can be calculated according to the polarization state of the laser. According to Fresnel's law and Snell's law, the total transmissivity of the air–sea interface is [183]

$$L_{bd} = L_{bd1} + L_{bd2} \tag{31.19}$$

$$L_{bd1} = \frac{1}{2}\left|\frac{\sin 2\alpha \sin 2\beta}{\sin(\alpha+\beta)} \cdot \frac{1 + \cos^2(\alpha-\beta)}{\cos^2(\alpha-\beta)}\right|, \tag{31.20}$$

where L_{bd1} is the transmissivity of the air–sea interface itself, α is the reflection angle, β is the transmission angle, and L_{bd2} is the transmissivity of bubbles and white waves passing through the air–sea interface.

Currently, cross-medium wireless communication between underwater and air has become an important development field. Liu et al. [182] studied the distribution and loss characteristics of a cross-medium uplink laser in the transmission process, using a Monte Carlo simulation method at different underwater transmission distances and different sea surface wind speeds. Li et al. [184] used the Monte Carlo simulation method to analyze the downlink cross-medium transmission characteristics of light in an atmospheric air–seawater channel under sunny, stratiform, and cirrus cloud weather conditions.

Si et al. [185] studied seawater–atmosphere cross-medium uplink communication and described in detail the impact of the wave surface on optical uplink transmissions. Chen et al. [186] discussed light scattering across the air–sea interface using the Kirchhoff model and first-order small perturbation model theory in rough surface scattering. Wang et al. [187] studied the factors that affect laser transmission in the air–seawater cross-medium channel and deduced the energy equation of blue-green light passing through the cross-medium channel.

Li et al. [188] studied the transmission characteristics of the air–underwater cross-medium channel and concluded that its attenuation was mainly related to weather conditions, seawater transparency, etc. Zhang et al. [189] established a model for the dynamic downward transmission of a blue-green laser across the air–sea channel by considering real seawater conditions, such as different near-sea atmospheric sea-fog visibility, chlorophyll concentrations, and bubble concentrations.

Research on cross-medium channels is still limited. For example, in experiments on vertical links, researchers regard seawater as a uniform medium; however, the salinity and chlorophyll concentration differ at different depths in vertical seawater,

and the experimental results will not match the actual situation. At present, most research on cross-media channels is about downlink transmissions, while research on uplink and downlink transmissions is scarce.

Light Source Selection

Different light sources have different transmission distances underwater, and the stability of the light path is also different. The choice of the light source can determine the communication distance and modulation bandwidth. Seawater absorbs less blue-green light in the 450–550 nm wavelength range [39]. Seawater near the coast is more suitable for using green light as the light source, and the deep sea is more suitable for using blue light as the light source [190].

There are three types of light sources for underwater optical communication: light-emitting diodes (LEDs), laser diodes, and superradiant laser diodes. LEDs have the advantages of low cost, convenient production, and good safety; therefore, LEDs are currently the most widely used light sources. However, LEDs have disadvantages of non-aggregation, poor coherence, a large divergence angle, and difficulty with underwater transmissions.

The laser diode has good directivity and coherence, but is sensitive to temperature; therefore, a temperature controller is needed for applications. Superradiant laser diodes are semiconductor optoelectronic devices between light-emitting diodes and laser diodes that can output weak coherent light [191]. However, their reliability has not yet been evaluated and there is a risk of poor coupling [192]. Therefore, Table 31.8 only compares the main performance of LEDs and laser diodes.

The light sources used in underwater optical wireless communication systems are mainly blue-green diodes or laser diodes with a waveband between 450 and 550 nm. The communication distance and rate differ for different light source selections, and the communication distance can be increased by selecting an appropriate light source.

Tian et al. [193] used a blue GaN micro-light-emitting diode as the light source and successfully achieved a data rate of 200 Mbit/s, a communication distance of 5.4 m, and a bit error rate of 3×10^{-6} in underwater experiments. Liu et al. [194]

Table 31.8 Main performance comparison of LEDs and laser diodes

Parameter	Light-emitting diode	Laser diode
Coherence	Incoherent	Coherent
Modulation bandwidth	MHz magnitude	GHz magnitude
Divergence angle	Wide	Narrow
Spectral width	20–100 nm	0.01–5 nm
Photoelectric efficiency	About 50%	About 30%
Service life	Long	Moderate
Temperature sensitivity	Insensitive	More sensitive
Security	Good	Poor

experimentally demonstrated the use of white light generated by hybrid red, green, and blue laser diodes in underwater communication systems. The experimental results showed that the data rate was up to 8.7 Gbit/s in the 2.3-m underwater link.

Chao et al. [195] used a 450-nm laser diode as a light source in an underwater communication system. The experimental results showed that when the communication distances were 5 m, 35 m, and 55 m, the data transmission rates reached 19.6 Gbit/s, 13.2 Gbit/s, and 6.6 Gbit/s, respectively. Chen et al. [196] completed an underwater experiment with a net data rate of 3.31 Gbit/s and communication distance of 56 m using a 520-nm laser diode and 32-OAM mode.

Arvanitakis et al. [80] used a micro-light-emitting diode array composed of six 80-μm light-emitting diodes in series; it operated at 450 nm. When the communication distance was 4.5 m, the data transmission rate was as high as 3.4 Gbit/s.

Modulation Technology

Underwater optical wireless communication is limited by the devices in the blue and green light bands; thus, it is still in the low communication rate stage. It mainly includes on–off keying (OOK) modulation, pulse position modulation (PPM), and quadrature amplitude modulation (QAM). These modulation methods can achieve high data transmission rates in underwater communication systems; however, the communication distance is quite short.

In recent years, many scholars have achieved good results using improved modulation methods, such as polarized PPM [197], QAM orthogonal frequency-division multiplexing (OFDM) [198], polarized differential pulse position modulation [199], binary polarization shift keying [200], and binary phase shift keying [36].

Through the simulation and comparison of different modulation modes in underwater optical communication systems, Su et al. [201] concluded that PPM was more suitable for low-power submarine systems, and phase shift keying had the best performance in terms of bandwidth and error performance; however, its power efficiency was low. Xi et al. [103] used 4-PPM in underwater optical communications. The experimental results showed that the bit error rate of PPM was almost the same as that of switch keying modulation, and it had a higher spectral efficiency, which proved that 8-PPM and 16-PPM had higher bandwidth utilization.

Gabriel et al. [202] compared several commonly used modulation technologies in underwater optical wireless communication systems, in terms of their energy and bandwidth efficiency. The results showed that although PPM was optimal in terms of energy efficiency, differential PPM had advantages in terms of communication performance and equipment complexity.

Coding Technology

The influences of absorption and scattering on underwater light transmissions not only reduce the communication distance but also increase the bit error rate. Choosing

an appropriate coding technology can reduce the bit error rate. The coding technology used in underwater communication is mainly convolutional codes and block codes [203]. Convolutional codes include low-density parity check codes and turbo codes [204], which include cyclic redundancy check codes, Reed–Solomon (RS) codes, and linear cyclic error correction codes [203].

The RS code is the most widely used coding method in underwater optical wireless communication systems. Cox et al. [205] used a 405-nm laser diode to transmit data to a photodiode receiver using the RS (255, 129) code at a 500-kbit/s communication rate. The experimental results showed that, compared with the uncoded switch keying modulation system, the power required by this coding method was reduced by approximately 8 dB.

Simpson et al. [59] achieved a communication rate of 5 Mbit/s in 3-m and 7.7-m long water tanks by using RS coding. The experiment proved that when the bit error rate was 10^{-6}, the RS (255, 129) code improved the SNR by approximately 6 dB and the RS (255, 223) code improved the SNR by approximately 4 dB.

Cossu et al. [63] conducted an underwater experiment with a communication rate of 58 Mbit/s in a 3.3-m water tank using the RS-forward error correction (FEC) (272, 255) code. The bit error rate decreased from 1.5×10^{-3} to 10^{-9}. A few methods combine RS code and other coding methods. Doniec et al. [206] used a two-layer digital coding scheme that combined cyclic redundancy check codes and RS codes to transmit videos in an underwater optical wireless communication system. This multilayer coding scheme achieved low-delay transmission of video images underwater; however, the system was relatively complex.

Detection Technology

The detectors in underwater systems mainly include PIN photodiodes, avalanche photodiodes, and photomultiplier tubes. PIN photodiodes are mainly affected by thermal noise, whereas avalanche photodiodes are mainly affected by shot noise [207]. The PIN photodiode has a lower gain, whereas the avalanche photodiode has a higher gain. The communication distance in the underwater system is longer, but the internal circuit is more complex. Photomultiplier tubes have higher sensitivity, higher optical gain, and a lower noise level, but they are also have a high voltage supply (approximately 100 V) and high unit cost [208]. Their performances are compared in Table 31.9.

Chao et al. [195] used a silicon-doped PIN photodiode as a receiver to operate in the 320 nm–1100 nm wavelength range, with a response rate of approximately 0.15 A/W at 450 nm. Fei et al. [209] used silicon-doped avalanche photodiodes as receivers to achieve a data rate of 7.33 Gbit/s within 15 m. The avalanche photodiode operated in the wavelength range of 400 nm–1000 nm, and its response rate was approximately 4 A/W at 450 nm.

Sun et al. [210] used a 488-nm blue laser and a photomultiplier detector to achieve high-speed video transmissions with a transmission rate of 5 Mbit/s in a 4.5-m-long underwater channel. Dalgleish et al. [174] completed an underwater laser

Table 31.9 Detector performance comparison

Parameter	PIN photodiode	Avalanche photodiode	Photomultiplier tube
Volume	Small	Small	Large
Sensitivity	Low	Moderate	High
Detection area	Small	Small	Large
Equivalent noise power	High	Low	Extremely low
Use cost	Low	Moderate	High
Response speed	Slow	Fast	Ultrafast
Security	Good	Good	Low

measurement experiment of 500-ps laser pulse propagation using a photomultiplier detector at the receiving end in a 12.5-m water tank.

In underwater optical wireless communication systems, in addition to the three detectors described above, researchers have also doped with other chemicals to achieve better results. Hiskett et al. [66] used silicon avalanche photodiodes as detectors for underwater communication systems. An underwater experiment with a 40 Mbit/s transmission rate was completed in a 1-m-long water tank using a laser diode with a 450 nm wavelength. Li et al. [211] developed an underwater communication system, in which the receiver used a single-photon avalanche diode operating in Geiger mode as the detector, and realized long-distance communication.

Detectors that can detect weak underwater signals should be studied in the future. Detectors with high sensitivity, a large field of view, and low noise are future development directions. They are also a new challenge in underwater optical wireless communication systems.

Underwater Optical Wireless Communication System Design Model

To improve the optical power of the receiving end in an underwater optical wireless communication system, Ke et al. at Xi'an University of Technology studied an underwater communication system using wide-angle focusing double-layer fly eye lens optics [145]. The system used a 530-nm green LED as the emission light source of the underwater blue-green optical communication system and used a combination of a reflective cup and a focusing lens to focus and collimate the light source. In addition, a scheme for an LED drive circuit suitable for the transmitter of the underwater communication system was designed.

The receiving end adopted a compound eye lens optical receiving antenna with wide-angle focusing. According to the geometric optical principle of the lens array, the compound eye lens receiving system was designed and simulated using Zemax software. Finally, an experimental device for determining the receiving efficiency of an underwater communication system was developed.

As shown in Fig. 31.3, the communication performance of the system was tested with different turbidities and communication distances in the water tank and water

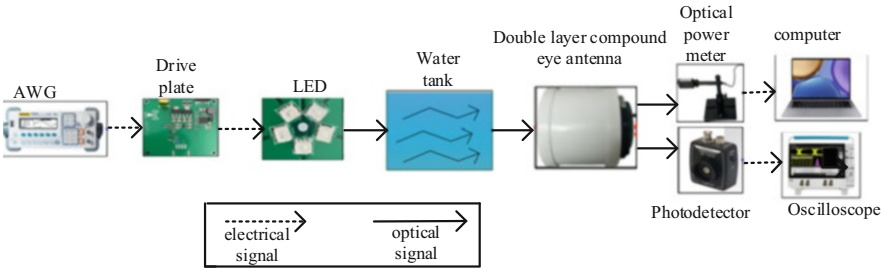

Fig. 31.3 Schematic diagram of the experimental device for reception efficiency

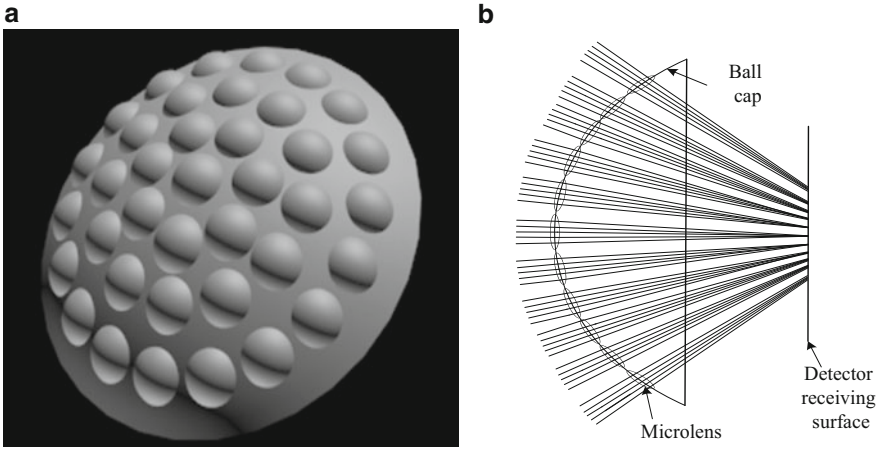

Fig. 31.4 Schematic diagram of an optical system with a single-layer curved compound eye lens array. (**a**) Single-layer curved compound eye lens structure. (**b**) Ray tracing of single-layer curved compound eye lens

pipe of the laboratory, respectively. The feasibility of this design scheme was verified by measuring the optical power of the receiving optical system.

The receiving end of the system adopted a compound eye lens optical receiving antenna with wide-angle focusing. Figure 31.4a shows the schematic of a single-layer curved compound eye lens. Because most of the detectors used in the laboratory are planar structures, the convergence effect of the microlens at the edge was reduced for the compound eye lens receiving antenna with a single-layer curved structure.

As shown in Fig. 31.4b, the lens at the center of the compound eye can focus the light beam on the surface of the detector; however, with the radial movement of the microlens on the surface of the spherical crown, the effect of the light beam focusing on the surface of the detector increasingly worsens, and the lens at the edge of the spherical crown can no longer focus the light beam on the surface of the photodetector.

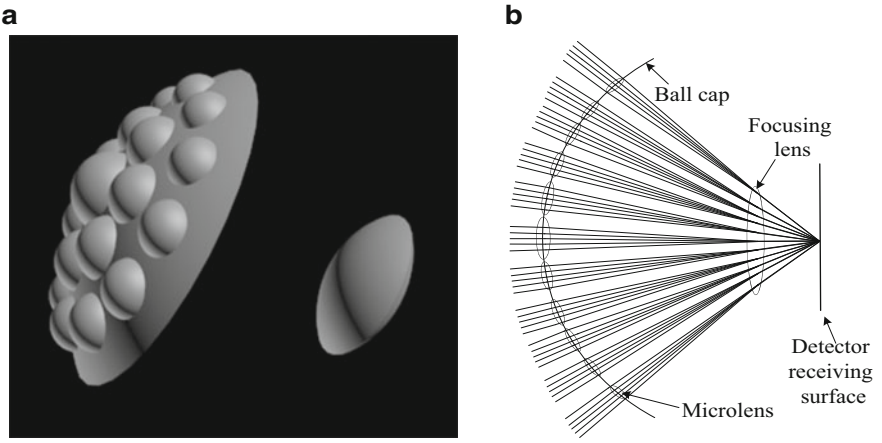

Fig. 31.5 Schematic diagram of a double-curved compound eye lens array optical system. (**a**) Double-layer curved compound eye lens structure. (**b**) Ray tracing of double-curved compound eye lens

To improve the beam convergence effect of the microlens at the edge of the curved structure, further concentrate the beam received by the receiving antenna, and address the defocusing phenomenon in the beam convergence process, a double-layer curved compound lens array optical system was designed based on a single layer.

Figure 31.5 shows a schematic diagram of the optical system of the double-layered curved compound eye lens array. First, the focal length of each small curved lens on the first layer of the system is determined by the position on the semicircle where the lens is located. Thus, small lenses at any position on the surface of the large lens can achieve an ideal beam convergence effect. Second, the light signal can be focused on the surface of the detector once it passes through the large curved lens on the second layer, thereby reducing the light energy loss caused by the inability of the edge lens to focus.

To apply this optical receiving antenna system to the underwater blue-green LED communication system, based on the geometric optical design and simulation of the lens array, the outer spherical crown model of the double-layer compound eye structure was processed, and the small lenses were inlaid and combined with the focusing lens. The actual object is shown in Fig. 31.6.

The light power on the incident plane of the double-layer composite eye lens can be estimated by measuring the power of the LED light source, based on the Lambert radiation model. As shown in Table 31.10, with an increase in the incident angle of the surface light source of the compound eye lens, the output power of the pinhole in front of the power meter decreases. This indicates that the insertion loss of the optical receiving antenna of the double-layer compound eye lens increases with an increase in the incident angle.

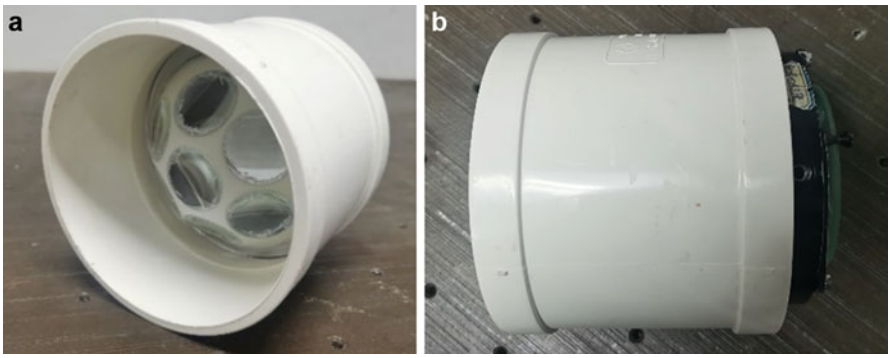

Fig. 31.6 Receiving end prototype with a double-layer compound eye array. (**a**) Front view. (**b**) Vertical view

Table 31.10 Incidence angle and insertion loss of the double-layer curved compound lens

Angle of incidence	0°	5°	10°	15°	20°
Incident power of compound eye lens (W)	4.89×10^{-5}	4.89×10^{-5}	4.89×10^{-5}	4.89×10^{-5}	4.89×10^{-5}
Effective area detector power (W)	3.1×10^{-5}	2.77×10^{-5}	2.17×10^{-5}	1.97×10^{-5}	1.69×10^{-5}
Insertion loss (dB)	1.97	2.48	3.51	3.95	4.60

Figure 31.7 shows the optical power values measured by the optical power meter at different distances and receiving terminals. It can be concluded that when the communication distance is fixed, the optical power received by the double-layer compound eye lens receiving antenna is optimal, followed by that of the single-layer compound eye lens receiving antenna.

When there is no compound eye lens receiving antenna, the optical power measured by the receiving terminal is very weak. When the receiving antenna remains unchanged, the optical power measured at the receiving end decreases with an increase in the communication distance; however, the optical power received by the double-layer compound eye lens receiving antenna is still higher than that of the other two cases.

Figure 31.8 shows the bit error rate of the communication system at different transmission distances. It can be seen from Fig. 31.8 that the bit error rate of the system increases with an increase in the communication distance. The bit error rate was 1.36×10^{-14} when the communication distance was 1 m. When the communication distance reached 3 m, the bit error rate also increased. When the communication distance reached 5 m, the bit error rate increased to 4.58×10^{-12}. In summary, the signal quality attenuation increases with an increase in the transmission distance.

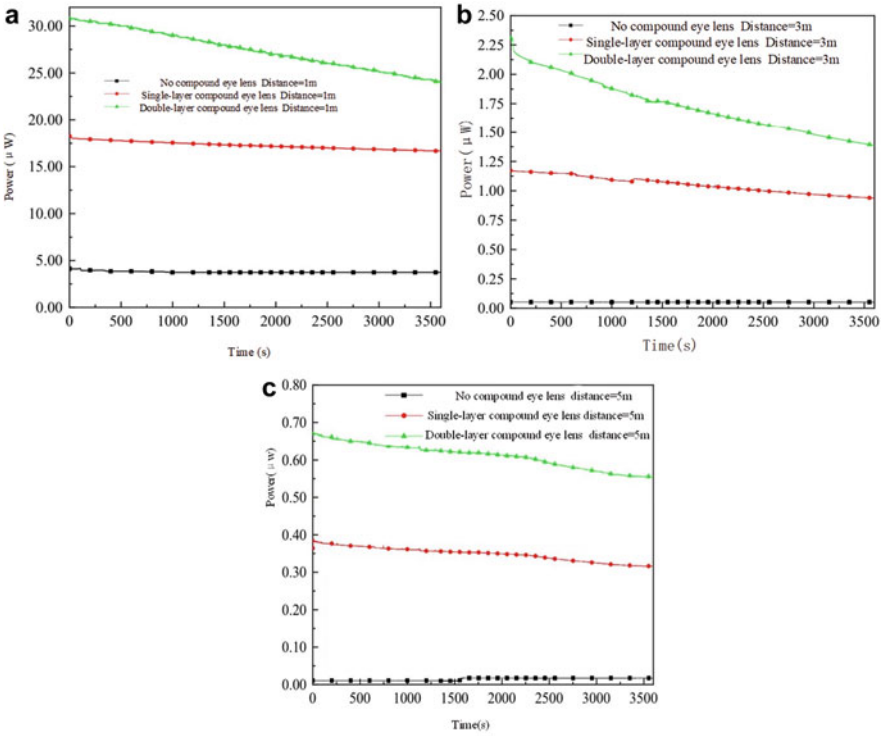

Fig. 31.7 Optical power measurements of different receiving terminals at 1 m, 3 m, and 5 m. (**a**) Power value at 1 m. (**b**) Power value at 3 m. (**c**) Power value at 5 m

Numerical simulation software was used to theoretically calculate the received optical power of the compound eye lens so that by comparing the theoretical data with the experimental data, the difference in optical power received by the receiver with no compound eye receiving antenna, a single-layer compound eye receiving antenna, and a double-layer compound eye receiving antenna can be seen more intuitively.

Because the experimental environment was still water, the influence of turbulence was not considered. The numerical parameters are consistent with the experimental design data: $P_0 = 500$ μW, $D_t = 38$ mm, $D_r = 100$ mm, $\sigma_r^2 = 10^{-10}$–10^{-13}, $\eta_t = 0.82$, $c(\lambda) = 0.151$, $B = 150$ MHz, $T = 290$, $R = 50$ Ω, and $\beta = 20°$. The calculation results are shown in Table 31.11, where P_s is the theoretical data and P_e is the mean value of the experimental data collected through experimental measurements.

Figure 31.9 compares the mean values of the fitted theoretical data and the experimentally measured data, based on the data in Table 31.11. The solid line in Fig. 31.9 is the curve fitted by the experimental data measured continuously by the optical power meter within 1 h. The dotted line is the curve fitted using the formula for the received light power of the double-layer compound eye lens receiving antenna.

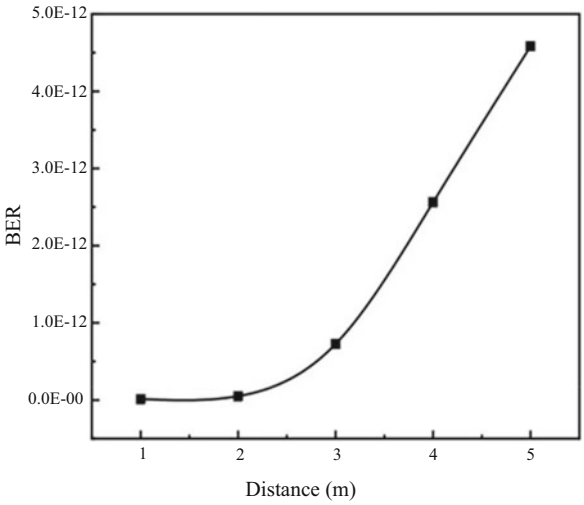

Fig. 31.8 Bit error rate at different communication distances

Table 31.11 Theoretical calculation data and experimental data

Distance	No compound eye lens (W)	Single-layer compound eye lens (W)	Double-layer compound eye lens (W)	Improvement of double-layer compound eye lens over single-layer compound eye lens (%)	Deviation (%)
1 m	$P_s = 4.771$	$P_s = 19.855$	$P_s = 30.762$	72	0.7
	$P_e = 3.765$	$P_e = 19.457$	$P_e = 33.431$	72.7	
3 m	$P_s = 0.048$	$P_s = 1.012$	$P_s = 1.683$	66.3	1.3
	$P_e = 0.052$	$P_e = 1.049$	$P_e = 1.731$	65	
5 m	$P_s = 0.014$	$P_s = 0.303$	$P_s = 0.485$	60.05	0.05
	$P_e = 0.018$	$P_e = 0.378$	$P_e = 0.605$	60	

According to the trend of the solid and dotted lines in Fig. 31.9, these three groups of curves are in line with the exponential decay trend. It can be seen from the figure that when the transmission distance is fixed, the power received by the double-layer compound eye lens is higher than that of the single-layer compound eye lens.

The experimental results show that when the link distances are 1, 3, and 5 m, the received optical powers of the double-layered compound eye system are 72%, 65%, and 60% higher than those of the single-layered system, respectively. A double-layer fly eye lens receiving antenna can significantly improve the optical power received at the receiving end. Therefore, the proposed antenna structure has strong practicability and good development prospects in the field of underwater optical wireless communication.

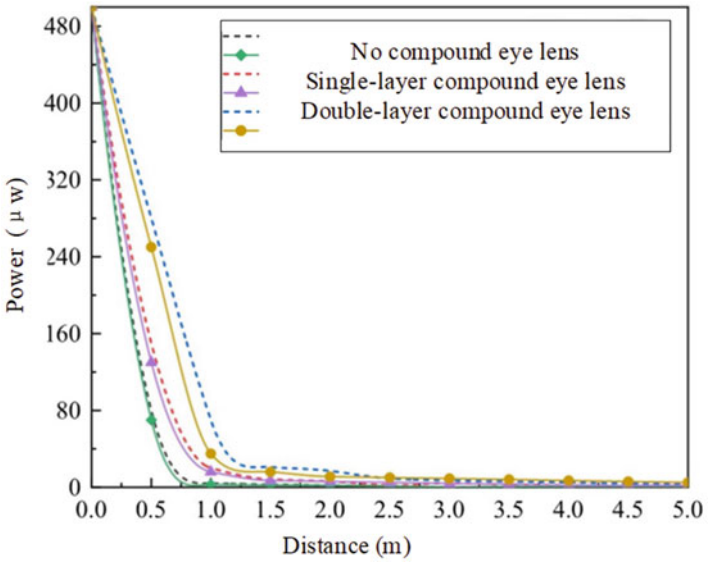

Fig. 31.9 Experimental and theoretical data curves

The double-layered compound eye receiving antenna provides a feasible solution for increasing the underwater optical wireless communication distance. Future research can focus on improving the transmission performance of communication systems by using channel equalization technology.

Summary

Considering the basic theory of underwater optical wireless communication, this chapter analyzed the advantages of underwater optical communication. First, a model for underwater optical communication was introduced. Then, the optical properties of seawater were analyzed, and factors affecting underwater transmission channels were proposed, including absorption, scattering, and turbulence.

Then, the key technologies used in underwater optical communication were introduced, including channel modeling, modulation and coding technology, light source selection, and detection technology. The chapter summarized the research progress and experiments in these aspects and finally introduced a new underwater optical system design model in detail, which provided a feasible solution for underwater long-distance transmission.

According to the research progress in this chapter, many aspects in underwater optical wireless communication systems need to be improved and perfected:

1. The experiments mentioned in this paper are mostly applicable to simplex communication. In the future, high-bandwidth LEDs and high-sensitivity

photodetectors can be combined to achieve half- or full-duplex communication systems.

2. The receiving end of an underwater optical communication system is mostly a single receiving detector. In the future, multiple detectors can be used at the receiving end, and multiple focusing lenses can be added, which can increase the communication distance and reduce the bit error rate [145].
3. An adaptive coding modulation scheme could be designed in the future. In underwater optical wireless communication systems, appropriate modulation and coding methods can be selected according to the actual situation so that the system can save energy and have a longer working time [33].
4. For the cross-medium transmission model, most vertical link experiments assume that seawater is a homogeneous medium; the model can be further studied according to real ocean conditions in the future [183].
5. Owing to the weak optical signal strength received underwater and the fact that the current underwater weak light detection technology is not yet mature, a set of underwater weak light signal detection systems can be studied in the future [212].
6. With the development of the Internet of things and 6G, underwater optical communication is expected to connect with the Internet in the future. Thus, new network protocols will need to be proposed, and underwater acoustic, RF, and optical communication will need to be combined to overcome the problems of unstable channels and low transmission rates.

Abstract

When a laser beam propagates underwater, it attenuates because of absorption, scattering, and turbulence; this results in light power attenuation and light intensity fluctuation. Considering that communication links have different water speeds, directions, and distances, an underwater optical wireless channel model is proposed to conduct field measurements in river and ocean nearshore waters. The light intensity fluctuation, received light power loss, and underwater structure constant were measured and analyzed in different water areas. The results showed that rivers have weak turbulence and offshore waters have moderate turbulence. The higher the water speed, the greater the scintillation index of the received

optical signal power and the more unstable the signal. When transmitting horizontally, the scintillation index of the received optical signal power is independent of the water direction; the greater the scintillation index of the received optical signal power, the more unstable the signal.

Underwater optical wireless communication · Channel model · Bit error rate

Introduction

With the deployment of large numbers of unmanned underwater vehicles, the denseness of underwater sensor networks, and the sharp increase in underwater sensor nodes, the demand for underwater wireless data transmissions will increase greatly. Compared with traditional acoustics, optical wireless communication is becoming the main solution for high throughput and big data underwater wireless communication.

However, the serious attenuation loss of underwater optical wireless communication (UOWC) channels, including signal attenuation caused by absorption, scattering, and turbulence, inhibits the transmission of signals. To make UOWC available for a longer link range, it is necessary to conduct a comprehensive study of underwater optical communication and accurate channel modeling.

In 1963, Duntley found a blue-green band with a low-attenuation window (450–550 nm) for the absorption and scattering effects of seawater [1]. In 1966, Gilbert et al. [2] experimentally confirmed this conclusion. In 1972, Petzold divided seawater into four types, according to turbidity, and provided the absorption and scattering coefficients for each type of water [3].

In 2000, Nikishov deduced the power spectrum of the ocean turbulence refractive index, based on the theory that it was affected by both temperature and salinity [4]. In 2008, Jaruwatanadilok modeled an underwater optical wireless channel with absorption and scattering effects and obtained an analytical solution of the radiated transport equation using the vector radiation theory [5]. In the same year, Jaruwatanadilok based on the small-angle approximation hypothesis, a beam diffusion function model was obtained, and the results were verified experimentally [6]. In 2012, Cox used the particle Monte Carlo method to study channels of different water qualities and obtained an optical power attenuation model and a channel impulse response model for different water qualities [7]. In 2013, Li proposed an accelerated algorithm to improve the above method, which reduced the computational complexity [8].

For the first time, Lu et al. derived the wave structure function of plane and spherical waves in ocean turbulence propagation [9]. In 2014, Huang investigated the propagation properties of an underwater Gaussian–Schell model vortex beam under water [10].

In the same year, Lu et al. studied a Gaussian array beam and obtained a distribution function for the average intensity of partially coherent and incoherent light [11]. McGlamery [12] and Roddier [13] proposed power spectrum inversion and Zernike polynomial methods, respectively, to generate a turbulent random-phase screen that satisfied these conditions [14]. In 2021, Cui et al. studied the intensity distribution and scintillation of Gaussian convergent array beams passing through a phase screen. In 2021, Zhang et al. simulated the coexistence of absorption scattering and turbulence using a ray tracing-based particle Monte Carlo numerical method [15].

Many statistical models exist for the random fluctuation of light intensity caused by turbulence, including the log-normal distribution model based on weak turbulence [16] and the gamma–gamma distribution model [17]. In 2017, Oubei proposed a Weibull distribution model [18], and in the same year, Jamali et al. proposed an exponential log distribution model to fit the effect of different bubbles on light intensity fluctuations [19]. In 2019, Zedini et al. developed a mixed exponential generalized gamma function distribution model that considered the effects of temperature, salinity, and bubbles [20].

The above research on laser propagation in seawater is generally based on theoretical analyses and numerical simulations and lacks simulations of real environments. In this study, an underwater channel model was established, based on detailed environmental measurements of nearshore and turbid water bodies. The received light intensity at different flow velocities and flow directions was measured in different turbid waters of the Chan and Ba rivers in Xi'an, Shaanxi Province. In addition, measurements were carried out at different distances in the Yantai No. 1 beach. Compared with the indoor simulation of an underwater environment, the model has more practical significance and reference value and can be used as a reference for future underwater communication work.

Foreign and Domestic Research Status

During the Shang and Zhou dynasties, circa 1600–256 BC, soldiers used beacons to relay information about enemy attacks. Around the first and second centuries, the Roman army continued the practice of Greek soldiers, sending signals using polished shields to reflect sunlight. In 1880, Bell, the father of the telephone, invented a wireless telephone system that used sunlight as a transmission medium. It was the earliest optoelectronic communication system in history.

The advent of the laser in 1916 introduced a large number of optical wireless communication applications to the world. However, because the serious attenuation of visible light in seawater could not be solved, early research on UOWC did not make substantial progress.

With the development of ocean exploration, real-time and high-speed underwater communication has become increasingly important. Underwater optical wireless communication has many advantages, such as high speed, high bandwidth, and large capacity; therefore, an increasing number of researchers have begun to study

it. After more than half a century of development, researchers worldwide have achieved remarkable progress in underwater optical wireless communication.

Foreign Research Status

In 1963, Duntley first proposed a variation in the attenuation coefficient of light waves propagating in different water conditions (pure water, distilled water, and natural water) and found that the attenuation of light in water was weakest when it was in the blue-green light band [21]. This indicated that blue-green light was an important window for light propagation in water, which laid the foundation for the future development of UOWC.

In 1977, Doherty et al. implemented a one-way underwater optical wireless communication system from the shore to a submarine using a focused blue-green laser diode (LD) as the light source [22]. This proved that it was feasible to establish an underwater optical wireless communication system with an LD transmitter to communicate at greater depths and higher cruise speeds.

Between 1980 and 1990, the United States Navy and former Soviet Navy conducted several submarine-to-submarine and satellite-to-submarine underwater optical wireless communication system test studies [23]. They proved that underwater optical wireless communication systems worked well under severe conditions, such as heavy rain and turbid seawater. Since the beginning of this century, the United States, Italy, Japan, and other countries have conducted further research in the field of underwater optical wireless communication.

In 2004, Tivey et al. designed a low-power UOWC system using an array of light-emitting diodes (LEDs), silicon-based photodetectors, and an Infrared Data Association (IrDA) protocol [24]. This proved that underwater optical wireless communication systems could transmit data using low-power, low-cost LEDs.

In 2004, Schill et al. established a small real-time optical communication transceiver using a group of small autonomous underwater vehicles. The transceiver used a 3-W high-power blue-green LED and a photodiode sensitive to wavelengths between 460 and 520 nm, achieving a data rate of 57.6 kbit/s in the 1–2-m communication range [25].

In 2008, Hanson et al. used the Monte Carlo method to simulate the transmission effect of underwater optical wireless communication systems in three different water bodies; a data transfer rate of 1 Gbit/s was realized in a 2-m water link [26]. Since the first demonstration of Gbit/s data rates, underwater optical wireless communications have explored higher data rates and longer transmission distances.

In 2013, Cossu et al., using two low-cost blue LED arrays as light emitters and an avalanche photodiode module as a receiver, made measurements using a 3.3-m-diameter outdoor water tank. It consisted of two waterproof boxes holding the water tank boundary transmitter and receiver. It achieved 2.5-m high-speed underwater wireless error-free transmissions using 6.25-Mbit/s phase coding, 12.5-Mbit/s non-return-to-zero (NRZ) 8B/10B coding, and 58-Mbit/s discrete multi-audio modulation [27].

In 2015, Nakamura et al. conducted an experiment with a 1.45-Gbit/s communication rate in a 4.8-m communication distance by using a 405-nm blue light LD and a field programmable gate array (FPGA) to generate 16-quadrature amplitude modulation (QAM)–orthogonal frequency-division multiplexing (OFDM) modulation signals in real time. Its bit error rate was 9.1×10^{-4} [28].

In 2016, Oubei et al. conducted research on a UOWC system using a 448-nm blue light LD 16-QAM-OFDM modulation scheme. A transmission rate of 3.2 Gbit/s over a transmission distance of 2.5 m was achieved by placing a reflector in a 0.6-m water tank; the bit error rate was 6.83×10^{-4} [29].

In 2019, Tsai et al. first proposed a 30-Gbit/s four-stage pulse-amplitude modulation (PAM4) underwater optical wireless communication system. The system was equipped with a beam reducer/expander on a 12.5-m pipe underwater channel and 2.5-m high-turbidity harbor underwater channel link. The large amount of scattered light received by the optical receiver of the PAM4 system improved with the use of the beam constrictor/expander [30].

In 2022, Kong et al., of King Abdullah University of Science and Technology, built a 2-K real-time digital video surveillance system using 458-nm LEDs, based on a wide-field underwater optical wireless communication system. The video stream was processed through transmitter circuits including video coding (H. 256) and on–off keying (OOK) modulation, in a 1.5-m pure water channel and 1.53-ml/s bubble-induced turbulent pure water channel. They transmitted a real-time video at a 2.5-Mbit/s communication rate [31].

From the foreign research progress of underwater optical wireless communication, it can be seen that researchers are keen to study UOWC through different modulation and coding methods, by changing the modulation mode of the UOWC system to improve the transmission rate and transmission distance, and through a variety of UOWC system analysis simulation models. By comparing simulation data, such as communication rate and communication distance, with engineering experiments, the theoretical data were verified experimentally, confirming that the models improved the communication performance of the UOWC system.

Domestic Research Status

In 2006, Zhou et al. used photoelectric detector array reception, high-speed analog-to-digital conversion, efficient data acquisition, and digital signal processing (DSP) technology to design and implement a high-sensitivity underwater receiver with a DSP processor that could receive pulse-position modulation (PPM) signals. Compared with a hard receiver, a receiver with DSP improved the sensitivity by at least 3 dB [32].

In 2008, Luo et al., using a blue-green LED as the emitting light source, designed a set of UOWC systems according to the IrDA physical protocol. The system realized underwater visible light communication and detected the light intensity using a linear distance measurement method. The transmission rate reached 125 kbit/s without the influence of any light source within 2 m. The average distance

difference was 5% when the LED light source and receiver were aligned in a straight line [33].

In 2009, Sui et al. simulated a UOWC communication channel link. By combining the Bose–Chaudhuri–Hocquenghem (BCH) error-correcting code and OOK modulation technology, the communication performance in water was analyzed through the simulation of different modulation modes. Using an LED as the light source of an underwater communication system, information was reliably transmitted when the communication transmission rate was 4 Mbit/s [34].

In 2013, Pang et al. used seven blue LEDs in series as the emitting light source and a blue light-enhanced PD as the receiving system. A set of underwater optical wireless communication systems was designed, based on the binary open–close keying principle, and a 3-Mbit/s data transmission was realized through a 13-m communication channel [35].

In 2014, Tao et al. designed and implemented an underwater optical wireless communication node and transplanted the μC/OS-II embedded operating system onto the hardware platform of the communication node. The physical layer protocol and data link layer protocol were implemented, based on the IEEE 802.15.7 visible light communication standard. The visible light communication nodes could communicate reliably within a range of 1 m under water [36].

In 2016, Xu et al. implemented an intensity modulation/direct detection (IM/DD)-OFDM-based underwater optical wireless communication system using a single compact blue LED and a low-cost PIN photodiode. The system achieved a communication rate of 161.36 Mbit/s in a 2-m underwater tank [37].

In 2017, Huang et al. limited the frequency response of an avalanche photodiode by using a GaN blue laser diode as a transmitter and 16 QAM-OFDM for data transmission, with a data rate of up to 14.8 Gbit/s. The transmission distance in seawater was 1.7 m [38].

In 2019, Hong et al. realized an underwater laser communication system with a 5-m transmission distance and a net communication rate of 18.09 Gbit/s using discrete multi-tone (DMT) modulation with probability constellation shaping (PCS) technology. This was the first time that PCS-QAM-DMT was used in an underwater laser communication system; it was also the highest data communication rate achieved using a single laser diode in a UOWC system [39].

In 2019, Wang et al. successfully implemented an underwater laser communication system with a 500-Mbit/s communication rate through a 100-m tap water channel using a 520-nm green LD and NRZ-OOK modulation of a single-mode tail fiber [40].

In 2021, using spread-spectrum technology to improve the receiver sensitivity of a UOWC system, researchers extended the transmission distance of the system. In addition, the system's anti-interference ability was improved. The receiver sensitivity of a communication system loaded with 200-MHz signals was increased by 4.8 dB [41].

In 2022, Ke et al. proposed a design scheme for a wide-angle-focused double-layer compound eye lens optical system. A compound eye lens receiving system was designed and simulated using the Zemax software, and an experimental setup for

investigating the underwater communication system receiving efficiency was built. The results showed that the double-layer compound eye lens receiving antenna significantly improved the optical power received by the receiving end [42].

Underwater optical wireless communication research can be divided into two categories: theoretical and experimental. In the theoretical aspect, the underwater channel is modeled, and the track of each photon in the water is analyzed under a certain transceiver angle and emitting light power. The photon is captured by the receiving end of the system after being repeatedly scattered by water.

The experimental aspect is focused on developing an underwater optical wireless communication system with real-time communication. Researchers mainly focus on improving the power of the transmitter light source, adopting a high-sensitivity detector and a suitable signal-modulation format, and adding a signal processing method with higher anti-noise performance to improve the communication speed and transmission distance of the underwater optical wireless communication system.

To date, researchers around the world have conducted many theoretical simulations and experimental research; however, many underwater models and communication methods built using simulations still cannot be verified experimentally—for example, considering the complexity of the water environment—owing to technical problems and the inability to improve the detector sensitivity.

Furthermore, it is necessary to experimentally obtain different water environment data to build more perfect underwater models and guide theoretical experiments. With a solution to these problems, it will be easier for underwater optical wireless communication systems to meet the needs of different water environments and contribute to existing underwater communication.

Characteristics of Seawater Channels

Seawater is a complex and irregular mixed medium in underwater transmission channels. The turbulence caused by the movement of water molecules, the chlorophyll produced by phytoplankton, yellow substances (such as fulvic and humic acid) produced by various fish and algae, and various dissolved salts and mineral particles affect the transmission characteristics of laser beams in seawater.

The random fluctuation of ocean turbulence and the absorption and scattering characteristics of underwater suspended particles attenuate the laser beam energy and cause the expansion, drift, and scintillation of the laser beam. This increases the communication difficulty and affects the system performance. Therefore, this section introduces the components of ocean channels, basic theory of ocean turbulence, attenuation characteristics of underwater suspended particles, and key technical difficulties of underwater laser transmissions.

Ocean Turbulence Spectrum Models

Since the beginning of the 1990s, different ocean turbulence spectrum models have appeared one after another. The ocean turbulence spectrum model proposed by Nikishov is the most widely used. It considers the factors of temperature and salinity and is suitable for isotropic ocean turbulence.

The expression for the ocean turbulence spectrum is [43]

$$\begin{aligned} E_n(k) = {} & C_0 \chi_n \varepsilon^{-1/3} \kappa^{-11/3} \left[1 + C_1 (\kappa\eta)^{2/3}\right] \\ & \times \frac{\omega^2 \theta \exp(-A_T \delta) + \exp(-A_S \delta) - \omega(1+\theta)\exp(-A_{TS}\delta)}{\omega^2 \theta + 1 - \omega(1+\theta)}, \end{aligned} \tag{32.1}$$

where $C_0 = 0.07$, $C_1 = 2.3$, $\chi_n = \alpha^2 \chi_T + \alpha^2/\omega^2 \chi_T - 2\alpha^2/\omega^2 \chi_T$, $\theta = K_T/K_S$, K_T denotes the turbulent heat dissipation coefficient, and K_S denotes the turbulent salinity diffusion coefficient. χ_n is substituted into

$$\begin{aligned} E_n(\kappa) = {} & C_0 \left(\alpha^2 \chi_T + \frac{\alpha^2}{\omega^2}\chi_T - \frac{2\alpha^2}{\omega}\right) \varepsilon^{-1/3} \kappa_{-11/3} \left[1 + C_1 (\kappa\eta)^{2/3}\right] \\ & \times \frac{\omega^2 \theta \exp(-A_T \delta) + \exp(-A_S \delta) - \omega(1+\theta)\exp(-A_{TS}\delta)}{\omega^2 \theta + 1 - \omega(1+\theta)}. \end{aligned} \tag{32.2}$$

For isotropic ocean turbulence, $K_T = K_S$, $\theta = 1$, and the scalar spectral model of ocean turbulence in Eq. (32.2) can be simplified to [43]

$$\begin{aligned} E_n(k) = {} & C_0 \alpha^2 \varepsilon^{-1/3} \kappa^{-11/3} \left[1 + C_1 (\kappa\eta)^{2/3}\right] \chi_T/\omega^2 \\ & \times \omega^2 \exp(-A_T \delta) + \exp(-A_S \delta) - 2\omega \exp(-A_{TS}\delta). \end{aligned} \tag{32.3}$$

According to the relationship between the scalar spectrum and the power spectrum function, the power spectrum function $\phi_n(\kappa)$ in ocean turbulence can be written as

$$\begin{aligned} \phi_n(\kappa) = {} & (4\pi)^{-1} \kappa^{-2} E_n(\kappa) \\ = {} & 0.388 \times 10^{-8} \varepsilon^{-1/3} \kappa^{-11/3} \left[1 + 2.35 (\kappa\eta)^{2/3}\right] \frac{\chi_T}{\omega^2} \\ & \times \left[\omega^2 \exp(-A_T \delta) + \exp(-A_S \delta) - 2\omega \exp(-A_{TS}\delta)\right], \end{aligned} \tag{32.4}$$

where ε is the turbulent kinetic energy dissipation rate with a value range of $(10^{-1} - 10^{-10})\mathrm{m}^2/\mathrm{s}^3$ and the Kolmogorov-scale efficiency η has a value of $(6 \times 10^{-5} - 0.01)\mathrm{m}$. The temperature variance dissipation rate χ_T has a value range of $(10^{-4} - 10^{-10})\mathrm{K}^2/\mathrm{s}$ from the sea surface to the deep sea. In the temperature induction to salinity induction ratio $\omega = [-5, 0]$, $\omega = 0$ indicates that salinity changes play a major role; $\omega = -5$ indicates that temperature changes play a major role. Other parameters

include $A_T = 1.863 \times 10^{-2}$, $A_S = 1.9 \times 10^{-4}$, $A_{TS} = 9.41 \times 10^{-3}$, and $\delta = 8.284(\kappa\eta)^{4/3} + 12.978(\kappa\eta)^2$.

The expression for the power spectrum $\phi_n(\kappa_x, \kappa_y)$ of the refractive index of anisotropic ocean turbulence is

$$\begin{aligned}\phi_n(\kappa_x, \kappa_y) = {} & 0.388 \times 10^{-8} \mu_x \mu_y \varepsilon^{-1/3} \left[(\mu_x \kappa_x)^2 + (\mu_y \kappa_y)^2\right]^{-11/6} \\ & \left\{1 + 2.35\left[(\mu_x \kappa_x)^2 + (\mu_y \kappa_y)^2\right]^{1/3} \eta^{2/3}\right\}(\chi_T/\omega^2) \\ & \times \left[\omega^2 \exp(-A_T\delta) + \exp(-A_S\delta) - 2\omega \exp(-A_{TS}\delta)\right],\end{aligned} \tag{32.5}$$

where μ_x and μ_y are, respectively, the anisotropy factors of the x and y directions; the meanings of parameters ε, η, χ_T and ω are shown above; the expression is

$$\delta = 8.284\eta^{4/3}\left[(\mu_x \kappa_x)^2 + (\mu_y \kappa_y)^2\right]^{2/3} + 12.978\eta^2\left[(\mu_x \kappa_x)^2 + (\mu_y \kappa_y)^2\right]. \tag{32.6}$$

Attenuation Characteristics of Underwater Particles

Absorption Properties

When light travels through seawater, it is absorbed by water molecules, plankton, and algae; this is known as the absorption characteristic of seawater. The factors that affect the absorption properties of seawater can be grouped into four categories: seawater itself, chlorophyll-containing particles (phytoplankton), suspended particles in seawater, and colored dissolved organic matter. The combination of these four absorption types constitutes the absorption of light by seawater. Therefore, the absorption and attenuation coefficient of seawater can be expressed as [44]

$$\alpha(\lambda) = \alpha_w(\lambda) + \alpha_{\text{chl}}(\lambda) + \alpha_{\text{nap}}(\lambda) + \alpha_y(\lambda), \tag{32.7}$$

where $\alpha_w(\lambda)$ denotes the absorption and attenuation coefficient of pure water, $\alpha_{\text{chl}}(\lambda)$ denotes that of chlorophyll-containing particles (phytoplankton), $\alpha_{\text{nap}}(\lambda)$ denotes that of suspended particles, and $\alpha_y(\lambda)$ represents that by yellow matter. In the same area, when the salinity, depth, and measurement time change, the absorption characteristics of the seawater also change. These four effects are described below.

Light Absorption by Pure Water

The absorption of light by seawater is mainly caused by water molecules and dissolved salts. The concentration of inorganic salts in seawater is approximately 3.8%, including NaCl, KCl, and $CaCl_2$. A large number of experiments have shown that the effect of dissolved salts in seawater can be disregarded because of their low light absorption compared to that of water molecules [45]. Therefore, the absorption of light by seawater is primarily caused by the water molecules.

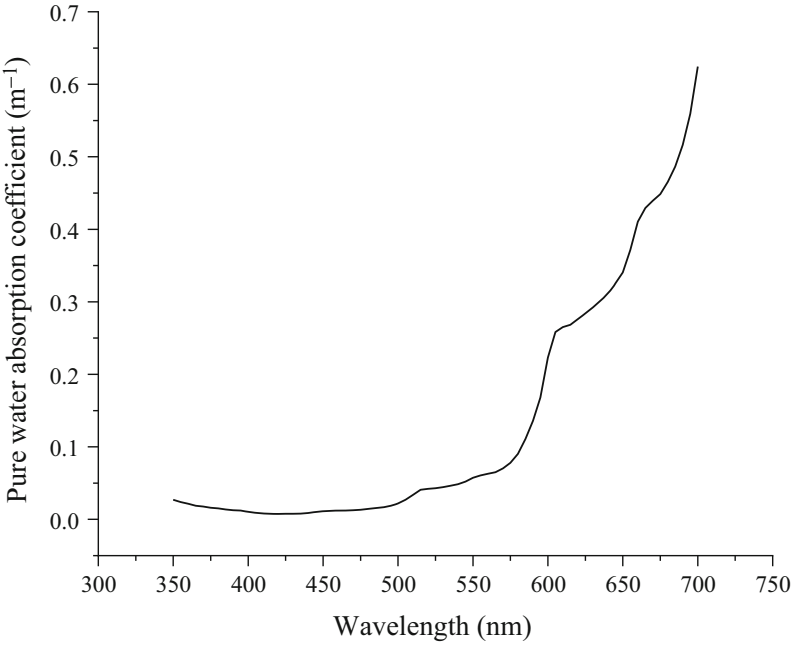

Fig. 32.1 Absorption coefficient of pure seawater at different wavelengths [47]

Morel et al. measured a large amount of pure seawater using a spectrophotometer. They first measured the attenuation coefficient of a pure water beam and then subtracted the scattering coefficient from the data to calculate the absorption coefficient of pure water to light. The relationship between the absorption coefficient $\alpha_w(\lambda)$ of pure seawater at different wavelengths and the light wavelength λ is obtained [46], as shown in Fig. 32.1.

As shown in Fig. 32.1, the absorption coefficient of pure water is minimal when the wavelength of light is between 350 and 550 nm, which is in the blue-green band. With an increase in the wavelength, the absorption coefficient of pure water increases gradually, with small shoulder peaks at 510 and 600 nm, and then increases rapidly.

Light Absorption Characteristics of Phytoplankton

Similar to plants on land, phytoplankton in seawater use chlorophyll for photosynthesis; therefore, their ability to absorb light waves depends on the amount of chlorophyll they contain. According to Prieur et al., different types of chlorophyll have different light absorption capacities at different wavelengths, and the ratio of chlorophyll a in phytoplankton is the highest. Therefore, the absorption coefficient of phytoplankton to light can be determined by the concentration of chlorophyll a. The absorption coefficient of chlorophyll a to light waves is [47]

$$\alpha_{\mathrm{chl}}(\lambda) = a_c{}^0(\lambda)\left(\frac{C_c}{C_c{}^0}\right)^{0.602}, \tag{32.8}$$

where C_c is the concentration of chlorophyll, $C_c{}^0 = 1$ mg/m^3, and $a_c{}^0(\lambda)$ is the absorption coefficient of the chlorophyll ratio in phytoplankton.

In this study, the absorption coefficient of the chlorophyll ratio at different wavelengths of light $a_c{}^0(\lambda)$ in reference [48] was substituted into Eq. (32.8). The absorption coefficient of chlorophyll at different light wavelengths $\alpha_{\mathrm{chl}}(\lambda)$ was calculated when the chlorophyll concentration was 1 mg/m^3. The relationship between the absorption coefficient of phytoplankton $\alpha_{\mathrm{chl}}(\lambda)$ and the wavelength of light λ is shown in Fig. 32.2.

As shown in Fig. 32.2, when the wavelength of light is between 550 and 650 nm, the absorption coefficient of chlorophyll a of phytoplankton is the smallest, with two peaks at wavelengths of 440 and 670 nm. This suggests that the chlorophyll of phytoplankton has the greatest absorption coefficient for blue-violet and orange-red light.

Light Absorption Properties of Yellow Matter

Yellow matter in seawater refers to the colored dissolved organic matter formed by humus from animal and plant decay; it is called yellow matter because of its yellow-brown color. Experimental measurements by Prieur et al. in 1977 showed that the

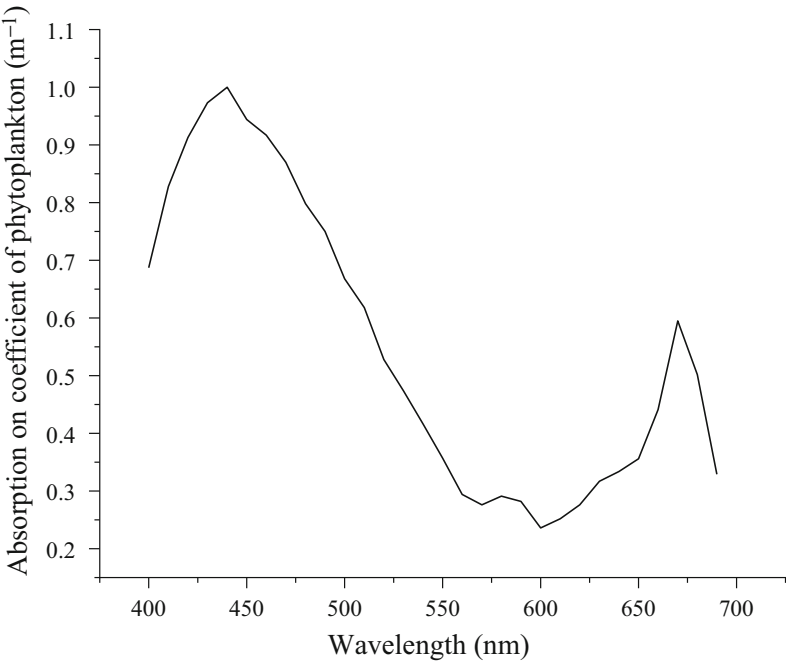

Fig. 32.2 Absorption coefficient of phytoplankton at different wavelengths [47]

decay of light absorbed by yellow matter in seawater is exponential [48]. In 2002, Wu et al. derived a mathematical model of the absorption characteristics of yellow matter during the transmission of light through seawater using experimental measurements [49]:

$$\alpha_y(\lambda) = \alpha_y(\lambda_0) \times \exp\left[-S_y \times (\lambda - \lambda_0)\right], \tag{32.9}$$

where $\alpha_y(\lambda_0)$ is the reference wavelength λ_0, the absorption rate of yellow matter in seawater is a constant, and S_y is the exponential slope of the absorption spectrum curve of yellow matter.

In 1977, Morel et al. provided an exponential slope parameter S_y value of 0.0140 nm^{-1} [48]. In 1981, Bricaud et al. collected 105 water samples from different waters and obtained a range of S_y values of 0.0100–0.0200 nm^{-1} [50]. Pegau et al. (1995) obtained a mean S_y value of 0.0170 nm^{-1} [51] by measuring 26 lake water samples. Wu et al. (2002) collected samples from waters, such as Jiaozhou Bay, and obtained a range of S_y values of 0.0131–0.0180 nm^{-1} [49].

The absorption coefficient of yellow matter to light is calculated with reference to the 2002 measurement data of Wu et al. Here, $\lambda_0 = 400$, $\alpha_y(400) = 0.650\ m^{-1}$, and the exponential slope $S_y = 0.0141$. The absorption coefficient of yellow matter to light is calculated, and the relationship between the absorption coefficient of yellow matter $\alpha_y(\lambda)$ and the wavelength of light λ is plotted, as shown in Fig. 32.3.

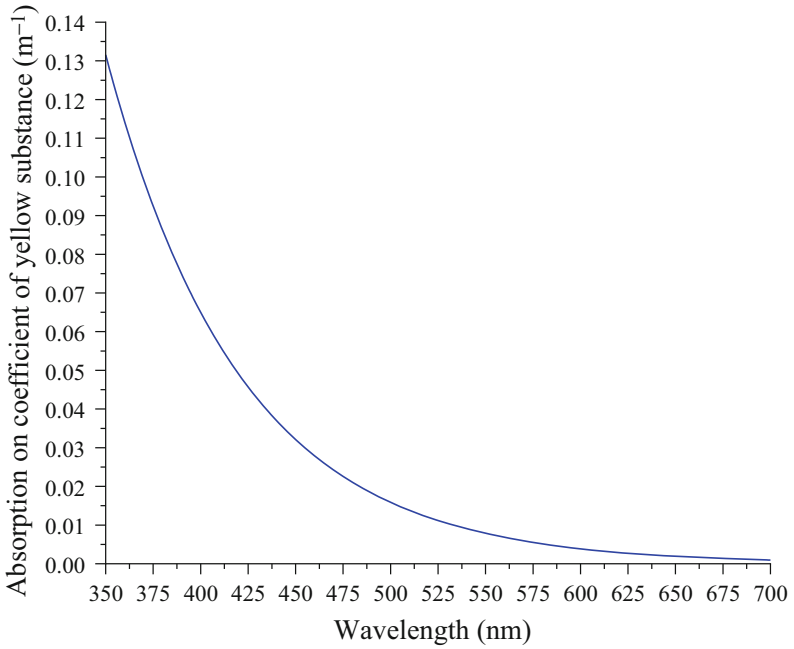

Fig. 32.3 Relationship between yellow matter and the wavelength [49]

As shown in Fig. 32.3, in the visible light band between 350 and 700 nm, the absorption spectrum of yellow matter in seawater shows an exponential change. With an increase in wavelength, a monotonically decreasing trend is observed.

Light Absorption Characteristics of Suspended Particles

Suspended particles in seawater are matter particles between a few and a few hundred microns in size, mainly biological waste, debris, and suspended sediment particles, which also absorb light waves. Owing to the insolubility of suspended particles, they are mainly distributed in coastal areas affected by river discharge and coastal erosion. The total amount of suspended particles is small in deep-sea areas far from the coast, owing to the low particle deposition and influence of human factors.

Gilerson et al. conducted field measurements at 42 sites along the Maryland coast and adjacent rivers and ports in the Chesapeake Bay. The absorption spectra of suspended particles in seawater measured by the ocean optical spectrometer were the same as those of yellow matter, and both were modeled as exponential decreases with the increase of the wavelength.

The functional expression for the absorption characteristics of suspended particles in seawater is [52]

$$\alpha_{\text{nap}}(\lambda) = \alpha_{\text{nap}}(\lambda_0) \times \exp\left(-S_{\text{nap}}(\lambda - \lambda_0)\right) \tag{32.10}$$

$$\alpha_{\text{nap}}(\lambda_0) = C_{\text{nap}} \times \alpha^*_{\text{nap}}(\lambda_0), \tag{32.11}$$

where $\alpha^*_{\text{nap}}(\lambda_0)$ is the specific absorptivity of suspended particles at the reference wavelength λ_0, C_{nap} is the concentration of non-algal suspended particles, and S_{nap} is the exponential slope of the spectral curve of light absorption of suspended particles.

According to the data of Gilerson et al. in 2007 [52], we calculate the absorption coefficient of light using Eq. (32.10), where the reference wavelength $\lambda_0 = 400$; then, $\alpha^*_{\text{nap}}(400) = 0.0375\ \text{m}^2/\text{g}$, $C_{\text{nap}} = 10\ \text{g/m}^3$, and the exponential slope $S_{\text{nap}} = 0.015$. The absorption coefficient $\alpha_{\text{nap}}(\lambda_0)$ of the suspended particles is calculated by simulation, and the relationship between the absorption coefficient $\alpha_{\text{nap}}(\lambda)$ and the wavelength λ is shown in Fig. 32.4.

As shown in Fig. 32.4, in the visible light band between 350 and 700 nm, the light absorption spectrum of suspended particles in seawater presents an exponential change form and with the increase in wavelength presents a monotonically decreasing trend. When the light wavelength is greater than 650 nm, the light absorption of the suspended particles approaches zero [52].

Scattering Characteristics

In addition to the loss caused by the absorption characteristics of seawater, a large number of particles and organic matter are found near land water, where the attenuation of seawater is dominated by scattering; at this point, the water's minimum attenuation window moves from the blue band (470 nm) to the green band (550 nm). The presence of water molecules in seawater, chlorophyll-containing

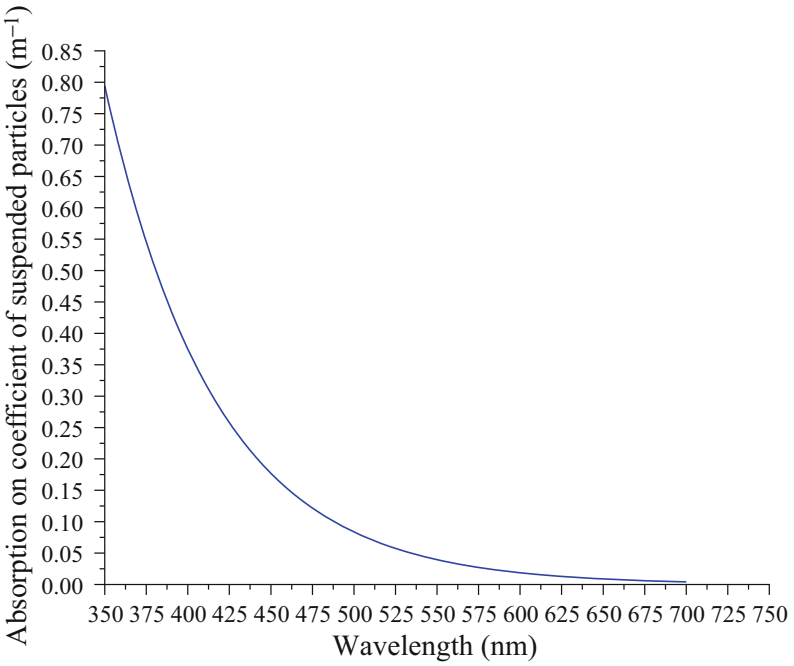

Fig. 32.4 Relationship graph of the absorption coefficient of suspended particles with different wavelengths

particles (phytoplankton), and suspended particles of different sizes also cause the light transmission to lose energy.

The combination of these three types of matter makes up the scattering of light by seawater. Therefore, the attenuation coefficient $\beta(\lambda)$ of light scattering by these three types of material can be expressed as [53]

$$\beta(\lambda) = \beta_w(\lambda) + \beta_{\text{chl}}(\lambda) + \beta_{\text{nap}}(\lambda), \tag{32.12}$$

where $\beta_w(\lambda)$ denotes the attenuation coefficient of light scattering by pure seawater, $\beta_{\text{chl}}(\lambda)$ denotes that by plankton, and $\beta_{\text{nap}}(\lambda)$ denotes that by suspended particles. These three types of effects are explained separately below.

Light-Scattering Properties of Pure Water

Water molecules in seawater absorb light and have scattering characteristics that follow the Rayleigh distribution. In 1977, Morel experimentally determined the equation of a light-scattering model using pure water [54]. The Rayleigh scattering coefficient $\beta_w(\lambda)$ of pure seawater is

$$\beta_w(\lambda) = 0.005826 \times \left(\frac{400}{\lambda}\right)^{4.322}. \tag{32.13}$$

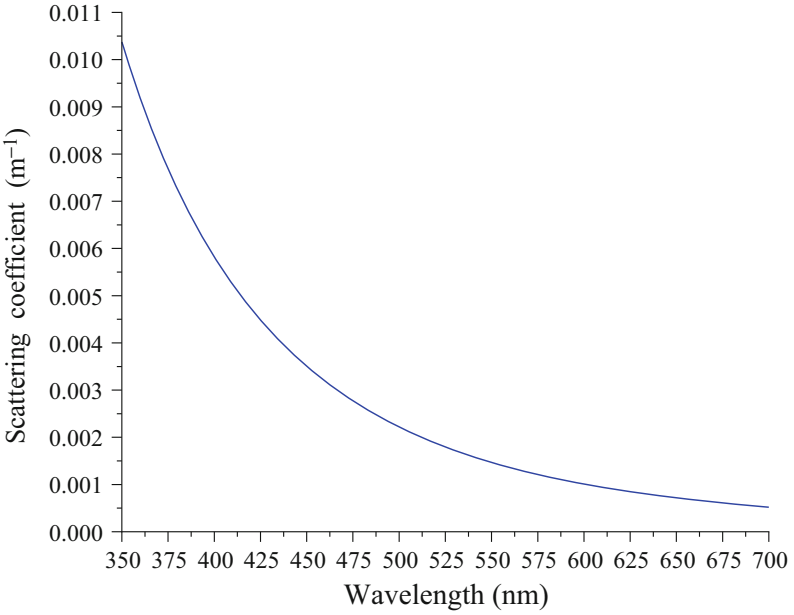

Fig. 32.5 Relationship between the scattering coefficients of pure seawater and different wavelengths

By substituting the wavelength λ (350–700 nm) of the visible light band into Eq. (32.13), the relationship between the scattering coefficient $\beta_w(\lambda)$ of pure seawater and that of the visible light band λ (350–700 nm) can be obtained. As shown in Fig. 32.5, the scattering coefficient $\beta_w(\lambda)$ of pure seawater decreases exponentially with the increase of light wavelength.

Phytoplankton Light-Scattering Characteristics

The light-scattering characteristics of phytoplankton are also related to their chlorophyll concentrations. To simulate the scattering of phytoplankton, Roesler et al. obtained the equation for scattering coefficient $\beta_{\text{chl}}(\lambda)$ of phytoplankton using the Mie theory and field measurements [54]:

$$\beta_{\text{chl}}(\lambda) = 0.45\left(\frac{550}{\lambda}\right)C^{0.62}, \tag{32.14}$$

where C is the concentration of phytoplankton chlorophyll.

Carina et al. optically simulated the change in the carbon concentration in the core by changing the real part of the refractive index of the particle and obtained a chlorophyll backscattering ratio of [55]

$$\beta_{\text{pc}} = 2\pi\chi_p\left(124^\circ\right)\beta_p\left(124^\circ\right), \tag{32.15}$$

where $\chi_p(124^\circ)$ and $\beta_p(124°)$ are the ratio constants, $\chi_p(124^\circ) = 1.076$, and $\beta_p(124°) = 0.00076$. Thus, the backscattering coefficient of chlorophyll to light is

$$\beta_{\mathrm{cb}}(\lambda) = \beta_{\mathrm{chl}}(\lambda) \times \beta_{\mathrm{pc}}. \tag{32.16}$$

The forward-scattering coefficient of chlorophyll is

$$\beta_{\mathrm{cf}}(\lambda) = \beta_{\mathrm{chl}}(\lambda) - \beta_{\mathrm{cb}}(\lambda). \tag{32.17}$$

By taking the chlorophyll concentration values of different phytoplankton, $C = 0.01$ mg/m^3, 0.05 mg/m^3, 0.1 mg/m^3, 0.5 mg/m^3, and 1 mg/m^3, the backscattering coefficient $\beta_{\mathrm{cf}}(\lambda)$ and the forward-scattering coefficient $\beta_{\mathrm{cb}}(\lambda)$ of phytoplankton to light were obtained using Eqs. (32.16) and (32.17), as shown in Fig. 32.6.

As can be seen from Fig. 32.6, the light-scattering coefficient $\beta_{\mathrm{chl}}(\lambda)$ of phytoplankton decreases with the increase of wavelength. While the light wavelength remains constant, the scattering coefficient of phytoplankton increases with the increase of the chlorophyll concentration.

Suspended Particle Light-Scattering Characteristics

Particles suspended in seawater are mainly composed of biological debris, excreta, decomposed matter, suspended sediment particles, etc. However, because the shape and size of suspended particles in seawater are difficult to determine, the scattering model of suspended particles is simplified by the Mie theory and the Rayleigh scattering model to facilitate the calculation of the scattering coefficient.

The suspended particles are divided into small and large particles according to their diameter. The scattering coefficient equation of the suspended particles is [56]

$$\beta_{\mathrm{nap}}(\lambda) = \beta^0_{\mathrm{snap}}(\lambda) C_s + \beta^0_{\mathrm{lnap}}(\lambda) C_l, \tag{32.18}$$

where $\beta^0_{\mathrm{snap}}(\lambda)$ is the specific scattering coefficient of small particles, $\beta^0_{\mathrm{lnap}}(\lambda)$ is the specific scattering coefficient of large particles, C_s is the concentration of small particles, and C_l is the concentration of large particles.

Specific Light-Scattering Properties of Small Particles

Particles suspended in seawater that are smaller than 5 μm in diameter are called small particles; they have a density of 2 g/cm^3 and a specific light-scattering coefficient $\beta^0_{\mathrm{snap}}(\lambda)$. It can be derived from the spectral correlation of small suspended particles as follows [53]:

$$\beta^0_{\mathrm{snap}}(\lambda) = 1.151302 \left(\frac{400}{\lambda}\right)^{1.7}. \tag{32.19}$$

In this equation, the concentration C_s of small suspended particles is mainly affected by the concentration C_c of chlorophyll in seawater. The expression of the correlation is [53]

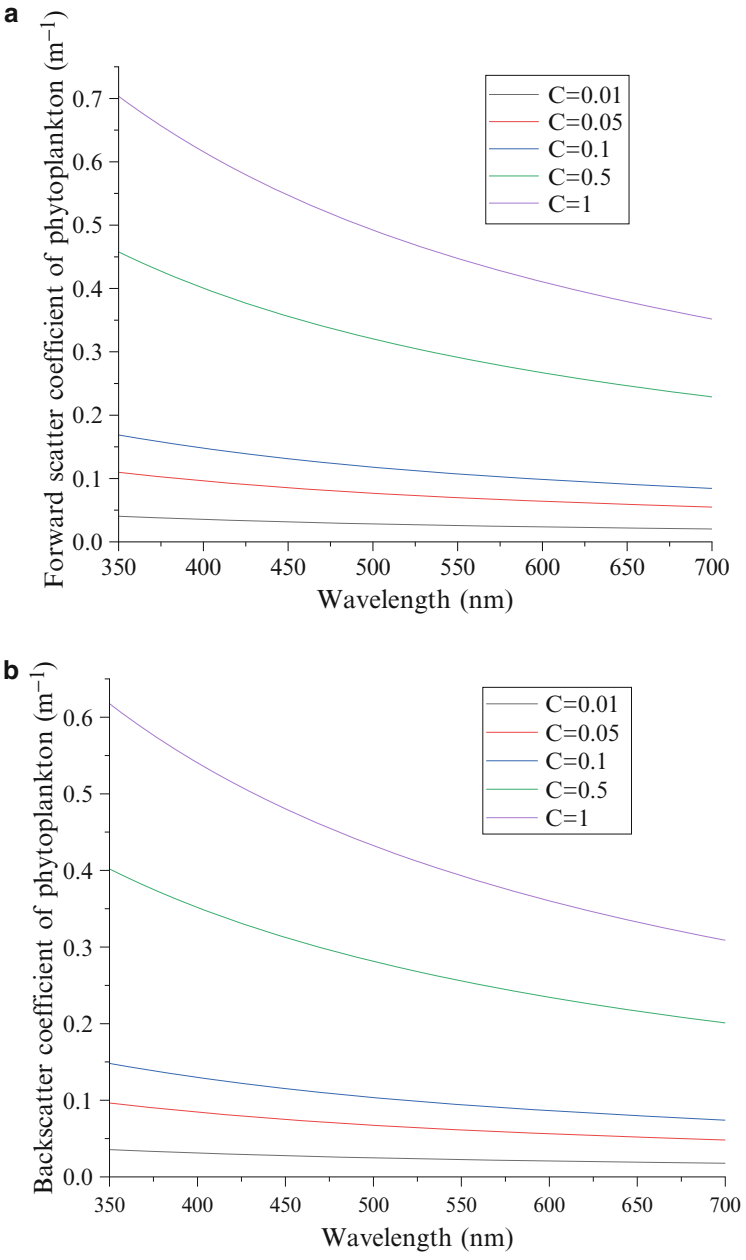

Fig. 32.6 Relationship between the scattering coefficient of phytoplankton and the light wavelength. (**a**) Forward scattering; (**b**) backscattering

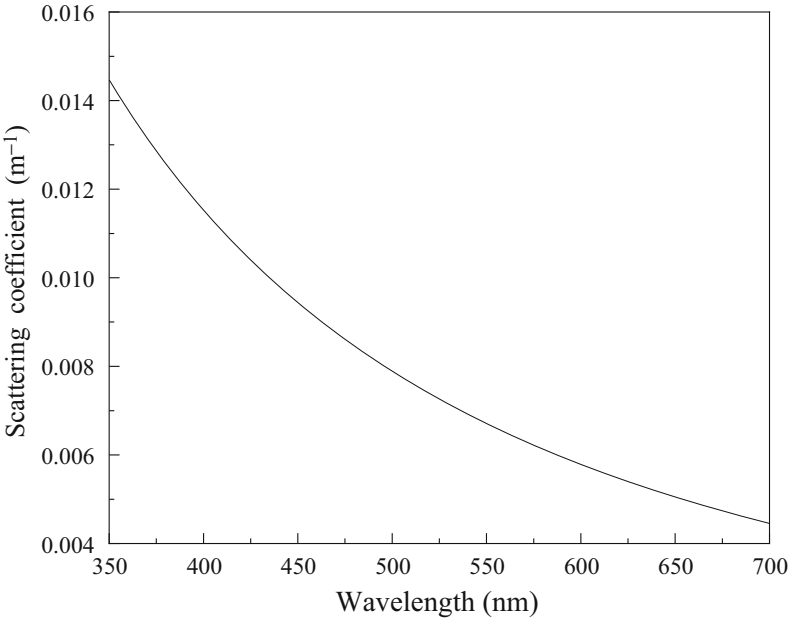

Fig. 32.7 Scattering coefficient of small suspended particles with different wavelengths

$$C_S = 0.01739C \exp\left[0.11631\left(\frac{C}{C_c^0}\right)\right], \tag{32.20}$$

where C is the chlorophyll concentration of suspended particles and ${C_c}^0$ is the chlorophyll concentration in seawater. Because Eq. (32.20) can calculate the concentration C_s of small particles when the chlorophyll concentration is ${C_c}^0 = 1$ mg/m^3, we substitute Eq. (32.20) for the visible light band λ (350–700 nm) to obtain the light-scattering coefficient of small particles, as shown in Fig. 32.7.

As shown in Fig. 32.7, the scattering properties of suspended particles decrease with an increase in wavelength; however, the scattering coefficient of small suspended particles changes very little over the entire visible wavelength range, decreasing only by 0.009 m^{-1}.

Light-Scattering Characteristics of Large Particles

Suspended particles larger than 5 μm in diameter are called large particles. The density of large particles is 1 g/cm^3, and the refractive index is 1.03. The specific scattering coefficient of large particles is $\beta^0_{\text{lnap}}(\lambda)$; it can be derived from the spectral correlation of large suspended particles as [53]

$$\beta^0_{\text{lnap}}(\lambda) = 0.341074\left(\frac{400}{\lambda}\right)^{0.3}. \tag{32.21}$$

In the equation, the concentration C_l of large suspended particles is mainly affected by the concentration C_c of chlorophyll in seawater. The expression of the correlation is [53]

$$C_l = 0.76284C \exp\left[0.03092\left(\frac{C}{C_c^0}\right)\right], \tag{32.22}$$

where C is the chlorophyll concentration of the suspended particles and ${C_c}^0$ is the chlorophyll concentration of seawater. The C_l concentration of large particles can be calculated as $C_c^0 = 1\,\mathrm{mg/m^3}$ from the Eq. (32.22). Hence, we substitute Eq. (32.22) for λ (350–700 nm) in the visible band to obtain the light-scattering coefficient of the large particles, as shown in Fig. 32.8.

As shown in Fig. 32.8, the scattering properties of large suspended particles in seawater decrease with an increase in the light wavelength. Compared with the scattering coefficients of small particles, when the wavelength of light is fixed, the scattering properties of large suspended particles in seawater decrease with an increase in the light wavelength, as shown in Fig. 32.8. When the light wavelength is constant, the scattering effect of large suspended particles in seawater is significantly higher than that of small suspended particles.

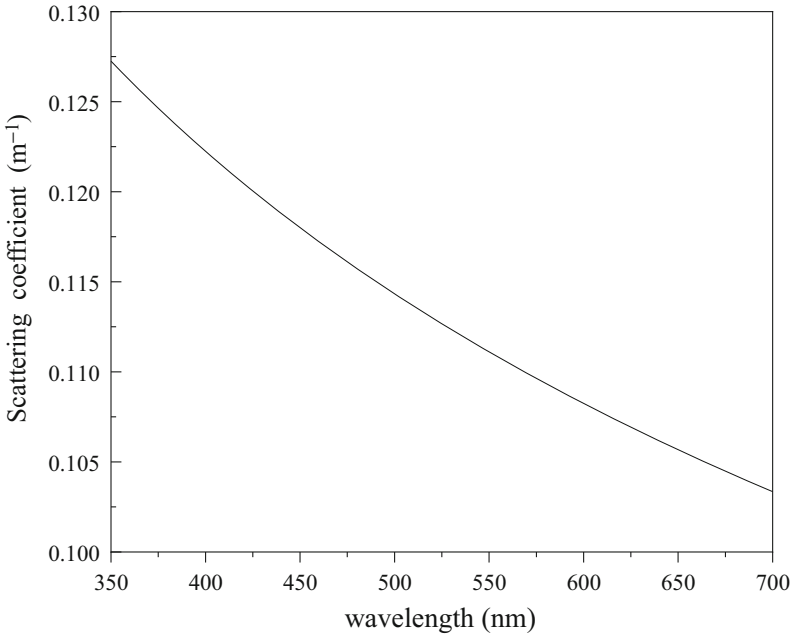

Fig. 32.8 Plot of the scattering coefficient of large suspended particles with different wavelengths

Experimental Measurements of Underwater Optical Wireless Communication

The effect of underwater turbulence on laser transmissions leads to a significant reduction in the accuracy and transmission distance of laser communication and may even interrupt communications. In this section, the Chan River, Ba River, and Yantai No. 1 beach in Xi'an, Shaanxi Province, were surveyed. The skewness and steepness, underwater structure constant, probability density distribution, scintillation index, optical power loss, and bit error rate (BER) of the underwater optical signal samples at different water velocities and distances were analyzed.

Experimental System

The experimental system is shown in Fig. 32.9. The emitting end had a 532-nm wavelength PL-E Pro green laser; its output power was 1 W, and the operating voltage was 4.2 V. The detector was a PD300-UV photodiode sensor with a spectral response range of 200–1100 nm and aperture size of 10 mm × 10 mm. The filter had a wavelength range of 513–545 nm and aperture of 20 mm. In addition, the underwater temperature was measured using a probe-type electronic thermometer and the current water velocity was averaged using the floating method.

After the laser was transmitted through an underwater channel, the emission of the green laser was analyzed, first, through a double-layer compound eye lens [57]. A curved lens on the second layer of the double-layer compound eye lens converged and superposed the light beams converged by the lens array, so that the light passing through each small lens was merged onto the detector surface. The detector and filter were then used to measure the instantaneous optical signal, which was converted into an electrical signal and sent to a computer for data acquisition and signal processing.

The experimental system is shown in Fig. 32.9. In this experiment, the transmitter and receiver were first aligned. The laser beam was passed through a double-layer compound eye lens. When the laser was stable, the PD300-UV detector was used to collect the optical signals. The temperature was recorded simultaneously. Finally, the light power of the light signal was analyzed, and the fluctuation characteristics of the light signal sample and light power loss under different turbulence intensities were obtained.

	T13	2023.3.6	1.5	1	8.2–8.4	Adverse water
	T14	2023.3.6	1.5	1	8.4–8.6	Horizontal

Table 32.3 Basic conditions of experiments at different distances

Location	Measurement sample	Date	Link distance (m)	Wind speed (m/s)	Water temperature (° C)
Yantai No. 1 Beach	T15	2023.4.2	1	3.3	8.5–8.8
	T16	2023.4.2	3	3.3	8.8–9.1
	T17	2023.4.2	5	3.3	9.1–9.4
	T18	2023.4.2	6.5	3.3	9.4–9.7

From November 2022 to June 2023, the research group conducted underwater laser transmission experiments in the Chan River, Ba River, and Yantai No. 1 beach in Shaanxi Province. The link consisted of a transmitter, channel, and receiver. During the experiment, the data parameters were measured, as shown in Tables 32.1, 32.2, and 32.3. To eliminate the error caused by wind speed on the measured results, the experimental links were maintained 10 cm from the water surface [58]. In the measured temperature range, the variance of the sample was almost constant; therefore, the effect of temperature on the results can be ignored in the following experiments.

Statistical Analysis of Data

The moment estimation estimates the total moment by the sample moment. The first-order origin moment of the measured signal sequence X represents the expectation of the measured signal sequence, and the second-order central moment represents the variance. The skew direction and degree of skew distribution of the skew statistics data are expressed by the third-order center distance and the 3/2 power of the sample variance. The expression is [59]

$$S_X = \left\langle (\mathrm{X} - \langle X \rangle)^3 \right\rangle / \sigma_X^3. \tag{32.23}$$

The steepness measures the amount of data clustered in the center, expressed by the fourth-order center moment and variance, with the following expression [59]:

$$K_X = \left\langle (\mathrm{X} - \langle X \rangle)^4 \right\rangle / \sigma_X^4. \tag{32.24}$$

Figure 32.10 shows the relationship between the skewness and steepness of the measured samples in different waters and the variance of the measured light signal samples in horizontal coordinates. The longitudinal coordinates are the skewness and steepness of the measured light signal samples in different waters.

Figure 32.10a, b show the statistical distribution of light signal samples at different water velocities in the Chan and Ba Rivers, respectively, and Fig. 32.10c shows the statistical distribution of light signal samples at different distances from the Yantai No. 1 beach. In Fig. 32.10a–d, the sample variance of the measured optical signal increases with increasing water speed, and in graphs Fig. 32.10e, f, the sample variance of the measured optical signal increases with increasing distance. In different waters, the range of the variance distribution of the optical signal samples differs, which leads to an increase in skewness and steepness.

In Fig. 32.11, the maximum values of the skewness and kurtosis of the Chan River optical signal sample are 1.362 and 3.5, respectively, the maximum values of the Ba River optical signal sample are 1.43 and 3.8, respectively, and the maximum values of the light signal samples from the Yantai No. 1 beach are 1.49 and 4.3, respectively. The Chan River light sample had the smallest skewness and kurtosis, the Ba River light sample had the second largest skewness and kurtosis, and the Yantai No. 1 beach had the largest skewness and kurtosis.

The skewness of the optical signal sample increases with an increase in its variance, which means that the symmetry of the probability distribution of the power value of the optical signal sample worsens with an increase in the water speed and distance, compared with the normal distribution. The steepness of the optical signal samples increases gradually; however, their power distribution is increasingly dispersed, compared to that of the normal distribution.

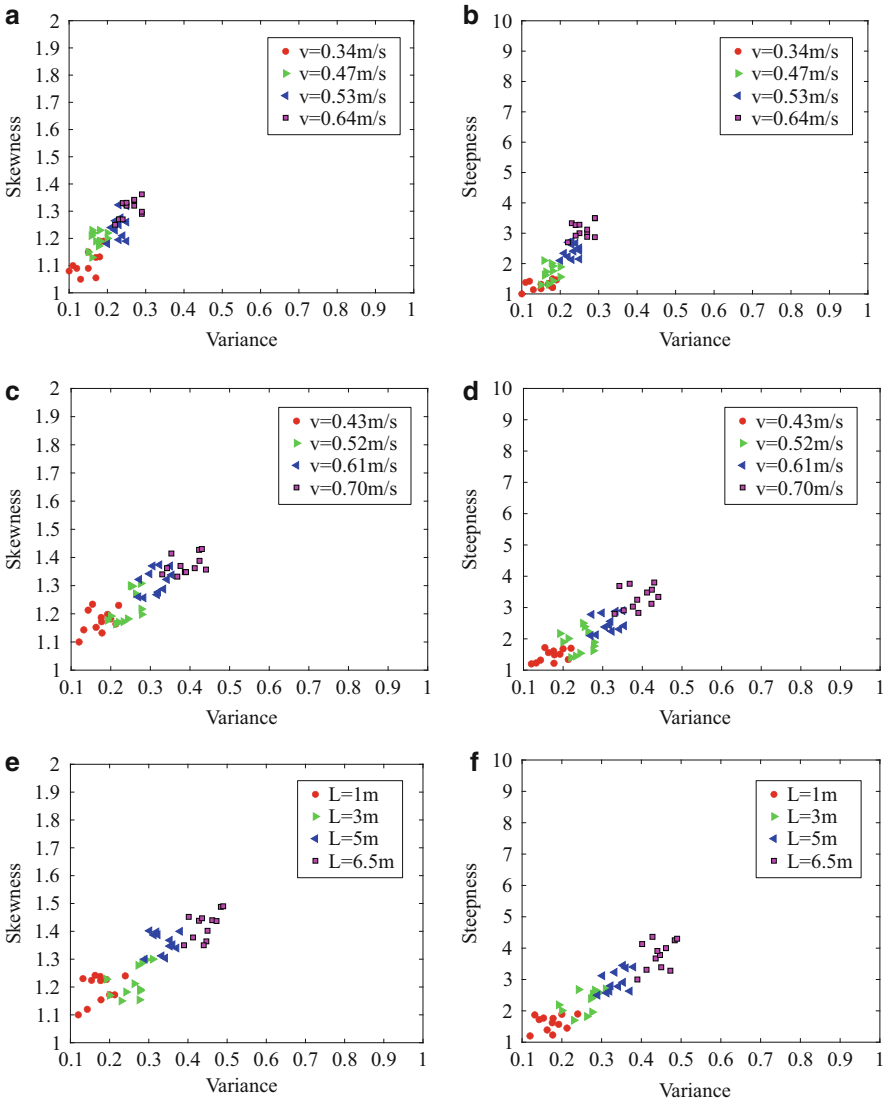

Fig. 32.10 Relationship between the deviation, steepness, and variance of measured samples in different waters. (**a**) Chan River skewness. (**b**) Chan River steepness. (**c**) Ba River skewness. (**d**) Ba River steepness. (**e**) Yantai No. 1 beach skewness. (**f**) Yantai No. 1 beach steepness

Underwater Structure Constant

The underwater refractive index structure constant C_n^2 quantitatively describes the intensity of optical turbulence. Baykal expresses the atmospheric refractive index structure constant using the ocean turbulence parameters through the modified Rytov theory. The expression is [60]

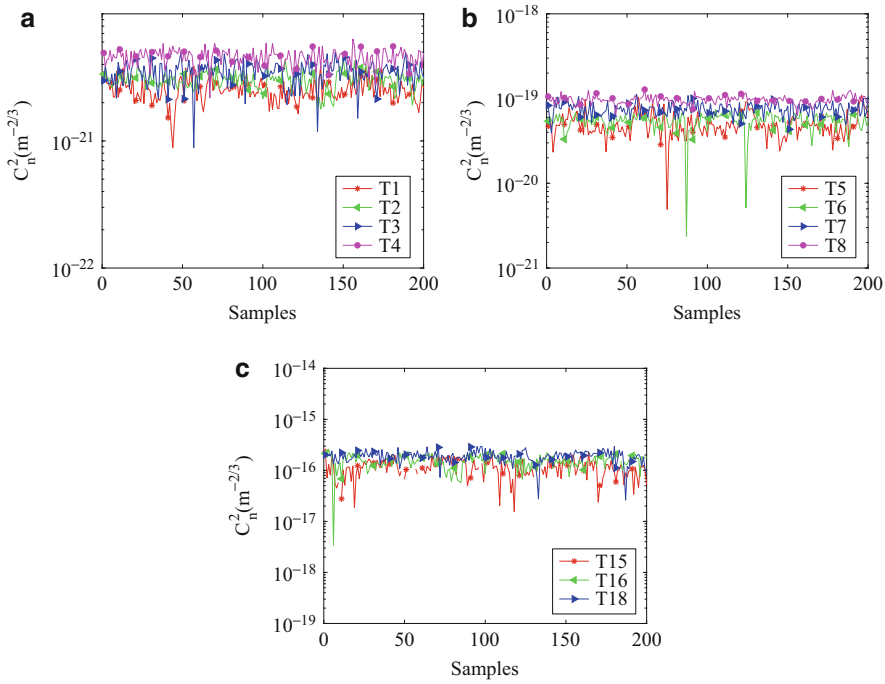

Fig. 32.11 Structure constants of light signal samples measured in different waters. (**a**) Chan River. (**b**) Ba River. (**c**) Yantai No. 1 beach

$$C_n^2 = 16\pi^2 k^{-7/6} L^{-11/6} \int_0^L \int_0^\infty \kappa \phi_n(\kappa) \cdot \left\{1 - \cos\left[\kappa^2 \zeta (L-\zeta)/(Lk)\right]\right\} d\kappa d\zeta, \tag{32.25}$$

where ζ is the distance between the Gaussian beam and the lens at the emitting end of the laser, $k = 2\pi/\lambda$ is the wave number, and λ is the wavelength. The spectral density function $\phi_n(\kappa)$ of the refractive index is expressed as

$$\Phi_n(\kappa) = 0.388 \times 10^{-8} \varepsilon^{-\frac{1}{3}} \kappa^{-\frac{11}{3}} \left[1 + 2.35(\kappa\eta)^{\frac{2}{3}}\right] \times \frac{\chi_T}{\omega^2} \times \left(\omega^2 e^{-A_T \delta} + e^{-A_S \delta} - 2\omega e^{-A_{TS} \delta}\right), \tag{32.26}$$

where the kinetic energy dissipation rate ε is defined as the rate at which the kinetic energy per unit mass of turbulence is converted into molecular thermal kinetic energy, with a typical value of 10^{-10}–10^{-1} m^2/s^3. $\delta = 1.5{C_1}^2(\kappa\eta)^{\frac{4}{3}} + {C_1}^3(\kappa\eta)^2$. The mean-square temperature dissipation rate ω is defined as the amount of turbulence acting on the temperature field through molecular heat conduction. The typical

value is 10^{-10}–10^{-4} K^2/s. The temperature–salinity contribution ratio is typically defined as the ratio of temperature-induced ocean turbulence to salinity-induced ocean turbulence, typically [−5, 0]. κ represents the magnitude of the spatial frequency, $A_T = 1.863 \times 10^{-2}$, $A_s = 1.9 \times 10^{-4}$ and $A_{TS} = 9.41 \times 10^{-3}$.

According to Davis' theory, C_n^2 can be divided into three types: strong turbulence in $C_n^2 \geq 2.5 \times 10^{-13} m^{-2/3}$, moderate turbulence in $6.4 \times 10^{-17} m^{-2/3} \leq C_n^2 \leq 2.5 \times 10^{-13} m^{-2/3}$, and weak turbulence in $C_n^2 \leq 6.4 \times 10^{-17} m^{-2/3}$. Its value changes with the water body, water speed, etc.; this section uses the scintillation method to measure the constant [61], as follows:

$$C_n^2 = 4.48 C D_t^{7/3} L^{-3} \sigma_x^2, \tag{32.27}$$

where L is the link length; $C = D_r/D_t$, where D_r and D_t are the sizes of the receiving and sending apertures, respectively; the logarithmic amplitude variance is σ_x^2, which can be expressed as [62]

$$\sigma_x^2 = \frac{1}{4} \ln\left[1 + \left(\frac{s}{< I >}\right)^2\right], \tag{32.28}$$

where the formula is the mean $< I >$ and standard deviation s of the light intensity.

To obtain the change rule C_n^2 for different water velocities and distances, the received optical signal was normalized and divided into 200 groups. By calculating the mean and standard deviation of each group of 500 light intensity values, the change curve C_n^2 was obtained using Eq. (32.27) and then Eq. (32.25), as shown in Fig. 32.11.

The maximum C_n^2, minimum C_n^2, and mean C_n^2 are calculated simultaneously to quantitatively describe the rule of taking C_n^2 values at different water velocities and distances, as shown in Table 32.4.

In experiments T1–T4, the Chan River measured samples, and C_n^2 increased with the increase of water velocity; in experiments T5–T8, the Ba River measured samples, and C_n^2 increased with the increase of water velocity; in experiments T15, T16, and T18, the Yantai No. 1 beach measured samples, and C_n^2 increased with the increase of the distance. That is, the water speed increased as the link distance increased.

Considering Fig. 32.11 and Table 32.4, it can be seen that the C_n^2 of the Chan River spanned two orders of magnitude and fluctuated randomly for different water velocity variations; most of them were distributed between 1.16×10^{-21} $m^{-2/3}$ and 5.75×10^{-21} $m^{-2/3}$. The Ba River C_n^2 was divided into three orders of magnitude, that is, between 2.3715×10^{-21} $m^{-2/3}$ and 1.5142×10^{-19} $m^{-2/3}$, and fluctuated randomly; most values were between 5.65×10^{-20} $m^{-2/3}$ and 1.21×10^{-19} $m^{-2/3}$. The Yantai No. 1 beach had four orders of magnitude, between 5.5792×10^{-19} $m^{-2/3}$ and 4.7438×10^{-16} $m^{-2/3}$, which fluctuated randomly; most of them were distributed between 3.41×10^{-18} $m^{-2/3}$ and 2.93×10^{-16} $m^{-2/3}$.

Table 32.4 Structure constants of optical signal samples

Measurement sample	Maximum ($m^{-2/3}$)	Minimum ($m^{-2/3}$)	Mean ($m^{-2/3}$)
T1	3.9475×10^{-21}	7.5496×10^{-22}	2.5071×10^{-21}
T2	4.6414×10^{-21}	1.1592×10^{-21}	3.0325×10^{-21}
T3	5.1554×10^{-21}	8.8539×10^{-22}	3.51×10^{-21}
T4	6.7502×10^{-21}	2.1776×10^{-21}	4.5620×10^{-21}
T5	1.0438×10^{-19}	4.9211×10^{-21}	4.9773×10^{-20}
T6	7.3957×10^{-20}	2.3715×10^{-21}	5.5249×10^{-20}
T7	1.2376×10^{-19}	3.9042×10^{-20}	7.5235×10^{-20}
T8	1.5142×10^{-19}	4.3730×10^{-20}	9.5812×10^{-20}
T15	2.3255×10^{-16}	5.5792×10^{-19}	1.0531×10^{-16}
T16	3.1901×10^{-16}	3.4070×10^{-18}	1.4859×10^{-16}
T18	4.7438×10^{-16}	2.6121×10^{-17}	1.8970×10^{-16}

According to the Davis standard, the turbulence intensity of the Chan and Ba rivers is weak and that of the Yantai No. 1 beach is moderate; the stronger the turbulence, the more unstable the signal. The fluctuation of the light signal sample in the Yantai No. 1 beach was the largest, followed by those of the Ba and Chan Rivers.

Probability Density Function

Light intensity in underwater turbulence fluctuates randomly. The probability density distribution is the most basic method for describing the statistical characteristics of actual underwater turbulence. At present, many studies have been conducted on the probability density distribution of light intensity fluctuation.

It is generally considered that the probability density function (PDF) of the light intensity fluctuation follows a log-normal distribution; its expression is [63]

$$f_I(I) = \frac{1}{I\sigma_{\ln I}\sqrt{2\pi}} \exp\left\{ -\frac{\left[\ln(I) + 0.5\sigma_{\ln I}^2\right]^2}{2\sigma_{\ln I}^2} \right\}, \tag{32.29}$$

where the logarithmic variance $\sigma_{\ln I}^2$ of the light intensity can be expressed by the scintillation index σ_I^2, in which I represents the light intensity, and $< \cdot >$ is the mean value in weak turbulence.

The gamma–gamma light intensity fluctuation probability distribution model is a two-parameter model that is often used to describe the statistics of light intensity fluctuation in the middle and strong fluctuation regions [64]. The light intensity at the receiving end can be regarded as a multiplicative modulation process of large-scale to small-scale light intensity fluctuation.

When both large- and small-scale light intensity fluctuations follow the gamma distribution and are statistically independent, the light intensity fluctuation follows the gamma–gamma distribution, where the probability density function is [64]

$$f_I(I) = \frac{2(\alpha\beta)^{(\alpha+\beta)/2}}{\Gamma(\alpha)\Gamma(\beta)} I^{(\alpha+\beta)/2-1} K_{\alpha-\beta}\left(2\sqrt{\alpha\beta I}\right), \tag{32.30}$$

where I is the normalized irradiance, α and β are the outer and inner scale parameters used to describe the intensity scintillation, $\Gamma(\cdot)$ is the gamma function, and the second modified Bessel function is order $K_\nu(\cdot)$, when Gaussian beams are used. When the receiver aperture is used, the following are obtained:

$$\alpha = \left[\exp\left(\frac{0.196\sigma_l^2}{\left(1 + 0.18d^2 + 0.186\sigma_l^{12/5}\right)^{7/6}}\right) - 1\right]^{-1} \tag{32.31}$$

$$\beta = \left[\exp\left(\frac{0.204\sigma_l^2\left(1 + 0.23\sigma_l^{12/5}\right)^{-5/6}}{1 + 0.9d^2 + 0.207d^2\sigma_l^{12/5}}\right) - 1\right]^{-1}, \tag{32.32}$$

where $d = \sqrt{kD^2/4L}$ and $\sigma_l^2 = 1.23C_n^2k^{7/6}L^{11/6}$ is the Rytov variance under strong turbulence. $k = 2\pi/\lambda$, λ is the wavelength of light, D is the size of the receiving aperture, and C_n^2 is the refractive index structure constant.

Figure 32.12 shows the PDFs of the samples measured in different waters.

From Fig. 32.12a, b, we can see that the light intensity I on the receiving surface is normalized, and the value range of I increases with an increase in water velocity. It deviates to the left, and the distribution of $P(I)$ follows a log-normal distribution. It can be seen that an increase in water velocity will lead to an increase in turbulence intensity and an increase in the random fluctuation of the atmospheric refractive index, reducing the stability of the received optical signal.

As can be seen from Fig. 32.12c, d, the range of values of I in different water directions is basically the same, the probability density curves are basically coincidental, and the water direction has little effect on the change in the probability density function. It can be seen that the magnitude of the turbulence intensity is basically independent of the water direction when the laser propagates horizontally underwater.

Figure 32.12e shows the measurement results of the Yantai No. 1 beach at different distances. With an increase in the communication distance, the range of I also increases and it deviates to the left. Moreover, the combined turbulence

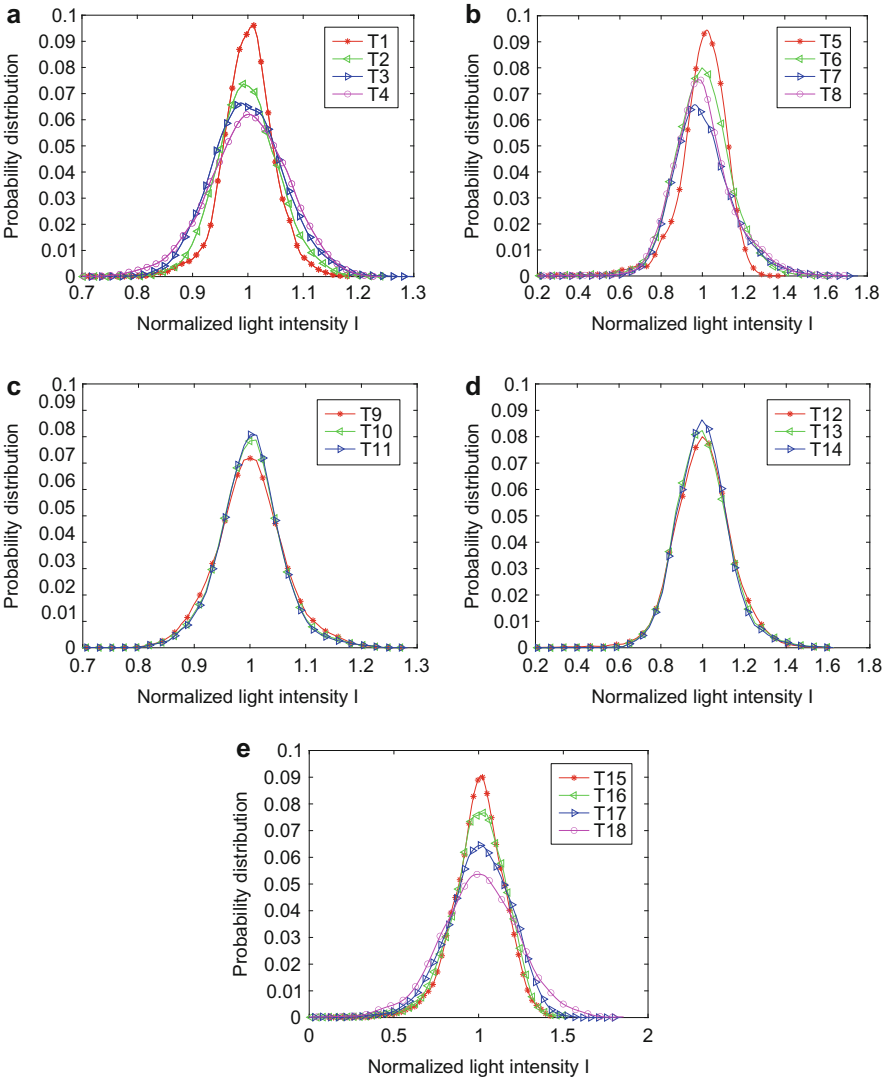

Fig. 32.12 PDFs of samples from different waters. (**a**) Chan River survey sample. (**b**) Ba River survey sample. (**c**) Chan River survey sample. (**d**) Ba River survey sample. (**e**) Samples taken at different distances from Yantai No. 1 beach

intensity is moderate, which is in accordance with the characteristics of the gamma–gamma distribution. Therefore, an increase in the distance increases the turbulence intensity, which reduces the stability of the optical signal received by the entire link.

Performance Analysis of Underwater Optical Wireless Communication Experiments

Underwater turbulence can affect the performance of communication systems, and even disrupt the system. In this section, the performance of an underwater communication system is further evaluated by studying the scintillation index, optical power loss, and bit error rate under different water speeds and distances.

Scintillation Index

The scintillation index is typically used to characterize the statistical characteristics of light intensity over time; the expression is [65]

$$\sigma_I^2 = \frac{\left(< I^2 > - < I >^2\right)}{< I >^2} = \frac{< I^2 >}{< I >^2} - 1, \tag{32.33}$$

where $< \cdot >$ denotes the ensemble average and I denotes the beam intensity. The normalized intensities in Fig. 32.13 were obtained by processing several groups of data from an underwater laser transmission experiment.

From Fig. 32.13, it can be seen that the normalized light intensity of the Chan River fluctuates randomly in the range of 0.9–1.1 that of the Ba River fluctuates randomly in the range of 0.8–1.2, and the intensity fluctuation range increases with the increase of water velocity. An increase in water velocity leads to an increase in the turbulence intensity and scintillation of the received optical signal, which reduces the stability of the received optical signal.

The normalized light intensity of Yantai No. 1 beach fluctuates randomly in the range of 0.5–1.5, and the fluctuation range increases with the communication distance. The intensity of underwater turbulence increases with an increase in the communication distance, and the scintillation of the received optical signal increases, reducing the stability of the received optical signal.

To explain quantitatively, the light intensity fluctuation at high water speeds is greater than that at low water speeds, and the fluctuation in light intensity at long distances is greater than that at short distances. Using Eq. (32.33), the scintillation index was calculated using the standard deviation of each set of samples.

The scintillation indices of the Chan River are 0.0032, 0.0041, 0.0050, and 0.0065, which are on the order of 10^{-3}. The scintillation indices of the Ba River are 0.045, 0.052, 0.060, and 0.068, which are on the order of 10^{-2}, from the quantitative scintillation index of the Chan and Ba Rivers. This proves that the fluctuation of light intensity at high water speeds is greater than that at low water speeds. The scintillation indices of the Yantai No. 1 beach are 0.27, 0.38, 0.52, and 0.61 at different distances, which are all on the order of 10^{-1}. This demonstrates that the turbulence intensity increases with an increase in the communication distance, by the quantitative scintillation index of the optical signal sample of the Yantai No. 1 beach.

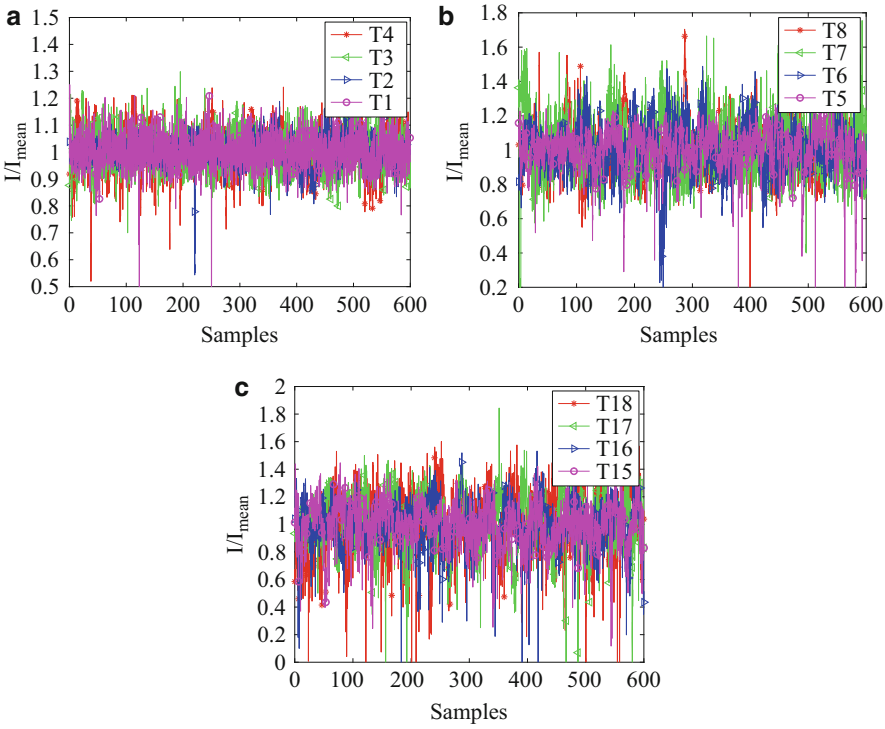

Fig. 32.13 Light intensity fluctuation of light signal samples in different waters. (**a**) Chan River. (**b**) Ba River. (**c**) Yantai No. 1 beach

Optical Power Loss

Based on Beer's theorem, the change in light power in seawater can be simplified as an exponential attenuation [66]:

$$I(L) = I_0 \exp(-c(\lambda)L), \tag{32.34}$$

where L is the distance of light propagation in water, I_0 is the initial light intensity, $I(L)$ is the received light intensity, and $c(\lambda)$ is the attenuation coefficient.

Figure 32.14 shows the power loss owing to turbulence in different waters. Figure 32.14a, b shows the decay curves of the received light power of the Chan and Ba Rivers, respectively, with the variation of the scintillation index at different water velocities. Figure 32.14c shows the decay curve of the received light power with the scintillation index at different distances of the Yantai No. 1 beach, and the loss of the light power increases with the scintillation index.

Comparing the measurements of the Chan River, Ba River, and Yantai No. 1 beach, we can see that the loss of the optical signal is different for different scintillation indices. The scintillation index of the Chan River was 10^{-3} orders of

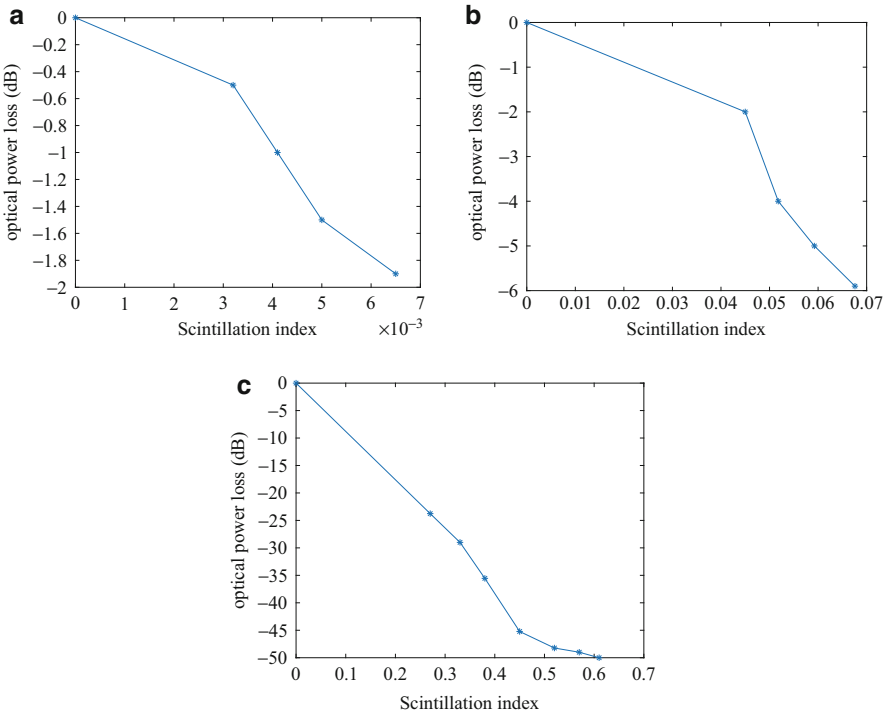

Fig. 32.14 Power loss due to turbulence in different water areas. (**a**) Power loss of the Chan River at different water speeds. (**b**) Power loss of the Ba River at different water speeds. (**c**) Power loss of the Yantai No. 1 beach at different distances

magnitude and the loss of the light signal was 1.9 dB; the Ba River's scintillation index was 10^{-2} orders of magnitude, and the loss of the light signal was 5.9 dB; the scintillation index of the Yantai No. 1 beach was 10^{-1} orders of magnitude at different communication distances, and the maximum loss of the optical signal was 50 dB.

Thus, the loss of the received optical signal increases with increasing water speed and communication distance. The Chan River, Ba River, and Yantai No. 1 beach can be transmitted for maximum distances of 1 m, 1.5 m, and 6.5 m, respectively. The corresponding attenuation coefficient of Yantai No. 1 beach is 2.13 and those of the Chan and Ba rivers are 10.79 and 9.21.

By comparing the longest distance that a laser could travel in different water qualities, it was found that the maximum distance was determined by the water attenuation coefficient, that is, the turbidity. Lasers can travel long distances in clear water and short distances in turbid water. As a result, the water quality of the Chan River was the worst, followed by that of the Ba River, and the water quality of the Yantai No. 1 beach was the best, which is consistent with reality.

BER at Different SNR

The instantaneous signal-to-noise ratio (SNR) probability density function $f_\mu(\mu)$ [67] of the received signal can be expressed as

$$f_\mu(\mu) = \frac{1}{2\mu\sigma_I\sqrt{2\pi}} \exp\left\{-\frac{\left[\ln(\mu/\overline{\mu}) + \sigma_I^2\right]^2}{8\sigma_I^2}\right\}. \tag{32.35}$$

In general, the average bit error rate in fading channels can be calculated by multiplying the instantaneous bit error rate by the probability density function $f_\mu(\mu)$ of the instantaneous signal-to-noise ratio of the received signal [68]:

$$\overline{P_e} = \int_0^\infty f_\mu(\mu) P_e d\mu, \tag{32.36}$$

where the instantaneous bit error rate $P_e = \frac{1}{2}\mathrm{erfc}\left(\frac{\sqrt{\mu}}{2}\right)$ is expressed by the average bit error rate formula [69]:

$$\overline{P_e} = \int_0^\infty \frac{1}{2\mu\sigma_I\sqrt{2\pi}} \exp\left[-\frac{\left(\ln(\mu/\overline{\mu}) + \sigma_I^2\right)^2}{8\sigma_I^2}\right] \times \frac{1}{2}\mathrm{erfc}\left(\frac{\sqrt{\mu}}{2}\right) d\mu, \tag{32.37}$$

where μ is the instantaneous signal-to-noise ratio, $\overline{\mu}$ is the average signal-to-noise ratio, and μ_{th} is the critical threshold of the SNR.

By introducing the probability density function of the gamma–gamma distribution into the above equation, we obtain [70]

$$\overline{P_e} = \frac{2^{\alpha+\beta-3}}{\pi^{3/2}\Gamma(\alpha)\Gamma(\beta)} \times G_{5,2}^{2,4}\left[\frac{4\overline{\mu}}{\alpha^2\beta^2}\middle|_{0,\frac{1}{2}}^{\frac{1-\alpha}{2},\frac{2-\alpha}{2},\frac{1-\beta}{2},\frac{2-\beta}{2},1}\right]. \tag{32.38}$$

Figure 32.15 shows the bit error rate for different signal-to-noise ratios in different water areas. Figure 32.15a, b show that the bit error rates of the four water velocities of the Chan River from small to large are 0.0133, 0.0134, 0.0135, and 0.0139, respectively; when the SNR is 10 dB, the bit error rates of the four water velocities in the Ba River from small to large are 0.0154, 0.0166, 0.0184, and 0.0210, respectively. When the signal-to-noise ratio is constant, the bit error rate of the sample with a high water speed is greater than that of the sample with a low water speed.

In Fig. 32.15c, when the signal-to-noise ratio is 10 dB, the corresponding bit error rates of the Yantai No. 1 beach are 0.0297, 0.0344, 0.0390, and 0.0449 when the communication distances are 1 m, 3 m, 5 m, and 6.5 m, respectively. The greater the communication distance, the higher the bit error rate. When the bit error rate is 10^{-2}, the SNRs of the Chan River are 11.0, 11.05, 11.1, and 11.15 and those of the Ba River are 13.5, 14, 14.5, and 15, respectively. The higher the water speed, the higher

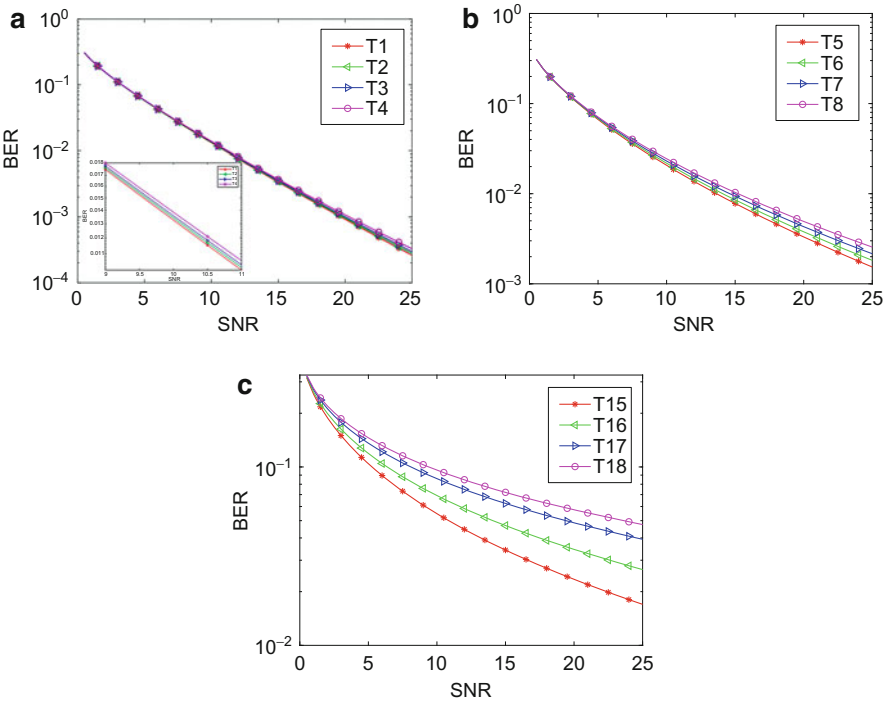

Fig. 32.15 Bit error rates at different signal-to-noise ratios for different water areas. (**a**) Chan River. (**b**) Ba River. (**c**) Yantai No. 1 beach

the signal-to-noise ratio. When the bit error rate is 0.15, the signal-to-noise ratios corresponding to different distances from the Yantai No. 1 beach are 5, 6, 7, and 8, respectively.

Figure 32.15 shows that the difference in bit error rate caused by different water speeds in the Ba River was greater than that caused by the Chan River. The change of the bit error rate of the Chan River at different water speeds was smaller than that of the Ba River at different water speeds.

Optical Cross-Medium Transmission Characteristics

At the air–sea interface, the laser propagates from a sparse medium to a dense medium. The random fluctuation of the sea surface leads to the spread, flickering, and drift of the receiving surface spot, which changes the communication performance. Underwater cross-medium optical communication is affected not only by the absorption and scattering of the light spot centroid but also by the sea surface wind speed. The spatial intensity distribution of the spot and offset of the spot centroid propagating across the medium were analyzed.

Optical Transmedia Model

Owing to the influence of the sea surface wind speed, the sea surface fluctuates randomly over time. When the laser irradiates the sea surface, the different refractive indices of the atmosphere and seawater cause the transmission laser to refract and reflect. Figure 32.16 shows the refraction of light at the air–sea interface, assuming that the refractive index of the medium in which the incident light resides is n_1 and the refractive index of the medium in which the refracted light resides is n_2.

The relationship between the incident angle θ_i, reflection angle θ_r, and refraction angle θ_t in the local sea surface coordinate system satisfies the reflection and Snell's laws:

$$\theta_i = \theta_r. \tag{32.39}$$

$$\frac{\sin\theta_i}{\sin\theta_t} = \frac{n_1}{n_2}. \tag{32.40}$$

The proportion R of the power of the incident light reflected by the air–sea interface to the power of the incident light is called reflectivity; the reflectivity of vertically polarized light is R_s, and the reflectivity of parallel-polarized light is R_p. Then,

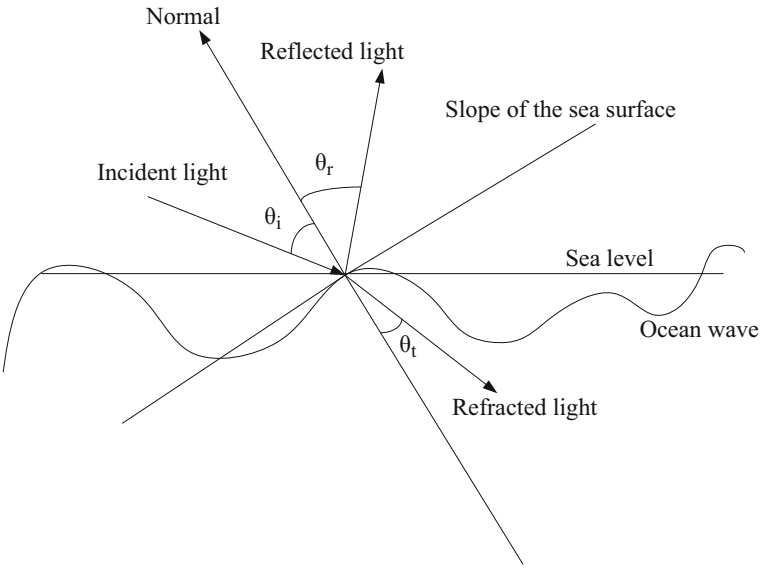

Fig. 32.16 Simplified model of the air–sea interface for light transmission

$$R_s = \frac{\sin^2(\theta_i - \theta_t)}{\sin^2(\theta_i + \theta_t)} \tag{32.41}$$

$$R_p = \frac{\tan^2(\theta_i - \theta_t)}{\tan^2(\theta_i + \theta_t)}. \tag{32.42}$$

The ratio of the power of the refracted light to that of the incident light is called the transmittance, T:

$$R = \frac{1}{2}\left(R_s + R_p\right) \tag{32.43}$$

$$T = 1 - R. \tag{32.44}$$

Considering the cross-medium light transmission background, a model of the center shift of the light spot caused by underwater cross-medium turbulence using a Gaussian function was proposed. The probability density function is defined as follows:

$$f(I) = A \times \frac{1}{\sqrt{2\pi} \times \sigma} \times e^{\left|-\frac{(x-\mu)^2}{2\times\sigma^2}\right|}, \tag{32.45}$$

where A is the normalized correction coefficient; the values are in the range of 0–1. $\int_0^\infty f(I) = 1$; hence, μ is the mean value and σ is the dithering variance of the spot center offset in the current turbulent state.

The Gaussian function was used to fit the cumulative distribution function of the spot center offset caused by the cross-medium turbulence:

$$F(I) = \int_0^I f(x)dx = \int_0^I A \times \frac{1}{\sqrt{2\pi} \times \sigma} \times e^{\left|-\frac{(x-\mu)^2}{2\times\sigma^2}\right|}dx. \tag{32.46}$$

When the signal-to-noise ratio of the optical communication system is less than γ_{th}, the communication system is interrupted:

$$P_{\text{out}} = F(\gamma_{\text{th}}) = \int_0^{\gamma_{\text{th}}} A \times \frac{1}{\sqrt{2\pi} \times \sigma} \times e^{\left|-\frac{(x-\mu)^2}{2\times\sigma^2}\right|}dx. \tag{32.47}$$

Therefore, the general expression of the bit error rate for the different binary modulation modes is

$$P_{\text{BER}} = \frac{q^p}{2\Gamma(p)} \int_0^\infty \exp(-qx)x^{p-1}F(x)dx, \tag{32.48}$$

where the different values of parameters p and q represent different modulation methods. $P = 1$ and $q = 1$ represent differential phase-shift keying.

Experiment

Spatial Distribution of the Spot Intensity

To obtain the spatial distribution of the light intensity in different water areas, several cross-medium laser transmissions were carried out in the Chan and Ba rivers in Xi'an City, Shaanxi Province, and in the upper reaches of Qianyou River in Shangluo City, Zhashui County, Shaanxi Province. In the experiment, an electronic thermometer was used to measure the temperature; the floating method was used to measure the water velocity many times to obtain the average value. Some of the experimental results are listed in Table 32.5.

To obtain the spatial distribution of the light intensity in different water areas, the image of the light spot collected by a charge-coupled device (CCD) camera was normalized. Typical images of light spots are shown in Fig. 32.17.

As shown in Fig. 32.17, the intensity distribution of the underwater wireless light across the medium follows a Gaussian distribution. The spatial distribution of the light intensity changes with the water quality. It can be seen from the picture that the light spot image of the Qianyou River is more concentrated and the light spot image of the Chan River is more diffuse. The distortion and dispersion degree of the light spot can be divided into the Chan, Ba, and Qianyou rivers, and the water quality of the Chan, Ba, and Qianyou rivers ranges from poor to good. The worse the water quality, the greater the degree of absorption and scattering and the greater the degree of distortion and dispersion of the light spot.

To analyze the difference in light intensity distribution in different waters, a two-dimensional distribution of the light intensity was obtained by projecting a gray image along the x-/y-axis. The results are shown in Fig. 32.18.

As shown in Fig. 32.18, the spatial distribution of the light spot intensity fluctuates randomly, and the shape of the light spot and degree of energy attenuation differ in different waters. The steepness of the light spot intensity distribution obtained from the Qianyou River was the highest, followed by that from the Ba River, and the Chan River was the smoothest.

With an increase in the attenuation coefficient, the water quality worsens, and the number of absorbed and scattered photons in seawater increases. Because of the increase in water turbidity, the absorption and scattering of photons were enhanced, and the intensity of the light spot was weakened.

The maximum normalized gray values of the received light spot in the Qianyou, Ba, and Chan rivers were 0.2550, 0.2318, and 0.2125, respectively. The light

Table 32.5 Environmental conditions of the experiments

Water	Date	Water temperature (° C)	Wind speed (m/s)	Water speed (m/s)
Chan River	2023.5.9	20–21.5	1	0.45
Ba River	2023.5.13	21.3–22.9	1	0.47
Qianyou River	2023.6.10	19.1–20.3	2	0.5

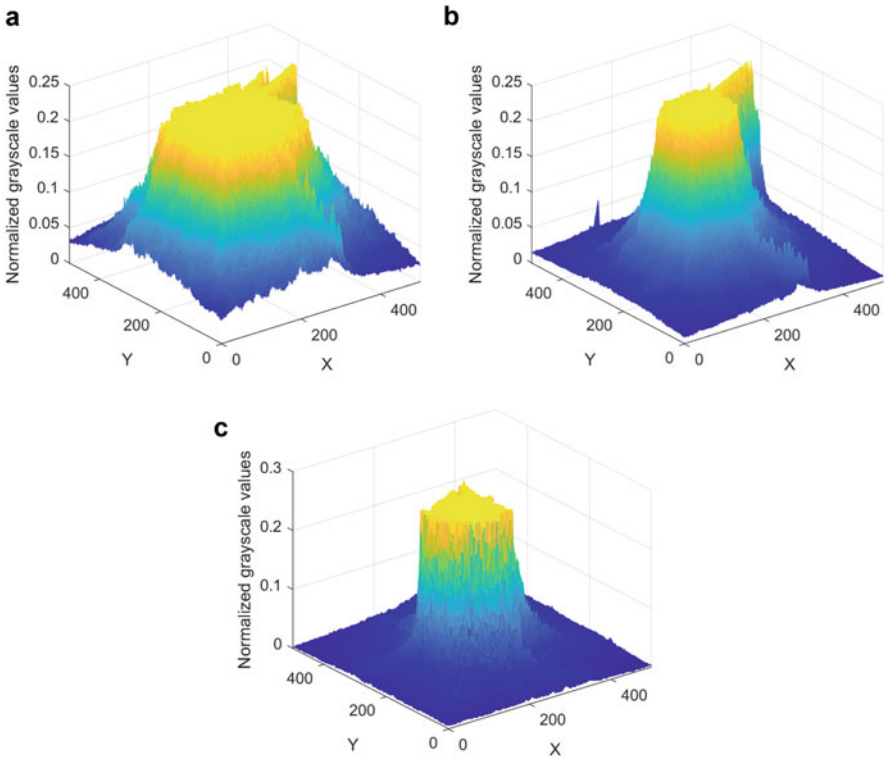

Fig. 32.17 Three-dimensional image of the light intensity in different waters. (**a**) Chan River. (**b**) Ba River. (**c**) Qianyou River

intensity of the Qianyou River was the lowest, followed by those of the Ba and Chan Rivers. In the light intensity distribution curve, we can observe the alternating appearance of the intensity distribution, which is caused by the diffraction phenomenon in the laser transmission process, resulting in light and dark rings on the receiving surface.

Spot Center Offset

The probability density function of the centroid offset of the light spot under different water conditions can be obtained by drawing the centroids of many light spot images measured over a long time under different water conditions, as shown in Fig. 32.19.

Figure 32.19 shows the probability distributions of the centroid offsets of light spots measured in the upper reaches of the Chan, Ba, and Qianyou rivers, respectively, which all satisfy the Gaussian distribution. From Fig. 32.19, it can be seen that the normalized offsets of the light spot centroid measured at the Chan, Ba, and Qianyou rivers are between 0.96–1.04, 0.92–1.08, and 0.85–1.15, respectively.

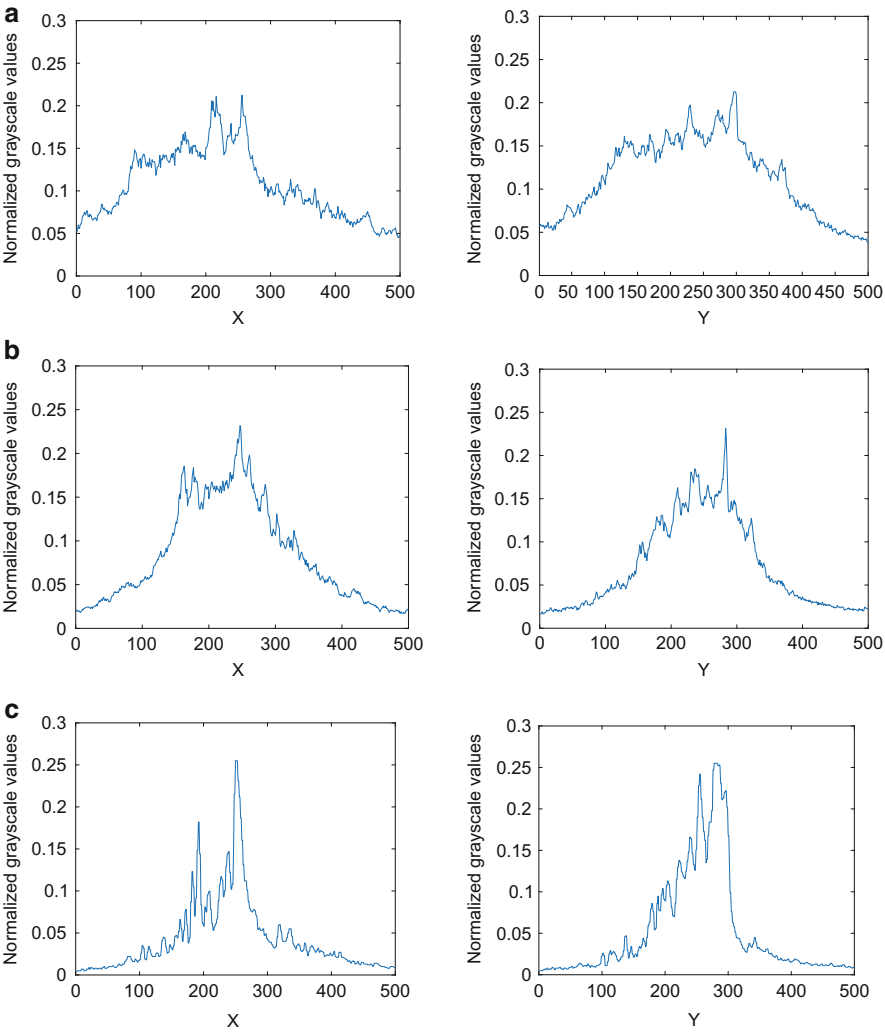

Fig. 32.18 Two-dimensional projection of the light intensity over different waters. (**a**) Chan River. (**b**) Ba River. (**c**) Qianyou River

With an increase in wind speed on the water surface, the random fluctuation of the water surface becomes more severe, which leads to an increase in the probability of a large sea surface inclination angle. When the photons project out of the sea surface, the direction deviates farther from the center of the receiving surface. In addition to the limitation of the receiving field angle, the photons sometimes fall outside the receiving field angle; thus, the number of photons on the receiving surface decreases and they are not included in the statistical results. As a result, the weight of the center of the receiving surface gradually decreases.

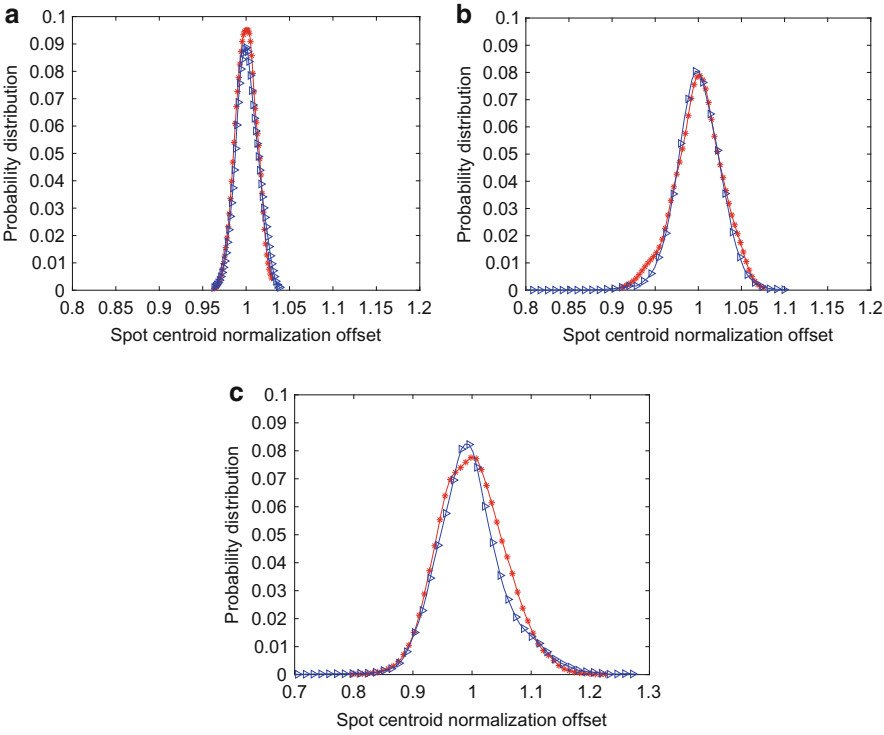

Fig. 32.19 Probability density distribution of the light spot centroid offset in different waters. (**a**) Chan River. (**b**) Ba River. (**c**) Qianyou River

The following experimental results can be obtained:

1. The spatial distribution of the light spot intensity follows the Gaussian distribution in different water areas, and the distortion and dispersion of the light spot image are higher in areas with poor water quality.
2. The light spot centroid offset of the cross-medium optical communication conforms to the Gaussian model.
3. The probability density distribution of the light spot centroid offset differs in different water areas. Under the experimental conditions, the light spot centroid offset is larger in water areas with higher wind speeds, higher water speeds, and severe water surface fluctuation.

Abstract

LED is highly valued by the society for its energy-saving, efficient, durable, green, environmental protection, and other advantages and has a wide range of applications in display screens, traffic lights, LCD screen backlights, greenhouse fill lights and daily lighting, and even communications. Starting from the principle of LED, this paper introduces the optical and electrical characteristics of LED,

Introduction

With the rapid development of science and technology, incandescent lamps, and fluorescent lamps, traditional light sources with low efficiency and high energy consumption are gradually moving into the historical stage [1]. Light-emitting diodes (LEDs) have attracted attention in the market, owing to their advantages of energy savings, long life cycle, high economic benefit, stable performance, environment-friendliness, and low-cost performance [2].

At present, LEDs are widely used in outdoor solid-state lighting equipment, such as street lamps and screen displays [3]. With the rapid development of LED lighting technology, LED energy efficiency has reached a very high level [4]; at the same lighting efficiency, LED lamp energy consumption is one-eighth that of incandescent lamps and half that of energy-saving lamps. Hence, they are more in line with the energy-saving green development concept. It is believed that, in the near future, LED lighting products will completely replace traditional lighting products [5].

At present, LEDs have entered the commercial application stage and become mainstream lighting, providing great convenience to people's lives. According to a 2021 report on the market prospects and investment opportunities of China's LED lighting industry, by the end of 2020, the global penetration rate of LED lighting had reached 59.0%, while the domestic penetration rate had reached 78%. This leaves room for more development in the future [6].

Basic LED Principles and Photoelectric Characteristics

LED Fundamentals

An LED is a widely used semiconductor light source. It uses the carrier radiation of the P–N junction composite luminescence, which can be used for optical communication. Typical luminescence wavelengths are 780 nm, 850 nm, 1300 nm, etc. LEDs are inexpensive and reliable, the driving circuit is simple, the characteristics are only slightly affected by the temperature, and the transmitting power and driving current have a good linear relationship.

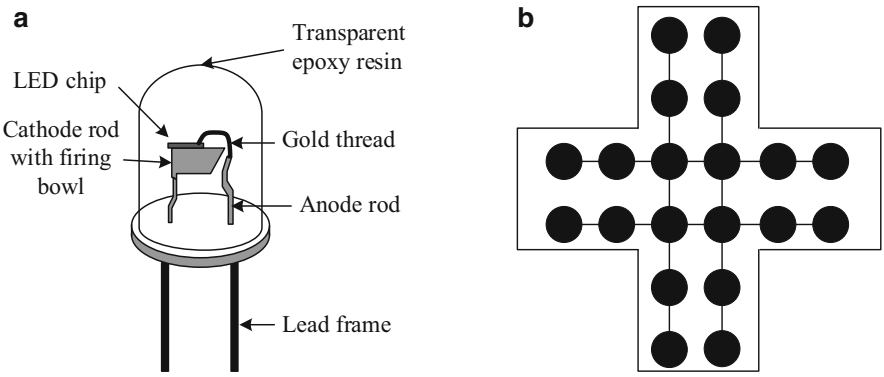

Fig. 33.1 Basic framework and LED surface light source. (**a**) Basic LED device structure [7] (**b**) LED surface light source [8]

The basic structure of common LED devices is shown in Fig. 33.1a [7]. Such LEDs are typical point sources with a high directivity. If multiple LED chips are packaged on a panel, a surface light source is formed that still has high directivity, as shown in Fig. 33.1b [8].

Similar to other diodes, the core of a light-emitting diode is a semiconductor chip consisting mainly of a P–N junction, which is unidirectionally conductive, as shown in Fig. 33.2 [9]. The P–N junction consists of two semiconductors: a p-type and an n-type, whose main carriers are holes and electrons, respectively. When a forward current passes through, the holes and electron carriers in the P–N junction flow to the N and P regions, respectively. The holes are recombined with the electrons, and the excess energy is emitted as photons [10].

If the energy emitted is in the range of visible light (390–760 nm), it can be seen by the human eye. The color depends on the size of the semiconductor band gap. In general, the smaller the band gap in the semiconductor materials, the less energy is emitted, and the longer the wavelength of the emitted light. Conversely, the larger the band gap, the greater the energy emitted by the photons and the shorter the wavelength of the emitted light.

For example, indium gallium nitride (InGaN) can be used as a blue light LED material, owing to its large band gap [11], while aluminum gallium phosphide (AlGaP) has a slightly smaller band gap and can be used as a green light LED material [12]. Aluminum gallium arsenide (AlGaAs) can be used as a red LED material, owing to its smaller band gap [13].

There are three main mechanisms for recombining excess carriers in a double heterojunction, depending on the energy exchange mode: Shockley–Read–Hall (SRH) recombination, radiative recombination, and Auger recombination [14]. Figure 33.3 shows a schematic representation of these three composite mechanisms, where (a) is the SRH recombination, (b) is the radiative recombination, and (c) is the Auger recombination.

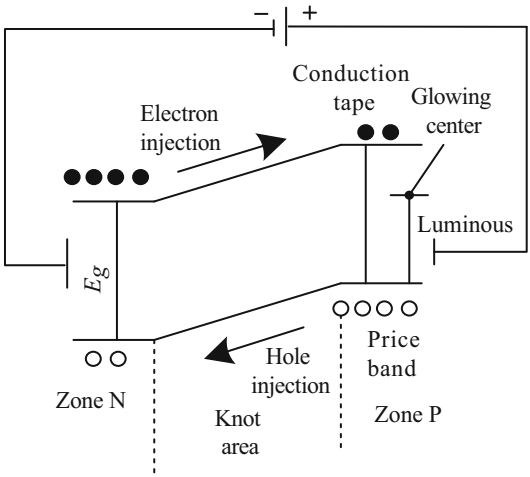

Fig. 33.2 LED emission principle

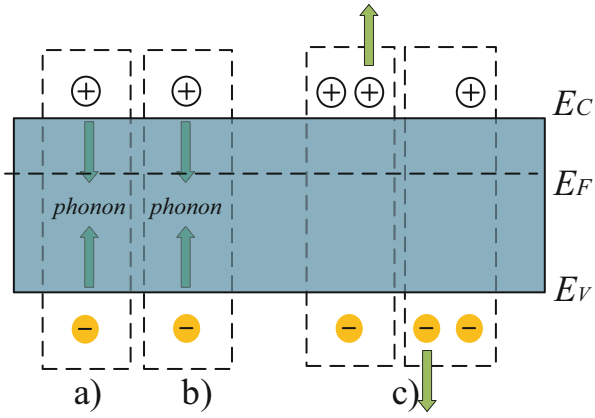

Fig. 33.3 Schematic diagram of three types of electron and hole recombination

SRH Recombination

SRH recombination is related to the existence of traps or defect energy levels, which is mainly the deep-level recombination of free carriers. The SRH recombination consists of two processes: a neutron process in which the defect center captures an electron to release a neutron and a phonon process in which the defect center loses an electron to release a phonon. The carrier-transport process can be expressed as [15]

$$\mathrm{Trap}^0 + e^- \rightarrow \mathrm{Trap}^- + E_{p1} \tag{33.1}$$

$$\mathrm{Trap}^- + h^+ \rightarrow \mathrm{Trap}^0 + E_{p2}. \tag{33.2}$$

$Trap^0$ and $Trap^-$ represent neutral and electronegative defect centers, e^- represents electrons, and h^+ represents holes. While E_{p1} represents the bandgap width between the conduction band E_C and the defect level E_T, E_{p2} represents the bandgap width between the defect level E_T and the valence band E_V:

$$E_{p1} = E_C - E_T \tag{33.3}$$

$$E_{p2} = E_T - E_V. \tag{33.4}$$

The non-radiative recombination rate of the defect center with a defect energy level of E_T is

$$R_{SRH} = \frac{p_0\Delta n + n_0\Delta p + \Delta n\Delta p}{\left(N_T v_p \sigma_p\right)^{-1}(n_0 + n_1 + \Delta n) + \left(N_T v_n \sigma_n\right)^{-1}(p_0 + p_1 + \Delta p)}, \tag{33.5}$$

where P_0 and N_0 are the equilibrium concentrations of holes and electrons, respectively; p_1 and n_1 are, respectively, the concentrations of holes and electrons when the Fermi energy level is at the defect level; Δ_P and Δ_N are the concentrations of holes and electrons, respectively; v_p and v_n are the thermal velocities of holes and electrons, respectively; σ_p and σ_n are the trap-capture cross sections; and N_T is the trap concentration.

Radiative Recombination

In radiative recombination, the electrons and holes recombine, and photons are produced. The carrier-transport process can be expressed as [16]

$$e^- + h^+ \rightarrow hv, \tag{33.6}$$

where e^- represents electrons, h^+ represents holes, and hv represents the photon energy generated.

Auger Recombination

Auger recombination is different from the first two methods, as it is composed of three carriers; that is, when the electron and hole combine to produce energy, the energy is received by a third carrier, which causes the energy absorption carrier to appear in the transition process. According to the carrier difference, Auger recombination involves two types of transition processes: One is the transition of the hole into the valence band, and the other is the transition of the electron into the conduction band; they can be expressed as [17]

$$e^- + h^+ + h^+ \rightarrow h^+ + E_p \tag{33.7}$$

$$e^- + e^- + h^+ \rightarrow e^- + E_p, \tag{33.8}$$

where E_p is the energy required for the third carrier to enter the band edge. Electrons or holes in the valence band that return to the conduction band will participate again in the recombination process.

Electrical Properties of LEDs

An LED is essentially a diode, so its volt–ampere characteristic is determined by the P–N junction of its light-emitting substrate, and its volt–ampere characteristic curve is similar to that of the P–N junction. Figure 33.4 shows the LED operating curve. As shown in the figure, the white LED has one-way conductive characteristics. When the reverse voltage exceeds the reverse voltage of the LED V_C, the LED breaks down, and when the reverse current instantaneously increases, the LED works in the reverse breakdown zone.

When the forward voltage of the LED reaches the operating threshold, V_A, the LED begins to emit light. When the loading voltage is between V_B and V_D, the current I through the LED is proportional to the voltage V at both ends of the LED, and the LED operates in a linear region, as shown by the workspace.

For a P–N junction without a bias voltage, the holes in the P-type doping region and the electrons in the N-type doping region diffuse and form a depletion region, which leads to the generation of a built-in electric field. The potential difference V_D of the built-in electric field is [19] for the P–N junction with the free-hole concentration of N_A in the P-type doping region and the free electron concentration of N_D in the N-type doping region. The potential difference V_D of the built-in electric field is

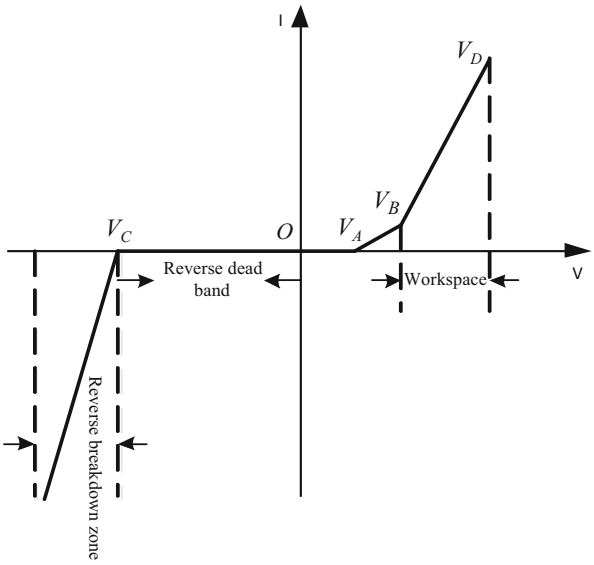

Fig. 33.4 LED operating characteristics [18]

$$V_D = \frac{kT}{q} \ln \frac{N_A N_D}{n_i^2}, \tag{33.9}$$

where T is the temperature, q is the charge, k is the Boltzmann constant, and n_i is the intrinsic carrier concentration.

Owing to the presence of a built-in electric field, the movement of the free carriers is limited by the need to overcome the barrier to reach a neutral region with opposite electrical properties. The width of the depletion layer is [20]

$$W_D = \sqrt{\frac{2\varepsilon}{q}(V_D - V)\left(\frac{1}{N_A} + \frac{1}{N_D}\right)}, \tag{33.10}$$

where $\varepsilon = \varepsilon_0 \varepsilon_r$ is the permittivity of the semiconductor materials, ε_0 is the permittivity of vacuum, ε_r is the relative permittivity of the dielectric relative to vacuum, and V is the external voltage applied to the P–N junction. It can be seen from Eq. (33.10) that the width of the depletion layer narrows when V_D approaches V.

A description of the I–V characteristics of the diode was first proposed by Shockley. For a diode with hole diffusion coefficient D_n, electron diffusion coefficient D_p, electron minority lifetime τ_n, and hole minority lifetime τ_p, when the cross-sectional area is S, the I–V characteristics of the diode satisfy the Shockley equation [21]:

$$I = qs\left(\sqrt{\frac{D_p}{\tau_p}}\frac{n_i^2}{N_D} + \sqrt{\frac{D_n}{\tau_n}}\frac{n_i^2}{N_A}\right)\left(e^{qV/kT} - 1\right). \tag{33.11}$$

At the reverse bias, the diode's I–V characteristics are satisfied, considering the diode's current saturation phenomenon:

$$I = I_{so}\left(e^{qV/kT} - 1\right), \tag{33.12}$$

where the reverse current $I_{so} = eA\left(\sqrt{\frac{D_p}{\tau_p}}\frac{n_i^2}{N_D} + \sqrt{\frac{D_n}{\tau_n}}\frac{n_i^2}{N_A}\right)$.

For a normal forward bias, $V >> kT/q$, and Eq. (33.11) can be simplified as follows:

$$I = Aq\left(\sqrt{\frac{D_p}{\tau_p}}N_A + \sqrt{\frac{D_n}{\tau_n}}N_D\right)e^{q(V_D - V)/kT}. \tag{33.13}$$

When the applied external voltage is higher than the built-in voltage, the current of the P–N junction increases sharply. The Shockley equation describes the theoretical relationship between the P–N junction voltage and current. In an experiment, considering the presence of ohmic contacts, junction defects, or losses, new formulas are required to describe the I–V properties of actual LEDs:

$$I = I_S e^{eV/(n_{\text{ideal}}kT)}. \tag{33.14}$$

For an ideal diode, $n_{\text{ideal}} = 1.0$. For an actual diode, n_{ideal} is between 1.1 and 1.5. For III–V arsenide and phosphide, n_{ideal} can reach 2.0, and for an InGaN/GaN diode, n_{ideal} can reach 7.0.

In the above model, the parasitic resistance of the device is not considered. If the parallel resistor R_p and series resistor R_S are added, the modified I–V characteristic accords with

$$I - \frac{(V - IR_s)}{R_p} = I_s e^{e(V-IR_s)/(n_{\text{ideal}}kT)}. \tag{33.15}$$

Optical Properties of LEDs

In indoor lighting, the luminous flux Φ (lm) of an LED is expressed as

$$\Phi = kP_{st}, \tag{33.16}$$

where k is the optical efficiency and P_{st} is the radiation power. The range of visible light is from 380 nm to 780 nm, so the above formula can be converted to [22]

$$\Phi = K_m \int_{380}^{780} p(\lambda)V(\lambda)d\lambda, \tag{33.17}$$

where K_m is the maximum visibility, $P(\lambda)$ is the radiation energy spectrum, and $V(\lambda)$ is the luminescence curve.

Researchers have focused on the illumination value, expressed by E (lux), that is, the luminous flux per unit area. Under ideal conditions, the illuminance of a horizontal plane is [23]

$$E = \frac{d\phi}{dA} = \frac{I(\phi)}{D^2}, \tag{33.18}$$

where A represents the irradiated area, D represents the irradiated distance, and $I(\phi)$ represents the light intensity (cd), which is related to the radiation angle ϕ:

$$I(\phi) = kR(\phi), \tag{33.19}$$

where $R(\phi)$ is the radiation intensity model, which satisfies the Lambert model:

$$R(\phi) = aP_t \cos^m(\phi), \tag{33.20}$$

where $a = 2\pi/m + 1$, P_t is the average radiation power, and m is the radiation order, determined by the half-power angle $\phi_{1/2}$, which can be expressed as

$$m = -\frac{\ln 2}{\ln\left(\cos\left(\phi_{1/2}\right)\right)}. \tag{33.21}$$

Combining the equations yields [24]

$$I(\phi) = \frac{m+1}{2\pi}\Phi\cos^{m}(\phi). \tag{33.22}$$

when $\phi = 0$ is introduced into Eq. (33.22), $I(0) = \Phi(m + 1)/2\pi$, where $I(0)$ denotes the central light intensity. Therefore, the intensity of the light source LED can be expressed as

$$I(\phi) = I(0)\cos^{m}(\phi). \tag{33.23}$$

LEDs with different emitting colors typically exhibit different optical properties. To produce visible light, the wavelength should be between 380 and 780 nm, and the peak luminescence wavelength λ depends on the bandgap width of the semiconductor E_g (eV), which is $\lambda \approx 1240/E_g$ [25].

Different colors have different energy barriers; that is, the voltage drop also depends on the color of the light. The on-voltage drop of the red LED is approximately 2 V and that of the blue LED is approximately 3 V. Table 33.1 lists the semiconductor materials corresponding to the light sources of the main colors.

Table 33.1 Light colors corresponding to different LED materials [26]

Color	Lambda wavelength (nm)	Forward voltage (V)	Semiconductor material	Symbol
Red	760 to 610	1.63–2.03	Gallium arsenide phosphide	GaAsP
			Aluminum gallium indium phosphide	AlGaInP
Orange	610 to 590	2.03–2.10	Gallium arsenide phosphide	GaAsP
			Gallium phosphide (doped)	GaP
Yellow	590 to 570	2.10–2.18	Gallium arsenide phosphide	GaAsP
			Indium gallium nitride	InGaN
Green	570 to 500	2.18–4.0	Gallium phosphide	GaP
			Aluminum gallium indium phosphide	AlGaInP
Blue	500 to 450	2.48–3.7	Gallium nitride	GaN
			Silicon carbide	SiC
Purple	450 to 380	2.76–4.0	Indium gallium nitride	InGaN
			Aluminum nitride	AlN

LED Research and Status

LED colors can be divided into red, yellow, green, blue, etc. Light-emitting surfaces can be divided into round, square, and rectangular lamps, surface light-emitting tubes, side tubes, micro-tubes for surface installations, etc. Circular lamps are divided into 2 mm, 4.4 mm, 5 mm, 8 mm, 10 mm, and 20 mm according to their diameter.

Research and Development of Red LEDs

The first practical LED was a red LED [27] developed in 1962. It was made from a composite semiconductor alloy, gallium arsenide phosphide (GaAsP), with the structure shown in Fig. 33.5. The LED's light efficiency was only a tiny 0.1 lm/W, but it set the stage for the future commercial expansion of LEDs. From 1968, when the red LED was made commercially available by Hewlett–Packard (HP), commercial LEDs were used only as indicators until the mid-1990s.

In 1969, gallium nitride (GaN) films were first grown on sapphire substrates using hydride vapor-phase epitaxy (HVPE) by Nakamura. Unfortunately, the crystal quality of these films was very poor [28]. To improve the quality of GaN films, Yoshida et al. used molecular beam epitaxy (MBE) [29] to grow an aluminum nitride (AlN) buffer layer in front of the GaN films.

Amano et al. first used metal–organic chemical vapor deposition (MOCVD) to grow a low-temperature AlN buffer layer and then grew GaN using thin organometallic chemistry [30]. In addition to the AlN buffer layer, Nakamura et al. used a low-temperature (LT) GaN buffer layer to grow GaN films, which produced GaN films with relatively high crystalline quality [31].

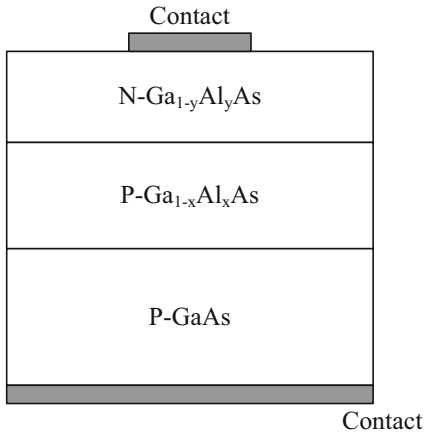

Fig. 33.5 Structure of the first-generation red LED [27]

In 1998, Lumileds Lighting introduced the first commercial high-power red LED [32]. At an input power of 1 W, the working power of the device was 20 times that of the traditional LED lamp, and the efficiency was improved by 50%. More importantly, the thermal resistance of the package was significantly reduced, from 300 K/W to less than the 15 K/W required by Luxeon, and the light efficiency reached 55 lm/W [32].

In 2000, red LED light efficiency reached 100 lm/W, which was sufficient light efficiency to move it gradually from indicator lights to common traffic lights, monitors, etc. Since the end of 2000, Stockholm, Sweden, has completely replaced traffic lights with LED lights, saving 85% of its electricity use, much more than expected [33]. The average power consumption per traffic light decreased from 70 W to 6 W. Simultaneously, Singapore and most parts of China also began to use LED traffic lights [33].

In 2012, Ohkawa et al. proposed a novel high-temperature growth technique to grow high-quality and high In-content indium gallium nitride (InGaN) layers. A large LED with a peak wavelength of 740 nm and electroluminescence (EL) emission was demonstrated.

In 2014, for the first time, Toshiba demonstrated an InGaN-based red LED with a wavelength of 629 nm, an optical output power exceeding 1 mW at 20 mA, and a structure shown in Fig. 33.6. The external quantum efficiency (EQE) was as high as 2.9% [34]. They used an AlGaN intermediate layer in the active region to improve the crystallization quality of InGaN quantum wells and increase the overlap of electron and hole wavefunctions. However, this structure had some disadvantages, such as a high forward voltage that negatively affected the wall-plug efficiency (WPE).

In 2017, to study their optical and electrical properties, Hwang et al. prepared ultrasmall InGaN-based LEDs with an area of 10^{-4} mm^2–0.01 mm^2 [35]. The out-of-peak quantum efficiencies of the smallest and largest LEDs were 40.2% and 48.6%, respectively. The experimental results showed that ultrafine-grained LEDs could be fabricated with a minimal loss of optical or electrical properties.

In 2020, an attractive approach taken by Bi et al. was to prepare high crystal quality InGaN templates using nanostructures, such as nanopyramids and wafers; the structure is shown in Fig. 33.7. These materials have great potential for fabricating

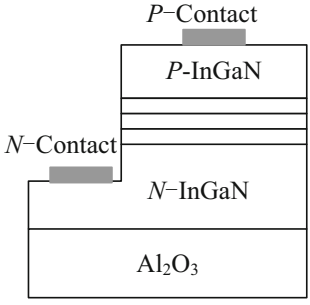

Fig. 33.6 InGaN-based red LED structure [34]

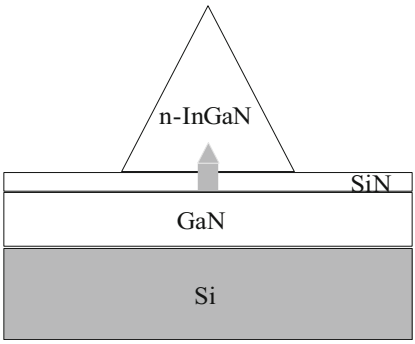

Fig. 33.7 InGaN pyramid growth structure [36]

efficient red LEDs [36]. This structure takes advantage of the strain relaxation, low dislocation density, and reduction of the piezoelectric field. In other words, InGaN quantum wells on these nanostructures can improve the internal quantum efficiency (IQE).

As the luminous efficiency of red LEDs increases annually, they are gradually being transferred to traffic lights, monitors, biomedicine, etc. The external quantum efficiencies of LEDs with different MOCVD sizes are compared in Table 33.2.

Research and Development of Yellow LEDs

The development of the power efficiency of LEDs with various colors has been very uneven, and the efficiency of green and yellow light, which is the most sensitive to light, is much lower than that of blue, purple, and red light in the long term. Studies of yellow LEDs date back to 1965, when Thomas and Hopfield of the American Bell Labs first observed yellow photoluminescence in nitrogen-doped gallium phosphide [53].

The first nitrogen-doped gallium phosphide arsenide P–N yellow LED was fabricated on a GaAs substrate using vapor-phase epitaxy (VPE) technology by Craford of Monsanto Company; the optical efficiency was approximately 0.01% at a current density of 20 A/cm^2 [54]. In 1990, an aluminum indium gallium phosphate double-heterojunction yellow LED with a 574 nm wavelength was grown on a GaAs substrate using MOCVD technology by the Hewlett–Packard company in the United States; at a current density of 30 A/cm^2, the light efficiency reached 0.5% [55]. In 1994, HP transferred an epitaxied AlGaInP yellow LED from a light-absorbing GaAs substrate to a light-transmitting GaP substrate with a 571 nm wavelength and an optical efficiency of 1.3% at a current density of 44 A/cm^2 [56, 57].

In 2008, Nakamura et al. used MOCVD technology to grow InGaN single quantum well yellow LEDs on a semi-polar GaN substrate with a 562 nm wavelength and an external quantum efficiency of 13.4% at a current density of 7 A/cm^2 [58]; however, the voltage was higher and the light efficiency was only 5.5%. In 2013, Toshiba (Japan) used MOCVD technology to grow InGaN yellow LEDs on a sapphire substrate at a 559 nm wavelength, with an external quantum efficiency of

18.7% at a current density of 9.5 A/cm^2; owing to high voltages, the light efficiency was only 9.6% [59].

In 2015, Jiang et al. used MOCVD technology to grow yellow GaN-based LEDs on a silicon substrate and used V-shaped-pit multi-quantum well structures, as shown in Fig. 33.8. A yellow LED with a 565 nm wavelength driven by 20 A/cm^2 achieved a light efficiency of 30.7%, corresponding to 164 lm/W [60].

In 2021, Zhao et al. used MOCVD technology to grow a yellow LED with an InGaN-based three-layer staggered quantum well on a sapphire substrate, the structure of which is shown in Fig. 33.9 [57]. The wavelength was 570 nm. At 15 mA, the optical output power and external quantum efficiency of the LED were 10.2 mW and 30.8%, respectively [61].

Research and Development of Green LEDs

In 1991, Nakamura et al. implemented a GaN-based high-power blue LED [62]. Prior to that, light-emitting diodes were dominated by long-wavelength LEDs, such

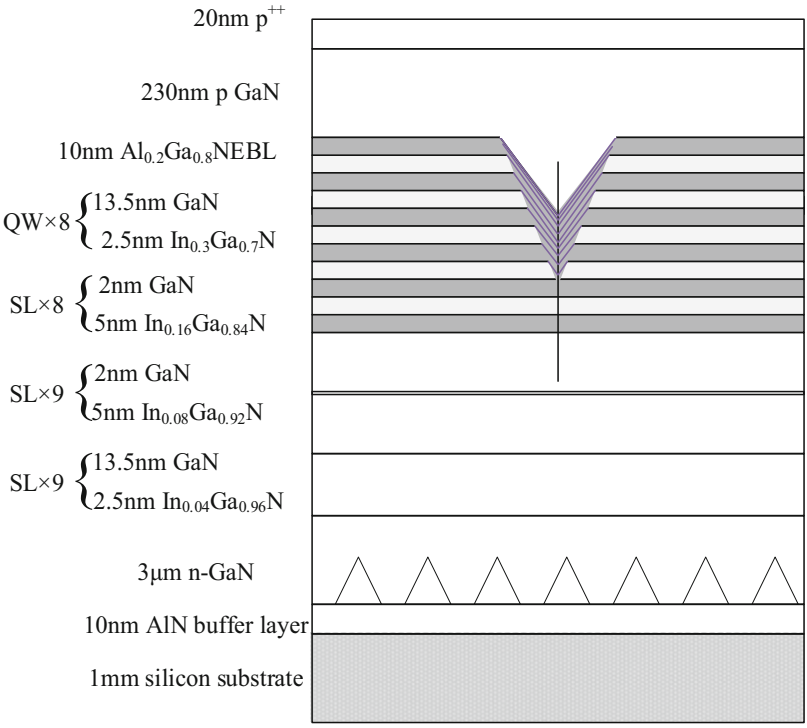

Fig. 33.8 GaN/Si-based yellow LEDs [60]

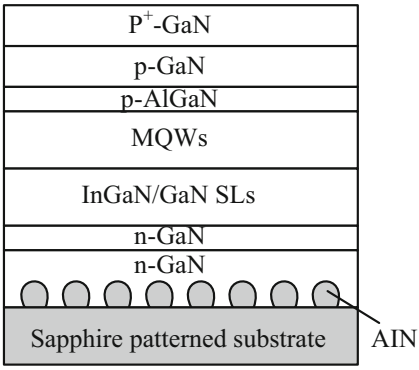

Fig. 33.9 InGaN-based three-layer interleaved quantum well yellow LEDs [61]

as red and orange, in phosphates. Since then, with the rapid development of AlGaN LED systems, short-wavelength ultraviolet LEDs and long-wavelength green and yellow LEDs have been developed. Both the blue LED of the AlGaInN system and the red LED of the AlGaNP system can achieve a high luminous efficiency.

However, LEDs with nitride and phosphide systems cannot achieve high luminous efficiencies in the green and yellow light bands.

In 1998, Lester et al. demonstrated an InGaN-based green LED, with the highest external quantum efficiency (EQE) at the time. The 12-cycle extended InGaN/GaN LED on a sapphire substrate had a multiple quantum well (MQW) structure as the active region, with only 4.5% of its EQE [63]. In 2013, Saito et al. fabricated GaN-based green-yellow LEDs with high efficiency on a C-plane sapphire substrate, using energy-band engineering to design the structure of the device and optimize the growth process; at an operating current of 20 mA, the light output power (LOP) and EQE reached 11.0 mW and 33.7%, respectively, with an almost fivefold increase in efficiency compared with that in 1998 [64].

In 2019, Pli et al. experimented with high-efficiency green LEDs by inserting AlGaN layers in the MQW region, as well as ultrasmall packaging technologies, to improve the EQE and LOP of LEDs [65]. At a current density of 20 A/cm^2, the EQE of the 523-nm nGaN-based green LED was 38%.

Since the twenty-first century, GaN-based green LED research has made significant progress and the luminous efficiency and power have greatly improved [66]. However, compared with blue and red LEDs, green LEDs have obvious disadvantages. In addition to the low quantum efficiency, they have low efficiency under high currents. As the operating current increases, the luminous power of the LED increases, accompanied by a decrease in luminous efficiency; this is called the droop effect [67].

Perovskite light-emitting diodes (PeLEDs) are light-emitting diodes with high color purity, tunable wavelengths, and low production costs. They have been studied extensively, and their EQEs have continued to rise, as shown in Fig. 33.10.

The PeLED device has a sandwich structure, in which the light-emitting layer is sandwiched between the electron injection layer (EIL) and the hole-injection layer (HIL) [69]. Depending on the order of the implanted layers, the specific device structures can be further divided into two types: positive and inverted.

In the positive structure (Figure 33.11a), the transparent conductive glass substrate acts as the positive electrode of the device, with the HIL, perovskite layer, EIL, and metal electrode (negative electrode) placed on top. In the inverted structure (Figure 33.11b), the transparent conductive glass substrate acts as the negative electrode of the device, with the EIL, perovskite layer, HIL, and metal electrode (positive electrode) placed on top [69].

The first green PeLED (GPeLED) device was developed in 2014 by Friend et al. at the University of Cambridge. They demonstrated a prototype device with an EQE of 0.1% and luminance of 364 cd/m^2; the structure is shown in Fig. 33.12. Shortly thereafter, the Greenham group produced a GPeLED with a 1% EQE by adding an additive to the precursor solution to inhibit crystal growth [70], early in 2015. Huang and Wang et al. lowered the electron injection barrier by adding a polyethylenimine buffer layer to increase the brightness of the GPeLED to over 20,000 candela per square meter (cd/m^2) [71].

At the end of 2015, Lee et al. [72] elevated the EQE of GPeLEDs to an unprecedented 8.53% by nanocrystalline pinning and changing the composition

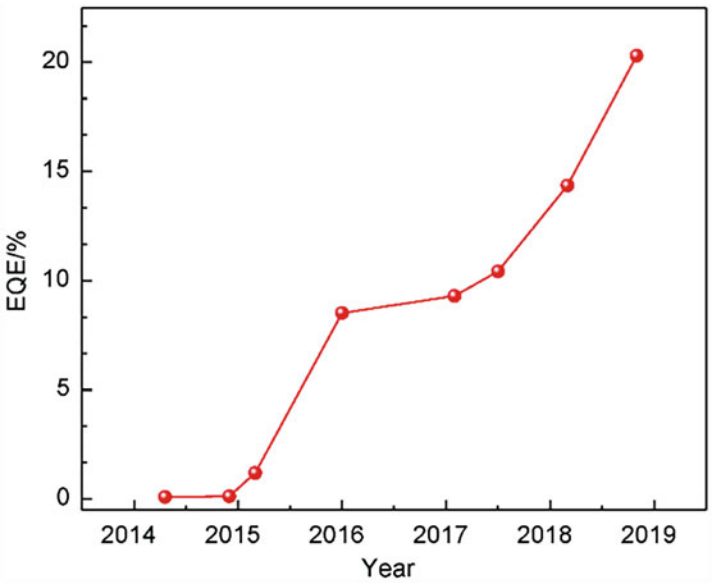

Fig. 33.10 Green PeLEDs' EQE growth trend [68]

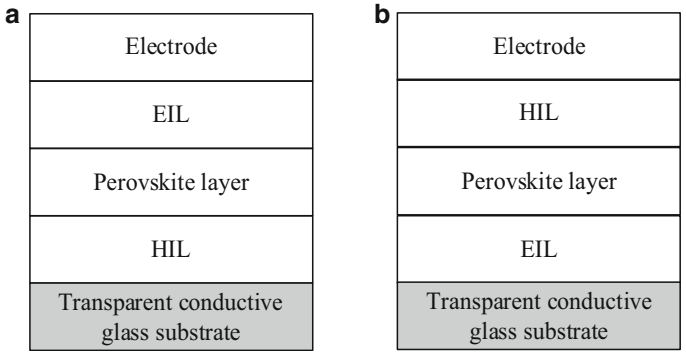

Fig. 33.11 Typical perovskite LED structures. (**a**) Positive structure (**b**) Inverted structure

ratio of the precursor solution. As the EQE continued to rise, the brightness of the GPeLED increased to a stunning 591,197 cd/m^2 [73]. In early 2017, Rand et al. produced GPeLEDs with an EQE of up to 9.3% [74]. In the same year, You et al. increased the EQE of GPeLEDs by 10% and then advanced it to nearly 15% [75]. Recently, the research results of Wei et al. greatly improved the EQE of GPeLEDs, breaking the 20% milestone, and laying a solid foundation for the commercialization of GPeLEDs [76].

Because green is one of the three primary colors (red, green, and blue), it is very important to produce high-efficiency green LEDs, whether to achieve high-

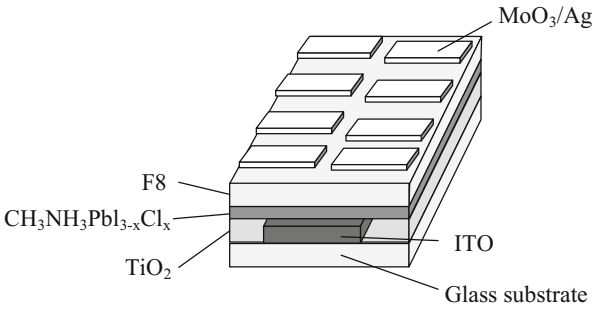

Fig. 33.12 GPeLED structure diagram

efficiency multi-basic white lighting or full-color displays with high resolution and fast reaction speeds.

Research and Development of Blue LEDs

Blue is a basic color in nature and one of the three primary colors of the plane panchromatic display. At first, SiC and ZnSe were the important materials for blue LEDs; GaN was neglected because of the lack of a single-crystal substrate, high dislocation density, and P-type doping. However, with continuing research and improving technology, GaN-based blue LEDs have become mainstream research. The parameters of GaN are listed in Table 33.3 [77].

The first blue GaN-based LEDs were introduced in 1971 [78]. Because GaN P-type doping was not possible at that time, a metal–insulator–semiconductor (MIS) structure was adopted, the basic structure of which is shown in Fig. 33.13. The LED luminescence efficiency of the MIS structure was only 0.03%–0.1%. The peak wavelength was approximately 485 nm, the full width at half maximum (FWHM) was 70 nm, the typical operating voltage (when the input current was 20 mA) was 7.5 V, with a light output of 2 mcd at 10 mA; however, it had a longer lifetime [78].

In 1983, Yoshida et al. deposited a layer of AlN as a buffer layer on a sapphire substrate, which greatly improved the surface structure and crystal quality of GaN P-type LEDs. The doped GaN was obtained by Mg doping and low-energy electron beam irradiation (LEEBI). These two breakthroughs laid the foundation for the generation of GaN-based LEDs [79].

In 1991, Nakamura et al. developed the Shuangliu District organometallic chemistry vapor deposition technique, which uses vertically injected $N_2 + H_2$ gas streams. High-quality GaN films were successfully grown on a low-temperature GaN buffer layer by suppressing the thermal-convection effect of the reactive gas flow (TMG + $NH_3 + H_2$) on a sapphire substrate at temperatures up to 1000 °C [80]. In addition, they developed a technique for obtaining high-quality P-type GaN materials by annealing in clean N_2 gas.

Table 33.3 GaN material characteristic parameters [77]

Characteristics of wurtzite GaN	Bandgap width ($T = 300$ k)	Lattice constant/nm	Coefficient of thermal expansion ($T = 300$ k)	Thermal conductivity/ $W \cdot cm^{-1} \cdot K^{-1}$	Refractive index	Electronic effective mass
	$E_g = 3.39$ eV	$a = 0.3189$	5.59×10^{-6} K	$K = 1.3$	n (1 eV) $= 2.33$	$m_c = 0.20$ $m_0 = 0.02$

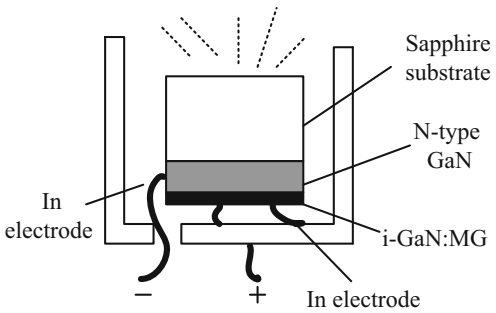

Fig. 33.13 GaN-based MIS epitaxial layer and device structure [78]

In 1993, Nakamura et al. began to commercialize their research and development of GaN-based blue light LEDs [81]. At the end of 1994, a high-brightness GaN-based blue LED device was developed [82]. Figure 33.14 shows the structure of the LED, which won the Nobel Physics Prize in 2014. The device has a double heterostructure, and Zn-doped InGaN is used as the active layer for emitting blue light.

In 2000, Li et al. of Kansas State University fabricated GaN quantum well micro-LED arrays with a single 12-μm diameter and a 10 × 10 array via photolithography and plasma dry etching. This shows that LEDs were moving toward smaller sizes. The results showed that the current density of micro-LEDs was five times higher than that of large LEDs at the same voltage [83].

In 2004, Choi et al. used a photoresist as a mask to etch GaN using inductively coupled plasma (ICP) with different inclined angles by adjusting the process parameters in the ICP dry etching process An InGaN-based micro-LED array device with passive driving capability was fabricated, which had a resolution of 128 × 96 [84].

In 2008, using Ni/Au/Ti/Au as a p-plane mirror and ohmic contact layer, Gong et al. of the University of Schottfried, UK, fabricated GaN epitaxial films with a 20-μm pixel size and micro-LED arrays in blue (470 nm) and purple (370 nm) with a

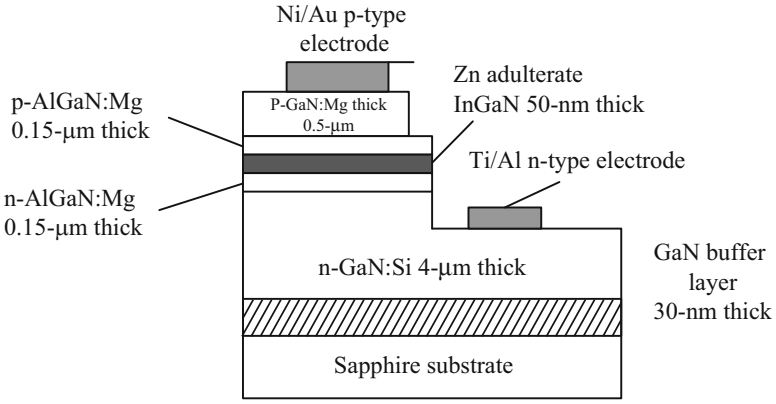

Fig. 33.14 Double-heterojunction GaN-based blue LED structure [82]

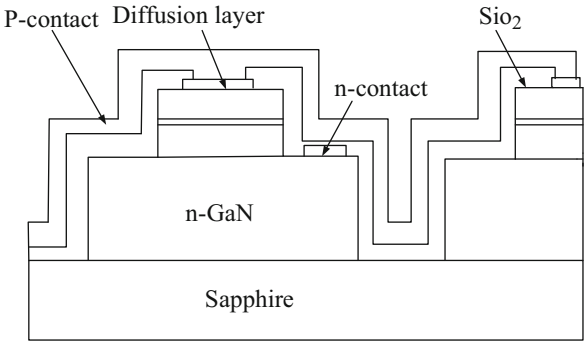

Fig. 33.15 Micro-LED with an inverted structure [85]

50 μm pixel center distance. The array device had 64 × 64 pixels, and the structure is shown in Fig. 33.15 [85].

In January 2014, Tian et al., from the University of Schleicher, UK, used metalorganic vapor-phase epitaxy (MOVPE) to grow GaN epitaxy on a six-inch Si (111) substrate. A GaN blue micro-LED array with passive driving capability was fabricated by layering the positive and negative electrodes. The number of pixels of the array was 10 × 10, the pixel size of each micro-LED was 45 μm, and the central wavelength was approximately 470 nm; a schematic of the array device structure is shown in Fig. 33.16 [86].

In March 2018, Lei et al. of PKU Blue Bird Display, Ltd. proposed wafer-level hybrid integration technology and fabricated three types of red, green, and blue micro-LED array display devices with a single-color active drive [87]. This wafer-level hybrid integration technology is different from flip-chip welding, which requires bonding the entire wafer to the CMOS drive circuit and then removing the substrate of the epitaxial wafer. A microdisplay device is fabricated on a CMOS driver using a standard semiconductor process. The structure is shown in Fig. 33.17 [87].

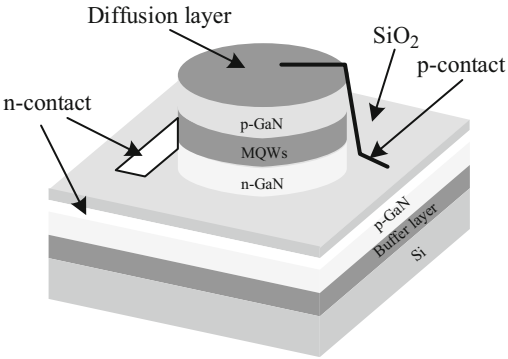

Fig. 33.16 Micro-LED structure on silicon substrate [86]

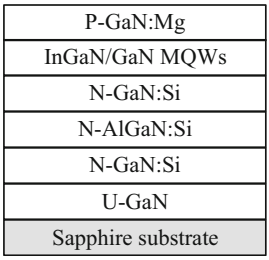

Fig. 33.17 Sapphire substrate micro-LED structure [82]

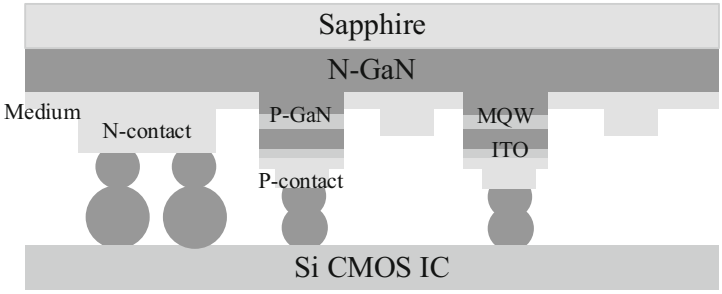

Fig. 33.18 Flip-chip micro-LED structure [88]

In April 2019, Chen et al. of National Tsing Hua University fabricated an inverted GaN-based blue light micro-LED M-array display device driven by CMOS via In–In bonding. The number of device arrays was 960 × 540, the pixel size was 8 μm, and the pixel center interval was only 12.8 μm. The test results showed that the leakage current of the device was only 0.1 pA at −5 V, and the open voltage was 2.73 V. The overall pixel yield of the display device reached 98.67%. A schematic is shown in Fig. 33.18 [88].

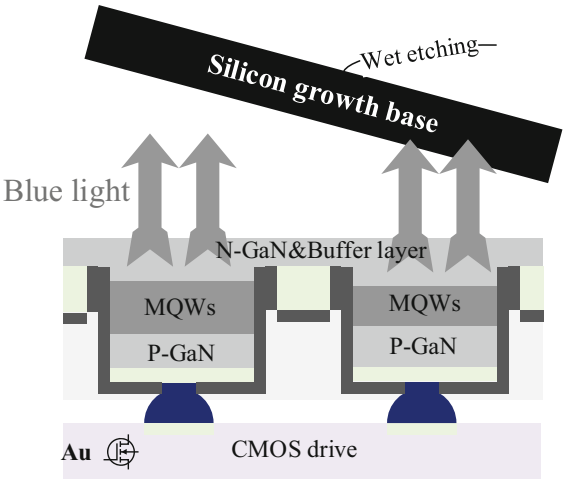

Fig. 33.19 Micro-LED structure on a flip-chip silicon substrate [89]

In March 2021, Qi et al. of the Hong Kong University of Science and Technology etched and fabricated an inverted micro-LED array on a blue GaN epitaxy on a silicon substrate and fabricated an Sn column on the anode back into an Sn sphere. The micro-LED array was combined with a CMOS driving backplane by Au–Sn bonding. The silicon substrate was then removed by wet etching, and the micro-LED microdisplay device was successfully fabricated. The microdisplay device had a resolution of 400 × 240 pixels, and the overall pixel yield was 95%. The single pixel size was 20 × 20 μm^2, the center distance of the pixel was 30 μm, and the number of pixels on the diagonal line per inch was 848. The structural principle is illustrated in Fig. 33.19 [89].

Research and Development of White LEDs

High-efficiency purple, blue, and green (GaInN LED) devices were developed in the early 1990s [90]. Since the mid-1990s, monochrome high-efficiency devices have been able to cover the entire visible spectrum with the necessary conditions to achieve white LEDs. The white LED principle and the monochrome LED principle are different; for white LEDs, there are several feasible methods.

The first method involves mixing red, green, and blue LED chips, in which the three LED chips emit the three primary light colors mixed together to produce white light [91]. This method is shown in Fig. 33.23. As can be seen from the diagram, the LED requires four lead electrodes to ensure that each of the three LED chips can be injected with the appropriate current. With the advent of efficient blue and green LEDs, this approach has become more feasible [92].

Nakamura et al. [93] showed that a combination of high-power and high-brightness blue InGaN SQW LEDs, green InGaN SQW LEDs, and red GaAlAs

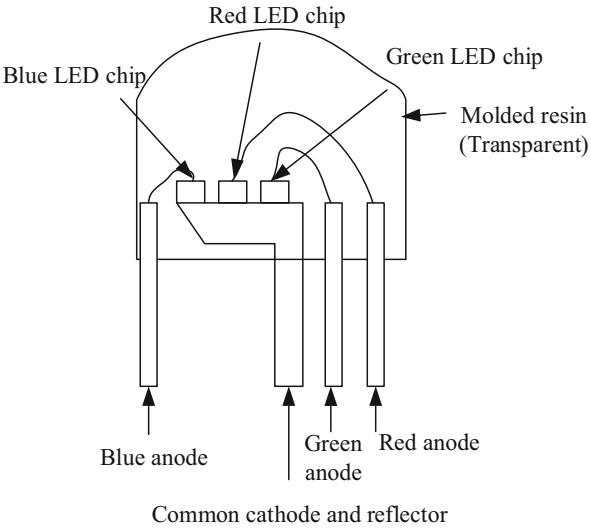

Fig. 33.20 White LED made of red, green, and blue LED chips

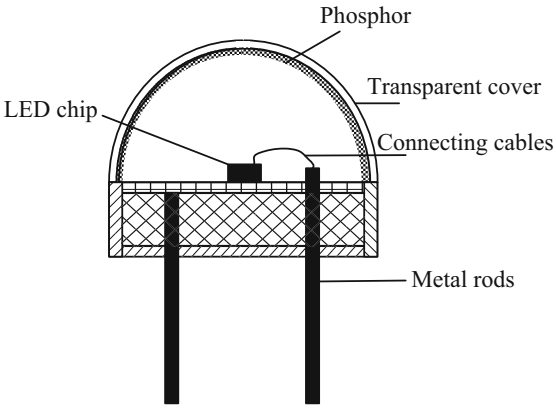

Fig. 33.21 UV-excited white LED

LEDs could be used for a variety of applications, such as LED full-color displays, and used to replace light bulbs or fluorescent LED white lamps (Figs. 33.20 and 33.21).

The second method is a white LED excited by ultraviolet (UV) light, which is used to excite red, green, and blue composite fluorescent materials by near-UV rays [72]. Because it is similar to conventional fluorescent lamps [95], this approach was proposed many times before the advent of GaN-based blue LEDs [96]. The LED structure is shown in Fig. 33.24. An LED chip and phosphor coating inside the transparent housing form a point-source white LED.

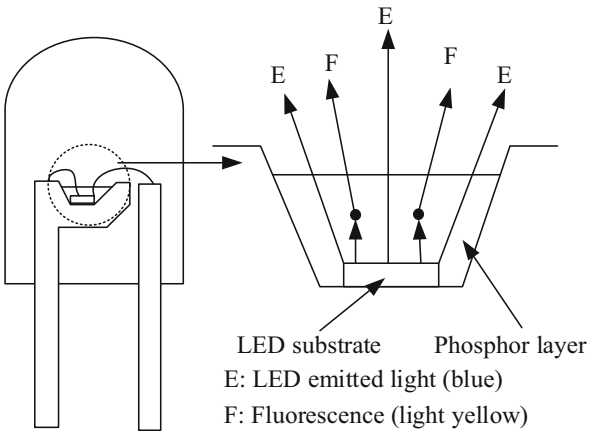

Fig. 33.22 White LED with a blue light and YAG phosphor

The third and most successful method is the combination of a blue LED chip and phosphor [97]. The principle is that the blue light from the LED chip is absorbed by the phosphor, whereas the other part of the blue light is transmitted through the phosphor. Thus, blue light (from LED chips), green light (from phosphors), and red light (from phosphors) together form white light [98]. The structure is shown in Fig. 33.26.

After realizing that organic phosphors could not reliably operate under the harsh operating conditions of blue LEDs, Shimizu et al. identified a very suitable inorganic phosphor, cerium-doped yttrium aluminum garnet (YAG:Ce), which absorbs blue light and emits red and green light [99]. This method was first demonstrated by Shimizu et al. and further improved by Bando et al. Nakamura and Fasol subsequently reviewed it. This approach has been commercially successful because it is efficient, simple, and requires only one LED chip to be powered by a single power supply (Fig. 33.22).

The last and most difficult of the three primary LEDs, blue, has been present since Nakamura developed a bright blue LED in 1994. Subsequently, LEDs gradually moved toward the white lighting stage.

In 1996, Shimizu [100], a Japanese company, published a Japanese patent application for a "Sheet Light Source," an RGB white backlight for full-color displays; it disclosed a flat white light source based on a blue LED and red and green phosphors. In the same year, an article in Nikkei Shimbun, a Japanese newspaper [101], announced a new white light source, based on blue LEDs, that excited a yellow YAG:Ce phosphor. According to reports, the white LED has high efficiency (5 lm/W), low cost, and a life expectancy of 50,000 h.

In 1997, Osram–Fraunhofer et al. [102] reported a combination of blue light GaN chips with luminescent down-conversion inorganic YAG:Ce phosphors and organic fluorescent dyes. The team demonstrated the use of LED chip–phosphor combinations to emit white light and blend colors, such as cyan and magenta.

Traditional LEDs are commonly used in lights, signs, and displays. Before 2000, the general lighting of homes, offices, and streets was not the primary use of LEDs. In 2000, LEDs with high efficiency, low energy consumption, durability, and other characteristics gradually became the future direction of lighting development. Moreover, LED power has rapidly developed, but also meets basic lighting requirements.

In 2004, Narukawa [103] reported that Nichia had broken the 100-lm/W barrier and its luminous efficiency was estimated to exceed 100 lm/W in the low current region (less than 1 mA), indicating that InGaN-based white LEDs had great potential to replace fluorescent lamps (75 lm/W) in the near future.

In 2006, Narukawa et al. [104] demonstrated efficiencies of up to 174 lm/W at a low current of 2 mA and up to 138 lm/W at a current of 20 mA (current density of 1.98 A/cm^2).

In 2010, Mukai, of Nichia, developed a white LED with very low current injection [105], resulting in a laboratory efficiency of 249 lm/W. In the same year, Cree announced that the correlated color temperature of white LEDs was approximately 4600 K at an injection current of 350 mA [106] and the laboratory result was 208 lm/W.

In 2014, Cree released laboratory results for a white LED lamp (excluding power) with a color temperature of 5150 K and an efficiency of 303 lm/W at an injection current of 350 mA [107].

LEDs in the general lighting and functional lighting fields continued to expand and the market size maintained rapid growth. From 2015 to 2020, the global LED market grew rapidly, and LEDs have gradually replaced incandescent lamps, fluorescent lamps, and other lighting sources, with the penetration rate continuing to rapidly increase [108].

By the end of 2020, the global LED lighting penetration rate had exceeded 60%. Using combined data from IHS Markit and LEDinside, the global market for LED devices was approximately $33.17 billion in 2019, up nearly 34.8% from $15.71 billion in 2015 (an average annual growth rate of 7.7%). LED devices for general lighting increased by 38.8% (8.1% average annual growth) from $4.62 billion to $6.41 billion, while those for functional lighting increased from $8.63 billion to $10.21 billion, an increase of 18.3% (average annual growth rate of 4.3%). The market share of LED devices for innovative applied lighting expanded from 3.7% to 5.2% [109].

The improvement in the efficiency of visible light LEDs is truly impressive. Assuming constant progress from 1960 to 2000, the LED efficiency has doubled every 4 years. This phenomenon is consistent with Moore's law [109].

Research and Development of UV LEDs

Ultraviolet light-emitting diodes (UV LEDs) are energy-efficient, environmentally friendly, and long-lived and have significant applications in fields such as sterilization and medical and biochemical testing. In recent years, increasing attention has

been paid worldwide to ultraviolet semiconductor optoelectronic materials and devices; in fact, they have become a research hotspot [110].

Research into AlGaN ultraviolet LEDs began in the 1990s. In 1992, with the realization of P-type doping of AlGaN materials, two researchers, Akasaki and Amano, from Nagoya University, Japan, used the double-heterojunction structure to prepare GaN/AlGaN ultraviolet LEDs for the first time, with a luminescence wavelength of 372 nm [111].

In 1998, in the American Sandia National Laboratories, Han et al. grew a GaN 0.2 GaN MQW epitaxial structure on a sapphire substrate using MOCVD, and successfully developed a UV LED with an MQW structure. The light-emitting wavelength was 353.6 nm, with an output power of 13 W, a start-up voltage of 4 V, and an EQE of less than 1% driven by a current of 20 mA. This was the first-ever development of the shortest-wavelength nitride material LED [112].

To reduce the piezoelectric effect of quantum well materials and improve the EQE of LEDs, in 1999, Nishida et al., [113] in NTT Fundamental Research Laboratory, Japan, used an Al0.06 GaN/Al0.12 GaN MQW structure to suppress the piezoelectric field and created an ultraviolet LED with a 346 nm wavelength.

In 2000, Kinoshita et al. of RIKEN, Japan, developed an LED structure epitaxy growth on a 6H-SiC (0001) substrate using a metalorganic vapor-phase epitaxy (MOVPE) technique. The hole-injection efficiency of an Al0.03 GaN/Al0.25 GaN MQW was increased by using an Mg-doped GaN/Al0.25 GaN superlattice, and the electroluminescence wavelength of the LED was 333 nm at a pulse current density of 0.13 kA/cm^2 [114].

In 2001, Nishida et al. proposed that an output power and internal quantum efficiency (IQE) of over 3 mW and 80%, respectively, could be obtained using bulk GaN as the substrate with a peak wavelength of 352 nm and 100 mA current injection, with an external quantum efficiency of 1%. Under a 400 mA high current injection, the maximum power exceeded 10 W, and the operating voltage was less than 6 V [115].

In 2006, Taniyasu et al. reported an AlN homojunction LED with a p-type/intrinsic/N-type (PIN) structure, which shortened the luminescence wavelength to 210 nm with an external quantum efficiency of 0.1% [116].

In 2009, Hirayama et al. of RIKEN, Japan, epitaxied AlGaN MQW LEDs on a sapphire substrate using an ammonia pulse multilayer growth technique. The maximum optical power was 0.15 mW, and the EQE was 0.2% [117].

In 2010, Nichia, Japan, used a high-quality AlN template to prepare deep-ultraviolet LEDs with a wavelength of 281 nm and an EQE of 2.78% at a driving current of 20 mA [118].

In 2013, deep-ultraviolet LEDs were grown on AlN substrates using HVPE technology by the Tokuyama Company of Japan. At 268 nm, the EQE was 2.4% (current 250 mA); at 261 nm, the EQE was 2.4% (current 250 mA), and the EQE was 2.2% (current 20 mA) [119].

In 2014, UV LEDs were fabricated by RIKEN, Japan, using the multi-quantum barrier (MQB) technique, with an EQE of 7% at 279 nm and a current of 25 mA [120]. In the same year, the UV Craftory in Japan produced UV LEDs with a

wavelength of 285 nm and an EQE of 14.3% at a driving current of 2 mA, using a novel packaging process [121].

In 2015, UV LEDs were fabricated by the US Sensor Electronics Technology company using an encapsulation process with excellent heat dissipation; the light-emitting wavelength was 278 nm, and the EQE was 11% at a working current of 10 mA [122].

In 2017, the Nippon Institute of Intelligence and Communications Technology (NICT) used nanoimprint lithography to fabricate nanoscale surface structures for photon extraction, enabling LEDs to emit light at a 265 nm wavelength and an 850 mA current with an EQE of 3.9%. The continuous output power was 150 mW, which was the highest continuous output power when the LED emission wavelength was below 280 nm [123].

In 2018, Zhang et al. designed an AlGaN-based deep-ultraviolet light-emitting diode with almost no efficiency drop, using a specially designed P-type electron barrier in a superlattice with a peak wavelength of 270 nm; the external quantum efficiency was 25% when the injection current density was 40 A/cm^2 [124].

In 2020, Ha et al. achieved a significant improvement in AlGaN deep-UV light-emitting diode efficiency via local surface plasmon resonance coupling mediated by high-density Al nanoparticle arrays. At an operating temperature of 300 K, the internal quantum efficiency was 12.3%, which was 100% more efficient than conventional UV LEDs [125].

In 2020, Yuan et al. fabricated an InGaN/GaN/AlGaN/GaN MQW UV LED with an output wavelength of 395 nm, an external quantum efficiency of 60%, and an output power of 659 mW at an injection current of 350 mA [126].

LED Device Material History

Before the advent of LEDs, owing to the development of semiconductor technology, there was complete theoretical knowledge explaining the phenomenon of electroluminescence, which laid the theoretical foundation for the development of LEDs. Since 1962, when the first practical red LED was developed, there has been intense discussion about the structure to be used to improve the luminous efficiency of LEDs.

First, SiC and ZnSe were important materials for the research and development of optoelectronic devices; GaN was put on hold because of the lack of a suitable single-crystal substrate, high dislocation density, and a complex fabrication process. The first GaN LEDs were not available until 1971; however, because P-type GaN doping was not possible at that time, only the metal–insulator–semiconductor (MIS) structure was used. Owing to the small number of carriers in the structure and the low efficiency of radiative recombination, the luminescence efficiency was very low, only 0.03–0.1 lm, with an optical output of 2 mcd at a current input of 10 mA [127].

In 1983, Yoshida et al. deposited a layer of AlN as a buffer layer on a sapphire substrate and obtained P-type doped GaN materials via Mg doping and low-energy

electron beam irradiation. This breakthrough laid the foundation for the subsequent generation of P–N junction LEDs [79].

In the late 1980s, the first GaN P–N junction LED was produced at Nagoya University by Amano et al., based on the work of Yoshida et al. n-GaN thin films were grown on an AlN buffer layer using the MOCVD method. The thickness of the N-GaN thin films was only 3 μm; however, the carrier concentration was 2×10^{-17} cm^{-3}. The experimental results showed that the performance of an LED with a P–N junction was better than that of an LED with an MIS structure [128].

Since then, the use of GaN-based LEDs has grown rapidly. In 1991, Nakamura et al. of Nichia Company successfully developed Mg-doped GaN blue LEDs, and for the first time, GaN thin films were grown on a GaN buffer layer by double-flow MOCVD. This greatly improved the film quality, making the hole mobility up to 600 cm^2 V^{-1} s^{-1}; the hole concentration of Mg: GaN was 3×10^{-18} cm^{-3}. The peak wavelength of the light emission was 430 nm, FWHM was 55 nm, light output power was 42 μW ($i = 20$ mA), operating voltage was only 4 V, and the external quantum efficiency was approximately 0.18% [129]. The spectrum quality was good with only one peak.

In homojunction LEDs, owing to the low barrier height, the restrictions on the injected carriers are weak, and the minority carriers are distributed over a wide range; these are orders of magnitude of several diffusion lengths, generally a few microns. In this range, the recombination efficiency of electron and hole radiation is low, so the luminescence efficiency is also low. Heterojunction LEDs were developed to increase the barrier height and enhance the recombination of electrons and holes.

In 1992, Nakamura et al. developed the first p-GaN/n-InGaN/N-GaN double-heterojunction blue LED. The peak wavelength of the output light was 440 nm, and the FWHM was 180 nm. The output power was 125 W, the operating voltage was 19 V when the input current was 20 mA, and the external quantum efficiency was 0.22% [131].

To strengthen the recombination of electrons and holes, a quantum well structure was created; it can be divided into single quantum well and multiple quantum well structures (MQWs). A single quantum well structure, such as a sandwich, consists of two broad bandgap materials sandwiched together. The main principle of MQWs is to introduce a multi-heterostructure as the active region of the LED and increase the probability of carrier trapping to improve the efficiency of radiative recombination.

In 2001, Lai et al. fabricated blue LEDs with an MQW structure. The active layer was composed of five layers of 2.5-nm-thick In0.25 Ga0.75 N and 4-nm-thick GaN, the output wavelength was 445 nm, and the FWHM was 28 nm. The input current was 20 mA, the output power was 2.2 mW, the saturation current was 1.4 A, the output power was 2.2 mW, the output power was 53 mW, and the external quantum efficiency was 4.5% [137].

Heat dissipation is a major obstacle to improving the efficiency of LEDs. Hence, engineers have developed flip-chip structures that place low heat dissipation sapphire substrates on top; heat dissipation materials are added to the substrate to enhance the heat dissipation function. In 2003, there were many patent applications for packaging technology for flip-chip LEDs.

Table 33.4 External quantum efficiencies of LEDs with different structures

Year	Author	LED structure	Wavelength	EQE (%)	Reference
1971	Ponce	MIS	485	0.1	[127]
1989	Amano	P–N junction	370	–	[128]
1991	Nakamura	Homogenous junction	430	0.18	[129]
1991	Sugawarah	Double heterojunction	620	1.5	[130]
1992	Huang	Double heterojunction	555	6	[131]
1993	Nakamura	Double heterojunction	440	0.22	[132]
1994	Mukai	Double heterojunction	500	2.4	[133]
1995	Nakamura	Single quantum well	450	9.2	[134]
1999	Wang	Single quantum well	530	–	[135]
2000	MODAKP	Multiple quantum wells	650	4.35	[136]
2001	Lai	Multiple quantum wells	445	4.5	[137]
2001	Tadatomok	Multiple quantum wells	382	24	[138]
2002	Koike	Multiple quantum wells	485	20	[139]
2006	Shchekin	Flip structure	441	38	[140]
2019	Zhous	Flip structure	460	46.8	[141]

In 2006, Shchekin et al. fabricated a thin-film flip-chip InGaN/GaN multi-quantum well LED with an output wavelength of 441 nm. It had a luminance of 191 mW/mm^2 and an external quantum efficiency of 38% under a driving current of 1 A [140].

These typical structures represent the development of diodes, from the MIS structure to the P–N structure to homogenous and heterogenous structures and then to quantum well and flip-chip structures. The output power and external quantum efficiency of the LEDs were improved by changing the structure. Table 33.4 shows the external quantum efficiencies of LEDs with different structures.

Visible Light Full-Duplex Communication

Research and Development of Visible Light Communication

Visible light wireless communication technology was first proposed by Professor Harald Haas, a German physicist. It is a green information technology that can realize high-speed data transmission by utilizing the fast response characteristic of LEDs. It is known in academia as visible light communication (VLC) technology [142]. As a type of access mode that broadens the resource spectrum, saves energy, and can be moved, it introduces a new idea for the development of traditional RF communication technology. Visible light communication uses LEDs as the light source, which enables it to communicate at high speeds [142].

In 1979, Gfeller created an indoor infrared communication system model, which divided indoor channels into line-of-sight (LOS) and non-line-of-sight (NLOS)

channels. Their impulse responses were calculated to reflect indoor channel characteristics [143].

In 1993, Barry proposed an indoor infrared communication channel model based on Lambert radiation by using a recursive loop algorithm to calculate the channel impulse response [144].

In 2000, Tanaka and Haruyama first proposed a VLC system. They presented the feasibility of using a white LED as the emitting light source of an indoor optical communication system and built a VLC system model [145]. In this study, the indoor VLC system was analyzed mathematically, the VLC channel was studied, and the problems of direct line-of-sight and scattering links were explained in detail.

In 2003, Komine et al. studied the channel model, light source characteristics, and noise model of white LED communication systems and obtained the bit error rate (BER) performance of different power ranges and modulation modes [146].

In 2007, Ke and Ding et al. of Xi'an University of Technology began to study the optimal layout of a VLC light source and designed a set of visible light wireless local area networks (LANs) [147].

In 2008, Arikan proposed channel polarization-based polarimetric codes, which are the only ones that can reach the Shannon limit. The coding algorithm for channel polarization performs well in binary discrete memoryless input channels [148].

In 2009, after extensive research, Komine et al. proposed an effective method to improve communication quality, which combined a decision feedback equalizer with least mean squares (LMS); thus, an adaptive equalization process was adopted for the VLC channel [149]. When the transmission rate was low, both the decision feedback and linear equalization had better effects. However, when the transmission rate was greater than (or equal to) 700 Mbit/s, the interference result of the former was better than that of the latter.

In 2010, Ke and Ding et al. created a new model of the visible light channel and proposed a fast simulation algorithm for light tracking [150].

In 2013, Bandara studied a recursive least-squares (RLS)-based VLC system that reduced the training sequence through theoretical analysis and the numerical simulation of an RLS-based adaptive equalization algorithm [151]. In the same year, He et al. developed a channel model and studied the path from communication access points to LED array access points and the path from there to each LED unit. The modeling effect was closer to reality [152].

In 2016, Li et al. used pulse amplitude modulation (PAM) modulated signals for transmission, based on preequalization. Experimental results showed that PAM signals had higher spectral efficiency than non-return-to-zero (NRZ) signals [153].

In 2017, Fang et al. provided polarimetric code-based VLC dimming control of an efficient forward error correction (FEC) coding scheme [154]. In the same year, Kim et al. studied a polarimetric code dimming control system for VLC [155] and, in 2018, analyzed the impact of reducing the intersymbol interference (ISI) caused by the multipath delay of the signal with polarimetric codes. Yao proposed a joint beamforming and DC bias design for multiuser, multi-input, multi-output (MU-MIMO) VLC systems that minimized the impact on lighting requirements [156].

In 2019, Haas achieved a real-time transmission rate of 15.73 Gbit/s in VLC using orthogonal frequency-division multiplexing (OFDM) based on a four-color wavelength-division multiplexing system [157].

In 2020, Wu et al. proposed a deep neural network (DNN) model for channel estimation based on DC-biased optical orthogonal frequency-division multiplexing (DCO-OFDM) [158]. In this scheme, the transmitted signals are used as tags and the received sampled signals are used as channel features for learning. The DNN model had a better BER performance than the traditional least-squares and least-square-error algorithms and eliminated the complexity caused by the minimum mean-squared error algorithm.

In 2020, Wang et al. proposed a VLC transceiver system that used three independent drivers with a feed-forward equalizer (FFE) to drive RGB LEDs to generate PAM-4 signals. The receiver used a cascading continuous-time linear equalizer (CTLE) as a post-equalizer. This VLC system increased the maximum data rate from 28 Mbit/s to 75 Mbit/s [159].

LED VLC has been widely studied and supported by many countries because of its advantages. To realize high-speed and long-distance transmission of visible light, researchers have thoroughly explored and researched advanced modulation technology, digital signal pre-/post-equalization technology, system transceiver devices, etc., and made a series of breakthroughs. Table 33.5 summarizes some important research results in the field of visible light communication at home and abroad.

Overall Full-Duplex Communication System Structure

As shown in Fig. 33.23, the indoor full-duplex communication system with a single visible light source consists of two parts: the active end and the reverse end. The optical communication link from the active end to the reverse end is the downlink, and the reply communication link from the reverse end to the active end is the uplink.

In this system, the active end is typically fixed to the ceiling of the room to provide lighting while sending information. The reverse terminal is located on all types of information terminals, receiving downlink information and returning data. The active end provides the modulated light source of the entire system. The uplink relies on the downlink modulated light signal as the carrier wave and uses the reverse modulator to carry the secondary modulation to the downlink light signal. The uplink data are then modulated to the reflected light signal and reflected back to the active end. The secondary modulated light signal is processed at the active end, and the uplink signal is extracted.

LED Optical Design

The optical design is divided into primary and secondary optical designs. The primary optical design includes LED packaging and LED photoelectric components to determine the LED light angle, light intensity, light flux, light intensity

Table 33.5 Domestic and foreign research results in visible light communication

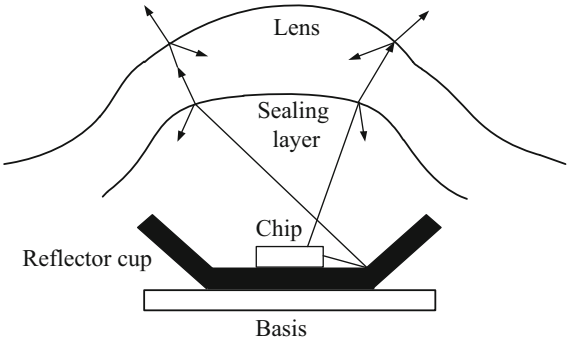

Fig. 33.24 Primary optical design diagram using a CREE-q5 flashlight [181]

distribution, and color temperature range and distribution. Figure 33.24 shows the primary optical design structure. This structure is designed to improve the light extraction rate so that the distribution of the half-light intensity angle is 120°.

To ensure the stability of indoor optical communication, the optical power on the receiving surface needs to be evenly distributed, and the secondary optical design adopts an optimized optical lens design algorithm. A VLC transmitter antenna [175] with uniform illuminance distribution, no inter-cell interference, and low design complexity can be realized.

The secondary optical design involves changing the optical performance of the beam after it passes through a lens and before passing through an optical lens. Therefore, the secondary optical design mainly optimizes the design of the LED lighting. The secondary optical light distribution design includes various elements, such as an external reflection cup, multiple optical lenses, and aspherical light surfaces, making it possible to respond to different scenarios.

The principle is shown in Fig. 33.25a, where the LED, after a single optical adjustment, diffuses light through a lens to a wider angle, mainly solving the lighting problem. In Fig. 33.25b, in contrast, the focusing problem is mainly solved by focusing the wide-angle light into a narrower light through a combination of mirrors and lenses or a single lens.

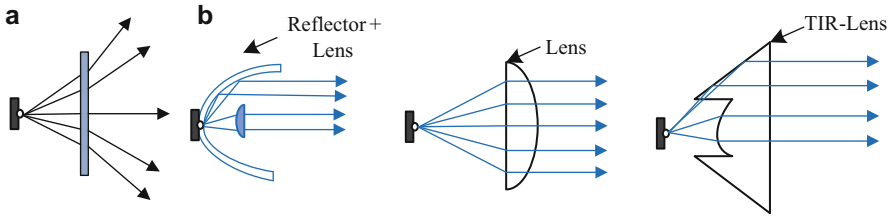

Fig. 33.25 Focused and astigmatic LED optical designs [174]

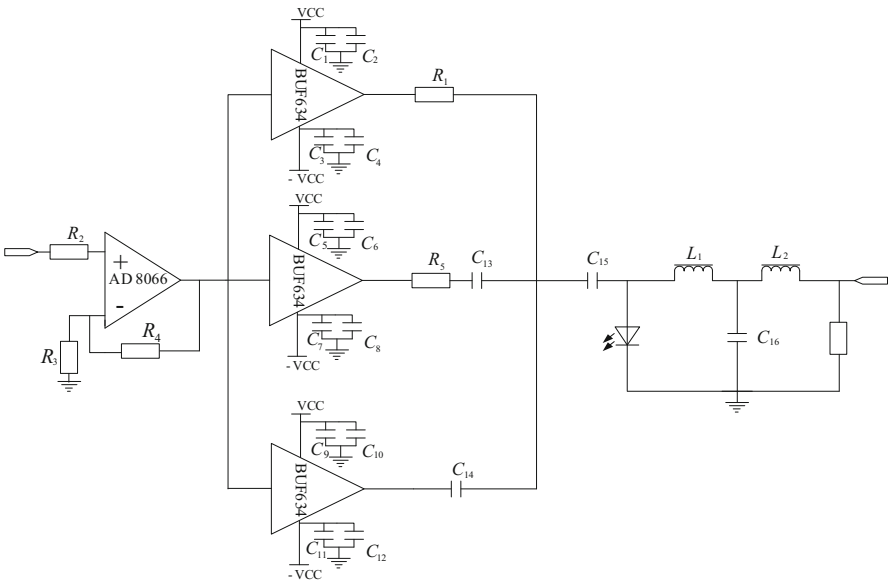

Fig. 33.26 LED driver circuit schematic [175]

LED Driver Circuit

The main function of the LED drive circuit is to convert the input voltage signal into a current signal and drive the LED to generate a modulated light-wave signal. The LED driver circuit consists of a DC bias circuit, preequalization circuit, and bias-T circuit [175]. The function of the DC bias circuit is to provide a stable one-way current to the LED and to make the LED work in a linear range.

The role of the preequalization circuit is to increase the modulation bandwidth of the LEDs by compensating for the fading component of the signal and reducing the signal distortion caused by the insufficient response strength of LEDs in the high-frequency band [176]. The main function of the bias-T circuit is to load the AC modulation component on the bias DC. The overall structure of the LED driver circuit is shown in Fig. 33.26.

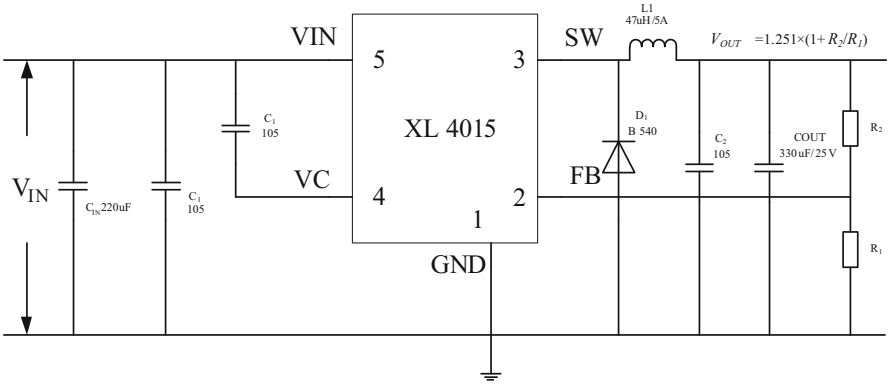

Fig. 33.27 DC bias circuit [175]

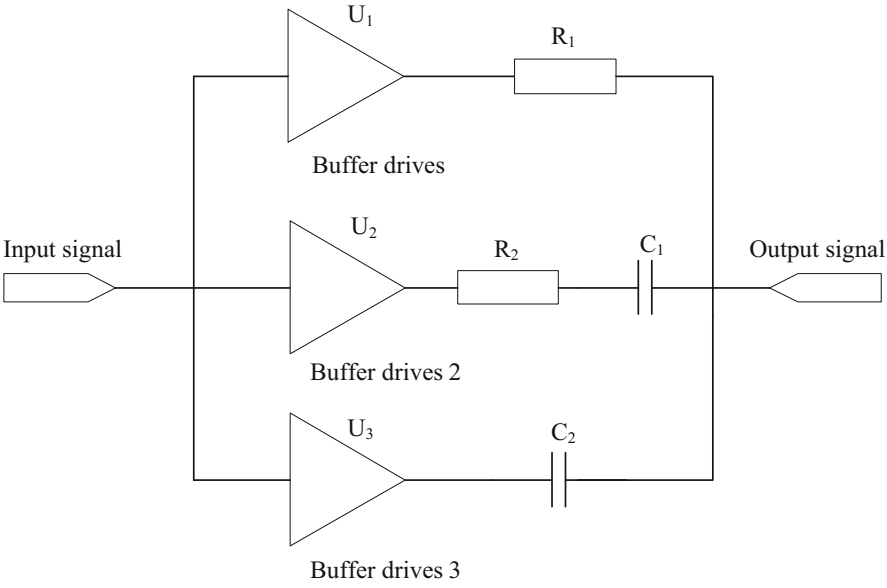
The LED driver requires a DC input; therefore, the LED modulation driver circuit biases the current source design requirements for a constant current source circuit. Figure 33.27 shows a bias constant current source circuit. XL4015 is a buck DC/DC converter with a fixed switching frequency of 180 kHz, which can provide up to a 5 A current output. The highest conversion efficiency is 93%. XL4015 has high integration, fewer peripheral devices, and flexible applications. The bias circuit design uses the output voltage and constant current output mode of the XL4015.

The modulation bandwidth of commercial high-power white LEDs is typically low, and the drive circuit plays an important role in extending their modulation bandwidth. A preequalizer can be used to increase the LED modulation bandwidth. When a white LED is used in a high-frequency circuit, its inductance characteristic exhibits a resonance effect with the capacitor in the circuit when the LED is working in the linear range.

The principle of the preequalization circuit is that the LED light source is equivalent to a low-pass filter with a cutoff frequency of 3 MHz in the driving circuit, while the preequalization circuit is equivalent to a band-pass filter with a pass frequency of 3 MHz or more. The central frequency of the resonance is controlled by changing the size of the capacitance in the circuit, extending the circuit in the high-frequency direction through the frequency range of the signal [177]. Considering that LED modulation requires a larger current, the buffer module in the pre-equalization circuit requires a higher current output capacity. The circuit is shown in Fig. 33.28.

The bias-T circuit is a three-port module that sets the DC bias points for certain electronic components without disturbing other electronic components [178]. Because of the unidirectional conductivity of the LED, the input modulation signal can only be a positive-amplitude voltage signal. Thus, it is necessary to transfer the AC signal produced by the modulator to a positive amplitude to be output from the LED.

The output signal power of the modulation circuit is very small, and its dynamic range exceeds the linear operating range of the LED. For LEDs to stably emit



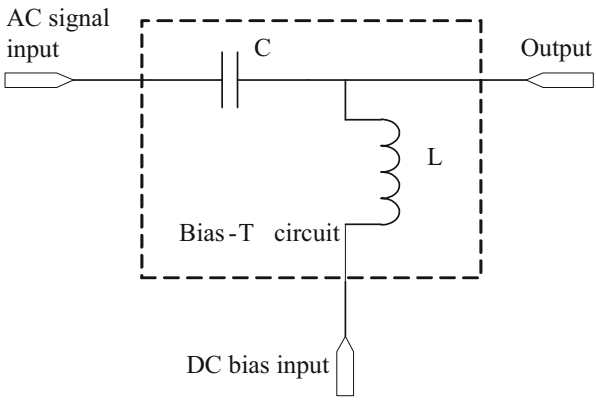


Fig. 33.28 Preequalizer circuit [175]

Fig. 33.29 Bias-T schematic [176]

modulated light signals, it is necessary to set a bias current to stabilize the bias of the LEDs and to superimpose the modulated current signal onto the bias current signal. The modulated signal is stabilized in the linear working range of the LED to obtain a good modulation effect.

Figure 33.29 shows a schematic diagram of the bias-T circuit. The DC bias is input through the inductor, the AC signal is input through the capacitor, and the two signals are superposed to the output through the output port.

Experimental Verification

Overall Uplink Design

In an optical full-duplex communication system, the uplink is a reverse communication link based on a reverse modulator. To realize a reverse communication link, we must first understand the characteristics of the reverse modulation device. There are many types of inverse modulators. Typical optical inverse modulators are divided into two types: the cube corner reflector and the "cat's eye" structure echo modulator [179].

A corner-reflecting prism is an optical device composed of three highly reflective planes placed perpendicular to each other. It is characterized by the fact that when the light beam is incident on any plane, the reflected light returns along the original incident side. Figure 33.30a, b show the attenuating reflection reverse modulator and externally modulated reverse modulator, respectively.

A reflector is placed on the focal plane of an optical lens, and the light rays are concentrated at the focal point of the lens after entering the lens. Owing to the reversibility of the light path, the reflector on the focal plane reflects the light beam back along the original path; this phenomenon is called the cat's eye effect. According to the difference in the modulation principle, the inverse modulation with a cat's eye structure can be divided into two types: defocus type and non-defocus type [180]. Figure 33.31a, b show electro-absorption-type and defocus-type inverse modulators, respectively.

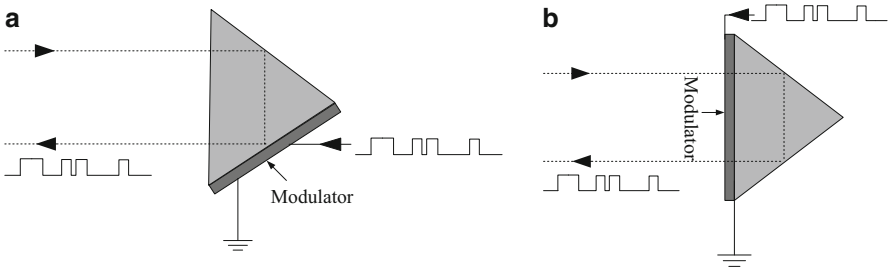

Fig. 33.30 Schematic diagram of the conic prism-type inverse modulator [179] (**a**) Attenuating reflection reverse modulator (**b**) Externally modulated reverse modulator

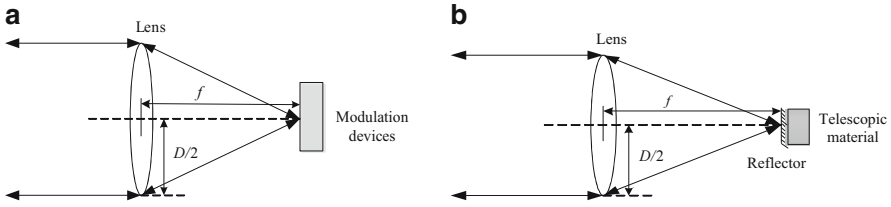

Fig. 33.31 Schematic diagrams of cat's eye reverse modulator models [180]. (**a**) Non-defocused inverse modulator (**b**) Defocused inverse modulator

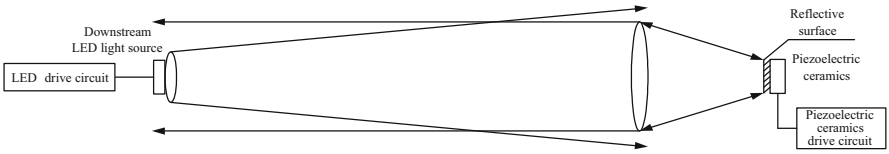

Fig. 33.32 Reverse communication system architecture diagram [181]

The uplink is a reverse communication link from the reverse end to the active end. The core of the reverse communication link is the cat's-eye reverse modulation system. The out-of-focus cat's-eye inverse modulator is composed of an optical lens, piezoelectric ceramic chip, modulation drive circuit, and echo-receiving circuit. Figure 33.32 shows the reverse communication system structure diagram.

When the system operates, the active end first sends the modulated light beam to the end of the reverse modulator. Because of the large divergence angle of the white LED beam, the receiving focusing lens and the cat's-eye reverse modulator are placed side by side at the reverse end and are located in the effective lighting area of the LED light source.

At the reverse end, the optical signal of the downlink is modulated twice by the reverse modulator, and the uplink information is modulated onto the downlink and reflected back to the active end. The active optical receiver receives the returned optical signal, separates the uplink modulation signal from it, and sends it to the demodulator for demodulation to realize a duplex communication link.

System Experiment

The Xi'an University of Technology experimental system was built, and the described full-duplex communication system was tested [178]. To verify the principle of single-light source full-duplex communication, a single-light source full-duplex communication experiment was carried out on the developed visible light full-duplex communication system.

The downlink adopted the differential quadrature phase-shift keying (DQPSK) modulation format; the carrier rate was set to 5.0 MHz, and the data rate was 5.0 Mbit/s. The uplink adopted the 4-way frequency-shift keying modulation format (4FSK) and used four carriers of different frequencies, f1, f2, f3, and f4, to represent different symbol combinations: 00 corresponds to f1, 01 to f2, 10 to f3, and 11 to f4. The carrier rate for f1 = 4 kHz, f2 = 8 kHz, f3 = 16 kHz, and f4 = 20 kHz. The data rate was 2.0 kbit/s.

During the experiment, the transmitted signal was collected, as shown in Figs. 33.33, 33.34, and 33.35. Figure 33.33 shows the measured figure of the signal sent by the active end and received by the reverse end in the downlink. Figure 33.34 shows the signal and its power spectrum after secondary modulation at the reverse end. Figure 33.35 shows a 4FSK modulated signal in the uplink.

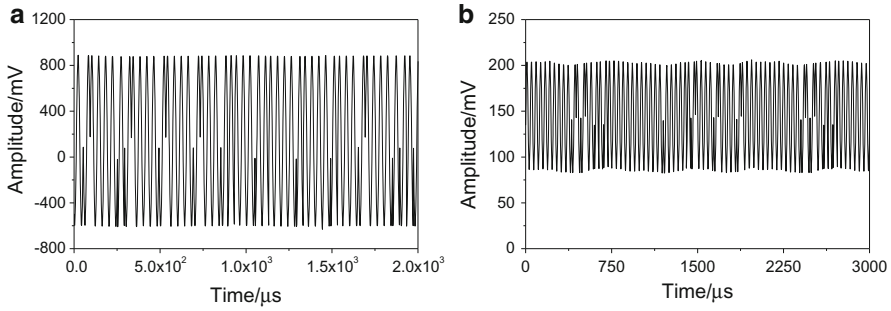

Fig. 33.33 Downlink communication signal [178]. (**a**) Active side sends the signal (**b**) Reverse side receives the signal

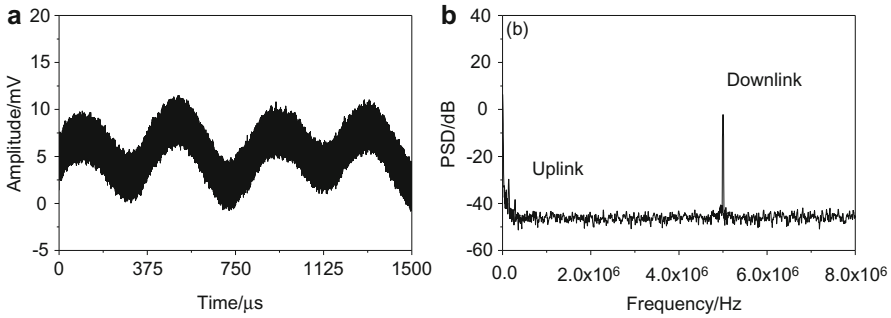

Fig. 33.34 Signal and power spectrum after secondary modulation [178]. (**a**) Signal after secondary modulation (**b**) Signal power spectrum

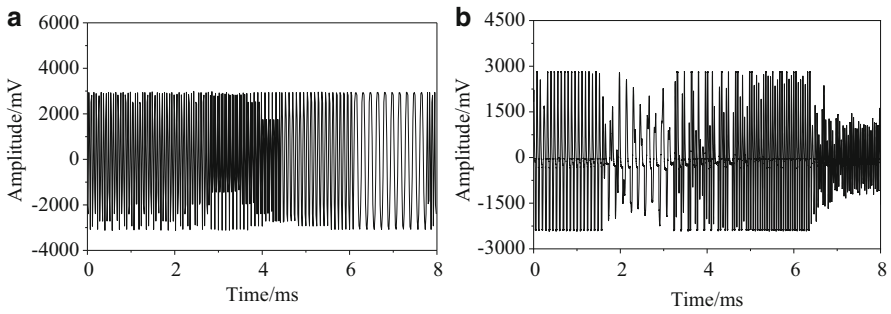

Fig. 33.35 Uplink Communication Link Signal [178]. (**a**) Reverse end transmits signal (**b**) Signal extracted by the active end

It can be seen from the graph that the received signal amplitude of the downlink is stable and clear, the visible light full-duplex communication system with an LED as a light source can meet the needs of reverse demodulation, and the two links can communicate without the influence of intersymbol crosstalk.

During the entire experiment, the downlink video communication was good, and there was no frame loss. The uplink data transmission involves normal, uplink, and downlink communication between each link without interference. It can be seen from the experimental results that full-duplex communication between the uplink and downlink can be realized independently and without interference by the two modulations of the unidirectional light source. The effectiveness of the inverse modulation technique for solving the uplink problem in indoor visible light communication was verified.

The experimental results show that the platform can achieve stable full-duplex communication with an active-end-to-reverse data transfer rate of 5.0 Mbit/s and a reverse-end-to-active transmission rate of 2.0 kbit/s over a communication distance of 3.0 m.

Summary

LEDs are widely used semiconductor light sources. They can be used for optical communication, with typical wavelengths of 780 nm, 850 nm, 1300 nm, etc. The LED manufacturing cost is low and reliable, the drive circuit is simple, and the temperature, emission power, and drive current have a good linear relationship (unless near saturation).

However, LED light sources have wide spectral lines (more than 20 nm, high dispersion) and divergent beams. They have low coupling efficiency with fiber, or need special lenses for coupling, and are not suitable for single-mode fiber applications with small core diameters. Therefore, they are only used for low-speed ($<$100 Mbit/s), short-distance ($<$100 m) communication.

At present, three regions—North America, Europe, and Asia—are the center of the global industrial pattern; each has a strong advantage in a different area. The developed economies, represented by the United States, Japan, and Germany, have the manufacturing capacity of the entire LED lighting industry chain and have an advantage in the high-end market, with advanced equipment levels and a relatively complete industrial chain system; however, owing to the high cost of labor, logistics, and supply-chain constraints, they do not scale well.

In emerging Asian market countries, India, Vietnam, and other countries represent the late development of the LED lighting industry. Although they have a certain product manufacturing capacity, their industrial chain is not perfect, it faces complex political and economic situations, and the social efficiency is low. In the short-term, it is difficult for these countries to be competitive.

China is the world's largest manufacturer and exporter of LED lighting products; it is extremely competitive in terms of production, research and development, and sales.

LED Industry Opportunities

Promote LED Lighting Products and Provide National Policy Support

To improve energy efficiency, protect the environment, and combat global climate change, the United States, European Union, Japan, and other developed countries/regions have introduced bans on traditional incandescent lamps and provided support to promote the development of LED lighting industry policies.

LED Lighting Technology Continues to Develop and Prices Continue to Decline

The rapid development of the LED lighting industry is determined by the progress of technology. In the lighting industry, LED lighting products have replaced energy-saving lamps. The progress in LED lighting technology is mainly reflected in two aspects.

The first is the continuous improvement of light efficiency. According to China's National LED Engineering Research and Development (R&D) and Industry Alliance, in 2018, the light efficiency of industrial high-power white LEDs exceeded 180 lm/mW, LED indoor lamps exceeded 100 lm/mW, and outdoor lamps exceeded 130 lm/mW.

The second is the continuous decline in cost. Owing to the improvement in upstream chip technology, the increase in production capacity, and the optimization of the production process, the cost of the main raw materials has gradually decreased, which reduces the production cost of LED lamps. The price of a 60-watt LED bulb was about $45 to $50 in January 2011; by July 2018, the price had fallen to less than $10 per bulb, and by May 2019, it had fallen further to $7. LED lighting is starting to approach the price of traditional energy-saving lamps.

LED Lighting Products Continue to Expand Their Application Fields

With the rapid development of LED lighting technology, LED lighting products' stability, service life, intelligence, light efficiency, and other performance indicators are becoming increasingly mature, to meet the market demand. LED lighting products not only meet the needs of general lighting. The market scope continues to extend and expand, according to different application scenarios, derived from a variety of application fields.

Before the 1990s, the LED lighting industry was in the early stage of development, with a single product color and higher prices. The application market was mainly driven by signal lights, indicator lights, and other similar demands. Then, the LED lighting industry entered a rapid development stage. The development of blue and green light technology and the decline in product prices rapidly promoted LED lighting in the commercial field and became the main driving force for the development of the LED lighting market at that time.

With the development of technology and the decrease in price, LED lighting products are widely used in home lighting, industrial lighting, etc. In the future, with the development of landscape lighting, automotive lighting, and other subindustries, the LED lighting market demand will continue to maintain rapid growth.

China Has a Complete LED Lighting Industry Chain and the Industry Is in a Mature Period of Development

China's LED lighting industry started in the late 1960s. After nearly 50 years of development, the lighting industry has made remarkable achievements, forming a complete industrial chain, including LED epitaxial chip production, preparation, packaging, and product application.

In addition, China attaches great importance to the research and development of LED lighting technology. It has launched green lighting and LED projects and supports R&D and industrialization of LED lighting technology in 10 key energy-saving projects, high-tech demonstration projects, enterprise technology upgrading and structural adjustment projects, and 863 new materials. Therefore, it has a good R&D basis and advantages in the integrated application of downstream LED lighting.

China's LED Industry Standards and Development Continue to Improve

In recent years, under the guidance of government departments, such as the Ministry of National Development and Reform Commission, the Standardization Administration of China, the Ministry of Science and Technology, the Ministry of Industry and Information Technology, and with the promotion of relevant industry organizations and bodies, the testing and certification of LED lighting standards in China has made phased progress.

According to statistics from the National Standard Information Public Service Platform, as of May 31, 2021, China had issued 187 current national standards, 174 industry standards, and 247 local standards related to LED lighting. It actively carries out group standard pilot work and actively participates in international ISO/TC274 standardization.

In addition, LED lighting products are increasingly used in a wide range of applications, such as outdoor areas, stadiums, and other downstream applications, and relevant management standards have been gradually established. In addition, the Ministry of Railways, Ministry of Transport, and Ministry of Public Security have established corresponding LED lighting application product standards. The establishment of these industry standards and norms will help promote the orderly and standardized development of the LED lighting industry.

LED Industry Challenges

The Core Technology Is Relatively Weak

At present, a large number of LED lighting products in China are used for export; however, the developed markets in Europe and North America are different from the domestic market. They have strict access thresholds, developed trust management mechanisms, and through high-tech regulations, high safety standards, and other means have set market access conditions for LED lighting products.

However, the core technologies of LED lighting enterprises in China have been weak for a long time in terms of high-end materials, optical design, power management, and heat dissipation technology. LED lighting enterprises have no competitive advantage in technology, which has become a major obstacle for LED lighting products being exported to developed countries/regions, such as Europe and the United States.

The Brand Influence of Domestic LED Lighting Enterprises Is Weak

The global LED lighting industry has formed a three-legged industrial distribution and competition pattern, dominated by the United States, Asia, and Europe. Japan, America, and Germany have the leading industries, followed by China, Taiwan, and Korea. They are followed by the echelon distribution of mainland Chinese countries and regions, such as Malaysia.

International giants, such as Xinnufei and Osram, occupy a large market share in the high-end product market and have their own characteristics in product and market aspects. They form a complete LED lighting industry chain and take advantage of its innovative advantages in the field of new products and technologies. They are mainly engaged in the production of high value-added products, master high-end materials, optical design, power management, cooling technology, and other key core technologies. However, domestic LED lighting enterprises have weak brand promotion and value-adding abilities or neglect brand construction in favor of sales scales.

The Homogeneous Competition Phenomenon Is Serious

Because the LED lighting market is in the high-speed growth stage, some small and medium-sized enterprises in the industry invest less in the research and development of products and technologies and occupy the market through using relatively low prices. This leads to the LED lighting industry having a certain degree of disorderly competition and product homogeneity. These problems not only affect the profit of LED lighting enterprises, but are also unfavorable to the health and sustainable development of the LED lighting industry.

Abstract

Visible light-emitting diode (LED) communication combines lighting and communication and has the advantages of high efficiency and energy saving, which are highly valued. This paper starts by elaborating on the LED light-emitting principle, introduces the progress of visible LED communication research, and analyzes some key technologies in the communication system. For the indoor application of white LED communication, the layout of LED light sources and visible light positioning are discussed, as well as several common visible light heterogeneous networking schemes. Finally, the future development direction of visible light communication is presented.

Keywords

LED · Visible light communication · Indoor LED layout · Visible light positioning · Heterogeneous network

Introduction

With the development of communication technologies, the traditional airwave spectrum is becoming increasingly crowded. Visible light communication (VLC) can make up for the lack of spectrum resources. White LEDs have high brightness, low power consumption, no pollution, long life, high emitted power, and other characteristics and are gradually replacing incandescent lamps to become the mainstream devices in the field of lighting [1].

In addition, VLC provides a communication function, making it a new wireless communication information carrier. Because of the many advantages of visible light communication, we conducted an in-depth study of the communication performance, including experimental simulations and other aspects, to explore the key technology of visible light communication. Future development trends and application prospects are presented to promote the development of visible light communication in all aspects.

Visible LED Communications

LED Light-Emitting Principle

LEDs, or light-emitting diodes, are mainly composed of LED chips, cathode rods, anode rods, lead frames, wedge-shaped brackets, etc., and then encapsulated in transparent epoxy resin [2]. Light-emitting diodes have unidirectional conductivity,

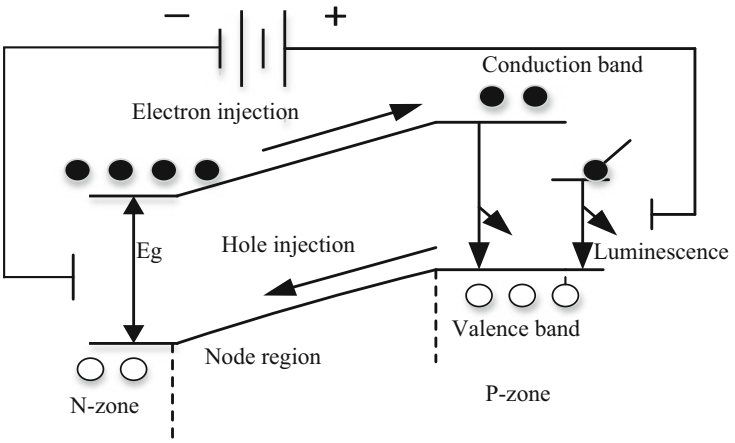

Fig. 34.1 LED light-emitting principle diagram [5]

the core of which is a semiconductor-doped P-N junction. The luminescence mechanism is compound luminescence using carrier radiation from the P-N junction, as shown in Fig. 34.1 [3].

When coupled with a forward bias voltage, the LED internal current flows through electron (N-type carriers) and hole (P-type carriers) composites in the light form to release excess energy by converting electrical energy into light energy [4]. The emitted light wave is the energy released by a high energy-level particle dropping to a lower energy level, and its frequency is $\nu = E_g/h$. Each particle is non-coherent, and the phase, polarization direction, and propagation direction of the emitted light wave are not the same. Therefore, LED luminescence is a spontaneous radiation process [5].

White light is a type of composite light. Typical white light LEDs are implemented using a multicolor LED combination method and phosphor-coating light transformation method, as described below [6, 7]:

Yellow phosphor is mixed on a blue LED chip to emit white light; as the white light generation must excite the fluorescent material, the modulation bandwidth is only a few tens of MHz, which does not meet the requirements of high-speed visible light communication systems.

An ultraviolet or violet LED is used as the light source and mixed with red, blue, and green phosphors to form white light according to the proportion. This method has a low luminous efficiency, and the modulation bandwidth has difficulty meeting the requirements of high-speed visible light communication systems.

A red, blue, and green three-color LED chip is packaged together; the three lights together emit white light. Although this method has a high production cost, it has a high diffractive color and the modulation response speed is very fast; thus, it is very suitable for high-speed visible light communication systems.

LED Communications

Visible light communication (VLC) is a optical wireless communication technology that uses light with a wavelength of 380 nm ~ 780 nm as an information carrier to transmit information in free space. The information is modulated by the LED transmitting light carrier, photodetectors and other photoelectric conversion devices are used to receive the light carrier signals, and the receiving end analyzes the received light intensity signals by judging and restoring the original information. This combines visible light communication with LED lighting, constructing LED lighting, and communicating dual-use base station lights [8].

The LED visible light communication system structure shown in Fig. 34.2 mainly consists of the transmitting and receiving parts. The optical signal transmitting part includes input and processing circuits (used to convert the signal source signals into electrical signals conducive to transmission in the channel) and a visible light drive modulation circuit (used to modulate the changes in electrical signals into changes in the intensity of the light carrier).

The optical signal receiving section consists of an optical system (for optimal reception of the signal source), a photodetector and preamplification circuit (for converting the optical signal to an electrical signal), and a signal processing and output circuit (to convert the electrical signal into a signal that can be recognized by the terminal).

Table 34.1 compares several wireless communication methods, including LED visible light communication [5, 9].

It can be seen that LED visible light communication has the following advantages [10]:

The spectrum does not require authorization. This is an effective solution to the current situation of tight wireless spectrum resources.

It can be used for simultaneous lighting and communication. It can realize point-to-point terminal barrier-free communication and reduce signal loss under lighting conditions.

Communication is safe and reliable. Because visible light cannot penetrate walls and other obstacles, the security and privacy of information are guaranteed.

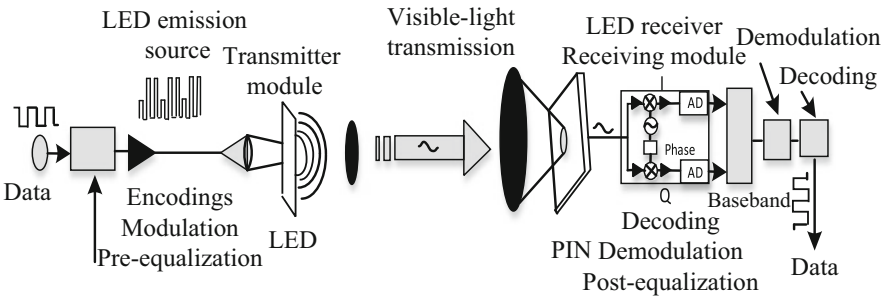

Fig. 34.2 Diagram of LED visible light communication system [8]

Table 34.1 Comparison of communication methods [5, 9]

Comparator	Radio	Infrared	Visible light
Is spectrum certification required?	Yes	No	No
Does it go through obstacles?	Yes	No	No
Presence of multipath fading	Yes	No	No
Presence of multipath dispersion	Yes	Yes	Yes
Is power limited?	Yes	Yes	No
Path loss	High	High	High
Main sources of noise	Other users	Backlighting	Backlighting
Shadow effect	Unaffected	Vulnerability to shelter	Mounting multiple LEDs eliminates shadow effects

It is safe for human eyes. Visible light LEDs are safe, radiation-free, and will not harm the human eye.

It has no electromagnetic interference. The signal transmission is not subject to other external interference and can be applied to the more sensitive environment of electromagnetic induction.

It has small shadow effect. Compared with infrared light, which is easily blocked and leads to a shadow effect, the shadow effect can be eliminated by installing multiple LED lights.

It has low construction and maintenance costs. The optical path can quickly form a temporary physical channel without the need to set up additional expensive base stations.

Current Domestic and Foreign Research Status

Current Foreign Research Status

In 2000, Tanaka et al. [11] from Keio University in Japan proposed a white LED communication system for wireless home links. Firstly, the light source was modeled as a Lambertian radiation model. Then, the direct view and non-direct view links were investigated, and multipath effects and intercode crosstalk were analyzed to avoid degrading the system performance. Numerical analyses and simulation studies confirmed that white light LEDs had both illumination and communication functions.

In 2001, Tanaka et al. [12] used a computer to conduct an analog simulation of the channel of a white LED indoor communication system, using on-off keying-return-to-zero (OOK-RZ) and orthogonal frequency-division multiplexing (OFDM)

modulation to address the effect of the optical range difference generated by multiple LED light sources.

In 2002, Fan and Komine et al. [13] of Nakagawa Research Laboratory investigated the effect of wall reflections on visible light communication systems. Their analyses revealed that the communication performance characteristics deteriorated at locations close to a wall, owing to increased interference from the reflected light signals.

In 2003, Komine et al. [14] proposed a wiring system that combined power line carrier communication and visible light communication, i.e., using existing wires for visible light communication. It remedied the visible light communication wiring problem of LEDs and also emitted LED light without demodulation, according to the signal wave transmitted by the power line. Its feasibility was proved through experimentation.

In 2004, Douseki et al. [15] introduced a self-powered optical wireless data transmission system that used solar cells and operated under white LED illumination. Using nonzeroed Manchester pulse digital optical modulation combined with an ultra-low-power CPU, a high-speed transmission of more than 100 kbit/s was successfully achieved over a 40-cm illumination distance.

The BER performance of the visible optical communication system is degraded due to intercode interference. In 2005, T. Komine et al. [16] proposed an adaptive equalization technique based on the minimum mean square error algorithm to effectively mitigate the intercode crosstalk.

In 2006, Sugiyatna et al. [17] proposed an inverted pulse position modulation and subcarrier inverted pulse position modulation technique, and the results showed that the subcarrier modulation can suppress the effect of background light.

In 2006, Afgani et al. [18] utilized extremely bright, white LEDs for optical wireless communication using OFDM. It was concluded that the high peak-to-average ratio property of OFDM could be constructively utilized for LED intensity modulation in visible light communication.

In 2007, Haruyama et al. [19] proposed two brightness control methods for lighting and visible light communication systems: pulse-width modulation (PWM) and changing the modulation depth. The results of the study showed that using PWM control controlled the brightness from 0% to 87.5%; when changing the modulation depth, the brightness could be controlled in the range of 0% to 100%, and the communication performance was better than that of PWM.

In 2008, Japanese scholars demonstrated an LED system using duplex communication at the Electronic High-Tech Exhibition. The signal transmission rate reached 100 Mbit/s with a communication distance of 20 cm between the transmitter and receiver [3].

In 2009, because the optical range difference between multiple light sources triggers intercode interference, which seriously degrades the system performance, Komine et al. [20] proposed a method that combined a judgment feedback equalizer with a least-mean-square algorithm. The results showed that the adaptive equalization system effectively mitigated the effect of shadows.

In 2009, Vucic et al. [21] from the Technical University of Berlin, Germany, achieved 200-Mbit/s visible light communication using 32 50-MHz subcarriers for discrete multitone (DMT) modulation.

In 2010, researchers in Heinrich Hertz's laboratory built a visible light communication system using ordinary commercial white LEDs and increased the communication rate to 513 Mbit/s using 128,100-MHz subcarriers, which was the world's leading level at that time [22].

In 2011, the IEEE promulgated the IEEE standard 802.15.7-2011 for short-range optical wireless communication using visible light. It was the first internationally accepted visible light communication standard and defined the physical and MAC layers for short-range visible light communication [23].

In 2012, Fujimoto et al. [24] completed experiments with a maximum transmission speed of 614 Mbit/s using a single commercially available red LED, for the first time. They employed pre- and post-equalization circuits and a simple RC network at both the optical transmitter and receiver ends using OOK modulation. They also confirmed the error-free operation of the proposed high-speed VLC system using an RGB-type white LED with a transmission speed of 603 Mbit/s.

In 2013, Bandara et al. [25] used multi-pulse amplitude modulation to significantly increase the data rate, while maintaining the LED switching rate limit. The receiver side was equalized using a recursive least-squares decision feedback equalizer to reduce the sequence length and improve throughput.

In 2014, Tsonev et al. [26] designed a VLC system using a single 50 μm gallium nitride LED using OFDM as a modulation scheme, which allows the limited modulation bandwidth of gallium nitride μLED devices to be fully utilized. Equalization and post-equalization techniques and adaptive data loading techniques were also successfully applied to achieve a VLC communication rate of 3Gb/s.

In 2015, Edirisinghe et al. [27] designed and implemented a bidirectional LED optical communication system. They conducted mathematical modeling and experimental evaluations of uplink and downlink crosstalk using infrared and white LEDs, respectively, and presented crosstalk cancelation methods.

In 2017, Miramirkhani et al. [28] proposed a visible light communication channel model for mobile users. Non-sequential ray tracing was used to determine the channel impact response at each point in the mobile user's trajectory, and then, the path loss and delay extensions were fitted to a curve as a function of distance. Experimental results showed that applying the adaptive scheme to a mobile channel allowed the transmission parameters to be adjusted according to changes in the channel environment.

In 2017, Islim et al. [29] achieved a data rate of 11.95 Gbit/s when considering only the nonlinear distortion of the LED device as the dominant noise source. A data rate of 7.91 Gbit/s was produced when all noise sources were present, using a violet micro-LED as the transmitter source for an OFDM-based VLC system.

In 2018, to address the problem of a high peak-to-average power ratio, owing to the limited dynamic range of LEDs, Ebrahimi et al. [30] proposed a hybrid OFDM-pulse-time modulation (PTM) scheme, which converted bipolar optical OFDM

samples into a pulse-width-modulated and pulse position-modulated digital PTM format for the intensity modulation of LEDs, which improved the bit error rate.

In 2019, Bian et al. [31] designed a four-color wavelength-division multiplexing system with DC-biased optical OFDM and optimized the experimental parameters. The data transmission rate reached 15.73 Gbit/s over a 1.6-m wireless link. In the same year, Ghassemlooy et al. [32] at Northumbria University, UK, proposed a relay-assisted scheme for visible light communication to enhance the stability of the system, which could help in the popularization and application of visible light communication technology.

In 2020, Mohapatra et al. [33] investigated a single-input single-output visible light communication system subjected to additive Gaussian white noise interference. A closed expression for the symbol error probability of the system was derived with complete knowledge of the channel and a least-squares estimation of the channel at the receiver.

In 2021, Raj et al. [34] developed an analytical model of a dimmable VLC system using channel equalization. It was analyzed and used to study the effect of dimming and the data rate on the error performance of variable switch keying and variable pulse position modulation schemes.

In 2021, Aravindan et al. [35] developed a VLC system for transmission using a 3-m indoor free-space direct vision link using a single phosphorescent white LED. It was proposed to overcome the bandwidth limitation of LEDs using dot pre-equalization circuits with nonzero switch keying to achieve data transmission rates up to 1.3 Gbit/s.

In 2022, Poulose [36] used the OptiSystem simulation software to investigate direct and non-direct path models for indoor VLC systems. The non-rectilinear link propagation model used a single LED as the transmitter and varied the system bit rate when the field of view varied.

In 2023, Agha et al. [37] investigated the order of multiple-input multiple-output (MIMO) arrays for an interference-free capacity system. The final simulation and theoretical results showed that the inter-cell interference in visible light communication was greatly mitigated using the MIMO system.

Current Status of Domestic Research

In 2006, Hu et al. [38] compared the characteristics of white LED and infrared wireless communication technologies and proposed a white LED indoor wireless communication technology. By analyzing the channel and link, the factors to be considered in designing an indoor optical wireless communication system were determined.

In 2006, Ding et al. [39] analyzed the structure of a VLC indoor system and further proposed that the optimal light source layout of the room, optimal number of LEDs, and selection of the receiver field of view (FOV) were key technologies to be considered for indoor VLC.

In 2008, Chen et al. [40] proposed a theoretical scheme for angle diversity optical receiver technology and gave the corresponding photodetector (PD) layout model for this scheme. It improved the signal-to-noise ratio of the communication system, as well as overcoming intersymbol interference.

In 2009, Cao et al. [41] analyzed the indoor channel characteristics in terms of both the background optical noise and the multipath effect and used angle diversity reception as a solution. The research results showed that the diversity reception technique effectively improved the system performance and laid a solid foundation for achieving stable communication in high-speed networks.

In 2010, Ding et al. [42] analyzed the multipath channel model of an indoor visible light communication system and proposed a new reflection model of the Lambert–Phong model after studying the reflection characteristics of the channel model. A Monte Carlo ray-tracing simulation was completed under the line of this model, and the results showed that the simulation calculation of the ray-tracing algorithm using the Lambert–Phong model had a linear relationship with the number of reflections, which reduced the computational complexity.

In 2012, Zhang et al. [43] proposed a multi-input single-output subcarrier-multiplexed VLC system. By analyzing the variation characteristics of the BER with the transmission distance, they concluded that the transmission was reliable when the communication distance was less than 140 cm.

In 2013, Chi [44] proposed a new visible light communication system with full-duplex bidirectional subcarrier multiplexing wave-division multiplexing (WDM). It used quadrature amplitude modulation–OFDM and pre- and post-equalization techniques to achieve a visible light communication rate of 225 Mbit/s for the uplink based on P-LEDs and 575 Mbit/s for the downlink based on RGB-LEDs.

In 2013, Li et al. [45] studied the optical–electrical–optical interconversion relationship between the transmitter/receiver and the transfer function of the generalized visible light link, combined with the time/frequency-domain response characteristics. They constructed a complete mathematical model of the visible light communication system and obtained the influence law of the signal-to-noise ratio and the bit error rate of the visible light link on the transmission rate. When the signal-to-noise ratio was fixed, the limiting transmission rate had an e exponential growth relationship with the BER; for a fixed BER level, the limiting transmission rate changed with the signal-to-noise ratio as a Boltzmann function.

In 2014, Wang et al. [46] proposed a parallel high-speed transmission scheme based on OOK modulation for a nonlinear low-communication channel model in VLC. The scheme used an interleaved-division multiple access technique to simultaneously transmit from multiple wick sources. Compared with the multicarrier DC-biased optical OFDM under the same conditions, this scheme had a lower bit error rate and better nonlinearity resistance.

In 2015, Guan et al. [47] proposed a dual-modulation technique for LED light sources based on chip-on-board packages. Specifically, a dual-modulation technique combining pulse amplitude modulation and pulse wavelength modulation was applied to modulate and dim the LED light source system, respectively. Simulation

results showed that the VLC system using the dual-modulation technique had a lower BER than the system using digital switch keying modulation.

In 2015, Kang et al. [48] proposed a multidimensional coding method to improve the spectrum utilization of visible light communication, built a visible light audio-transmission system based on RGB-LEDs, and experimentally validated it using 16-pulse position modulation for multicolor LEDs. The results showed that this coding method effectively utilized the spectrum resources and increased the channel capacity.

In 2016, Yang et al. [49] introduced a peak average-to-power ratio reduction technique, i.e., OFDM mu-law compression, into the VLC system. The required signal format for VLC transmission was achieved and a lower peak average-to-power ratio signal was obtained.

In 2017, Wang et al. [50] studied the effect of the visible light communication receiving plane tilt angle on the channel capacity. After analyzing the system model, the upper and lower limits of the VLC channel capacity were given. It was found that the channel capacity could be greatly improved by appropriately tilting the receiving plane.

In 2018, Ke et al. [51] designed an indoor visible light single light source full-duplex communication system with an out-of-focus catadioptric inverse modulation scheme to achieve mutually independent link communication. The experimental results yielded uplink and downlink communication rates of 2.0 kbit/s and 5.0 Mbit/s, respectively.

In 2019, Wei et al. [52] achieved a transmission rate of 40 Gbit/s in 2-m free space using polarization-multiplexed RGB laser diodes, using orthogonal frequency-division multiplexing.

In 2020, Wu et al. [53] proposed a scheme to introduce deep learning techniques into channel evaluation for VLC systems, using DC-biased OFDM as the fundamental and relying on deep neural network models of deep learning techniques to estimate the channel with low spectral occupancy. This model had better BER performance than the traditional least-mean-square error method and also reduced the computational complexity of the least-mean-square error algorithm.

In 2021, Yang et al. [54] designed an integrated power carrier and visible light communication system for sites with weak electromagnetic signals. After laboratory and tunnel field tests, it simultaneously supported five handheld terminals online for real-time positioning.

In 2021, Ke et al. [55] proposed the use of a double-Gaussian function superposition to represent the VLC background light noise model for vehicular networking in nighttime environments and conducted real measurements at night in different regions. The results showed that there was no significant difference in the probability density distribution under both rainy and sunny weather conditions. Moreover, the light intensity fluctuation of street lights was found to be less than that produced by other light sources.

In 2022, Li et al. [56] proposed a noise-suppressed three-layer hybrid optical OFDM VLC system, which was further combined with pulse-width modulation to control the dimming. This dimming scheme achieved a wide dimming range of 89.0% while maintaining a BER below 3.8×10^{-3}.

In 2023, Chen et al. [57] introduced a joint power and subchannel resource allocation algorithm into an OFDM multicolor visible optical communication system. The scheme sufficiently improved resource utilization and obtained a higher transmission rate.

In 2023, Yang [58] used an artificial neural network to estimate and suppress the nonlinear distortion of the signal at the receiving end. The results showed that the method was able to reduce the bit error rate in different channel environments and effectively improved the performance of the visible light communication system.

Since the concept of visible light communication appeared in 2000, scholars at home and abroad have deeply investigated each part of the system. They have proposed various schemes to increase the communication rate and improve communication performance. In addition, they have explored the theoretical model under certain communication environments to provide a solid theoretical foundation for practical applications. Research approaches include experiments and simulations, but are not limited to them. The research content has gradually changed from the communication field to cross-cutting research in other fields, such as deep learning and neural networks. The above research on communication rates is summarized in Table 34.2.

Table 34.2 Visible light communication achievements

Year	Authors	Modulation	Result
2004	Douseki et al. [15]	Nonzero Manchester pulse digital modulation	Successful high-speed transmission of more than 100 kbit/s at an illuminated distance of 40 cm
2009	Vucic et al. [21]	DMT	Achieved 200 Mbit/s visible light communication using 32 50-MHz subcarriers
2010	Vucic et al. [22]	DMT	Increased communication rate to 513 Mbit/s using 128,100-MHz subcarriers
2012	Fujimoto et al. [24]	OOK	First experiment using a single commercially available red LED with a transmission speed of 614 Mbit/s
2013	Chi et al. [44]	Orthogonal amplitude modulation–OFDM	P-LED-based uplink with 225-Mbit/s communication rate, RGB-LED downlink rate of 575 Mbit/s
2014	Tsonev et al. [26]	OFDM	3-Gbit/s VLC communication rate achieved using GaN μLED devices
2017	Islim et al. [29]	OFDM	Achieved 10.72-Gbit/s transmission rate at 1-m communication distance using pre- and post-equalization techniques
2018	Ke et al. [51]	Out-of-focus cat's eye reverse modulation	5.0-Mbit/s downlink communication rate, 2.0-kbit/s uplink communication rate in duplex communication
2019	Bian et al. [31]	DCO-OFDM	Accomplished 15.73-Gbit/s real-time transfer rate over 1.6-m VLC link
2019	Wei et al. [52]	OFDM	40 Gbit/s in 2-m free space
2021	Aravindan et al. [35]	NRZ-OOK	1.3-Gbit/s data rate in 3-m indoor free space

Key Technologies in LED Visible Light Communication Systems

Link Technology

The directionality of light in visible light communication, its susceptibility to occlusion, and the complexity and diversity of noise sources result in an optical link model that is vastly different from that of traditional wireless communication [59]. According to the chronological order of light transmission and reception, the visible light link consists of three parts, i.e., a visible light communication light source, visible light transmission, and visible light reception.

Uplinks and Downlinks

A visible light communication system has two links between the receiving and transmitting ends: the uplink and the downlink. In downlink communication, optical transmitters and optical receivers use non-directional transmissions with unrestricted pointing and range; in uplink communication, optical transmitters and receivers use directional transmissions with restricted pointing and range [60].

An uplink communication is achieved by direct alignment, and in the case of duplex communication, the light intensity at the transmitter end of the downlink is stronger and the radiation angle of the LED light source is large; consequently, it will cover the uplink channel and interfere with the optical signal at the receiver end of the uplink [61].

Therefore, a crucial and important issue in uplink realization lies in avoiding interference from downlinks with illumination [62]. Based on uplink communication technologies implemented using radio waves and wireless light waves, the following uplink schemes have been proposed for visible light communication [63, 64]:

Infrared light in the 780–950-nm band is used as the uplink to distinguish visible light from the downlink.

VLC and RF are combined, i.e., using VLC as the downlink and a radio-frequency (RF) system as the uplink.

A laser reflector is used to reflect some of the incident light back to the transmitting system and modulate the reflected light to achieve the uplink transmission.

A visible light uplink is used such as having the downlink communicate using white LEDs to transmit data. The uplink communication can also use visible light bands for data transmission. Time-division techniques are used to separate the information transmission time for the uplink and downlink.

A polarizing beam splitter is used to separate the transmitting light from the receiving light, thus eliminating the effect of the downlink light on the uplink light.

Direct Vision Links vs. on-Direct Vision Links

In applications, a line-of-sight (LOS) or non-line-of-sight (NLOS) link is determined, based on whether the link is obstructed by objects in the path [65]. The unobstructed linear propagation of optical signals between the transmitter and

receiver is a line-of-sight link, while the presence of obstructions and reflections resulting in nonlinear propagation produces a non-line-of-sight link.

In an indoor visible light communication system, the direct view link has no wall reflections between the LED light source and the receiving end. Its transmission path is shorter, which increases the system communication rate, and high-speed data communication can be achieved. The path loss is smaller, the background light interference is weaker, there is no multipath fading effect, and the utilization rate of the signal light source is high.

The transmission path of the non-direct view link is longer, and the signal power is reduced after the signal has been reflected by a wall, etc. The paths arriving at the receiver at different times cause intercode interference, which degrades the reception performance. However, the coverage range is slightly larger than that of the direct view link, and some shadow effects can be overcome [66, 67]. The two links are compared in Table 34.3.

Reverse Modulation Techniques

Reverse modulation technology can be used to solve the uplink problem of indoor VLC. The principle is to use the reverse modulator for modulation by the incident light, following the original path back to the transmitter. Thus, the communication process can be completed without needing an active light source.

The key technology to achieve dual full-time communication is inverse modulation technology, in which, the inverse modulator is the core device. Common inverse modulators include angular cone prism reflection types and cat's eye structure echo-modulation types [68]. Figure 34.3 shows the schematic diagram of a cat's eye structure modulator [67]. According to the cat's eye structure, the inverse modulator is divided into two types of modulators: non-defocused and defocused. The two modulator models are shown in Fig. 34.4a and b, respectively [68].

Inverse modulation optical communication has the advantages of a large field of view, low power consumption, and suitability for small platform workers, compared to traditional free-space optical communication [69]. By simplifying the uplink

Table 34.3 LOS link vs. NLOS link [61]

Comparator	LOS link	NLOS link
Communication rate	High	Low
Direction requirements	High	Low
Shadow resistance	Low	Intermediate
System mobility	Low	Intermediate
System complexity	Low	Intermediate
Background light effects	Small	Large
Multipath decay	No	Yes
Channel loss	Low	High

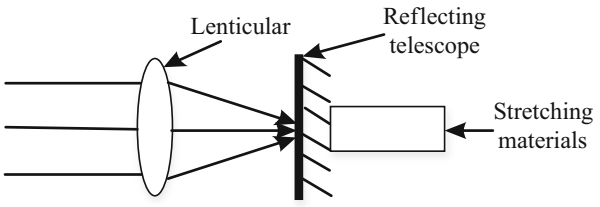

Fig. 34.3 Diagram of a cat's eye structure modulator [67]

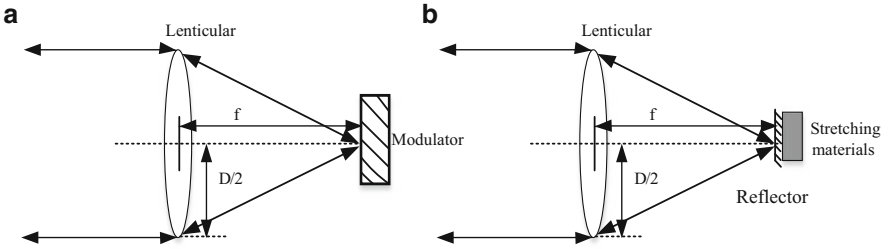

Fig. 34.4 Principle of a cat's eye reverse modulator [68]. (**a**) Non-depolarizing inverse modulator model. (**b**) Off-focus inverse modulator model

using inverse modulation, the complexity of the system structure is greatly reduced, while preserving the inherent advantages of visible light communication.

Equalization Technology

Equalization techniques improve the LED low-pass characteristics and overcome intercode interference by compensating for non-flat channels. Equalizers can be classified into two categories, pre-equalizers (located in the transmitter section) and post-equalizers (located in the receiver section) [70].

Pre-Equalization Technology

Pre-equalization improves the transmission rate and LED response bandwidth by compensating for the signal distortion caused by the device and channel. It can be classified into hardware pre-equalization and software pre-equalization, in terms of the implementation level [71].

Hardware pre-equalization techniques are mainly through the design of analog circuits. Pre-equalization circuit modules are connected in series in the transmitter circuits to counteract the nonlinear fading of the system and achieve the equalization effect [72]. Software equalization, i.e., using digital signal processing methods, automatically adjusts the transmitted signal waveform according to the channel characteristics, to achieve the equalization effect [73].

A finite impulse response (FIR) pre-equalization filter is the current mainstream software pre-equalization scheme; it mainly consists of a window function design method and a frequency sampling design method [71]. The advances in pre-equalization techniques are summarized in Table 34.4.

Post-Equalization Technology

A post-equalization technique is a scheme for equalizing the receiver side of the system to adapt to the time-varying nature of the multipath channel when the transmission environment is constantly changing.

Current analog post-equalization mostly uses passive equalizers or a combination of passive and active equalizers to compensate for the signal [70]. Minh et al. [74] presented the design of a first-order analog post-equalizer. It extended the bandwidth of the system to 50 MHz after equalization, and the communication rate reached 100 Mbit/s. A few years later, Chen et al. [75] proposed new post-equalization circuits, which combined two passive equalizers with an active equalizer and a blue-light filtering technique to obtain a 151-MHz system bandwidth and a 340-Mbit/s transmission rate.

Zhang et al. [76] used a circuit consisting of an op-amp and an R-C network as a post-equalizer to extend the system bandwidth to 220 MHz, which reached a maximum of 553 Mbit/s in OOK transmissions. Hao et al. [77] combined a pre-equalizer with a resonance effect and a third-order active high-pass filter circuit and compensated the system modulation bandwidth up to 42 MHz. Zhao et al. [78] designed a dual cascaded π-type equalizer as a passive post-equalization method. The flatness of the 50-MHz compensated signal modulation bandwidth was 3 dB.

Effective measures have been proposed to solve the problem of distortion caused by the multipath effect of channel software post-equalization, such as feedback-based adaptive equalization mechanisms. Mechanism-based adaptive equalization

Table 34.4 Comparison of pre-equalization technology [72, 73]

Pre-equalization type	Equalization technology	LED morphology	Wideband /MHz	Transmission rate /(Mbit/s)
Hardware	Series resonant circuit	Phosphor	2.5–45	80
Hardware	Transistor T circuit	RGB	6.2–91	477
Hardware	Passive overcorrection circuit	Phosphor	12–77.6	200
Hardware	NPN transistor circuit	Phosphor	3–175	460
Hardware	Improved bias-T circuit	Phosphor	1.0–30	190
Hardware	Single-cascade T amplitude equalizer	RGB	75–125	750
Hardware	Dual cascade equalizer	Phosphor	17–366	1600
Software	Power exponential equalizer	Phosphor	500	2080

and linear filtering–based linear equalization schemes include filter structures, such as linear lateral equalizers and judgment feedback equalizers [73].

Pre- and post-equalization techniques can be combined in visible light communication. Pre-equalization can be used to extend the LED modulation bandwidth at the transmitter side and post-equalization at the receiver side to solve the channel-generated signal distortion problem, thus significantly improving the transmission rate of the system [73].

Information Modulation Technology

Modulation is a key technology to improve communication transmission efficiency. The modulation methods currently applied to VLC systems include traditional modulation methods, such as switch keying and pulse position; derived modulation methods, such as differential pulse position modulation and double-ended pulse-spacing modulation, as well as color shift keying and orthogonal frequency-division multiplexing, etc., which are briefly described below [79].

Digital Pulse Modulation

Digital pulse modulation can achieve high speeds and efficient data transmission with many advantages. Ke et al. [80] of Xi'an University of Science and Technology conducted a detailed analysis and compared the characteristics of various pulse modulation methods in optical communications, including average symbol length, bandwidth requirements, bandwidth utilization, and average transmit power.

To meet the demand for high bandwidth, high power, and low BERs in visible light communication systems, new modulation schemes are constantly being proposed on the basis of mature applied modulation techniques. In practical experiments, the appropriate modulation method can be selected according to the need.

Color Shift Keying

Compared with white light monochromatic VLC systems, multicolor VLC systems can both increase the transmission capacity and modulate the chromaticity of the light source [81]. The visible light communication standard proposes color shift keying (CSK) modulation for different color LEDs, which is designed to solve the lighting compatibility problem in multicolor VLC systems [82].

Color shift keying uses RGB trichromatic light-emitting diodes to represent different transmitted data by different colors of visible light. If we use the binary numbers 00 for red, 01 for blue, and 10 for green, the receiver module will recognize and then demodulate the different colored LEDs into pairs of binary codes. This avoids the nonlinearities of monochromatic light sources due to the flickering intensity, which affects the system performance [83]. A schematic of the color shift keying system is shown in Fig. 34.5 [83, 84].

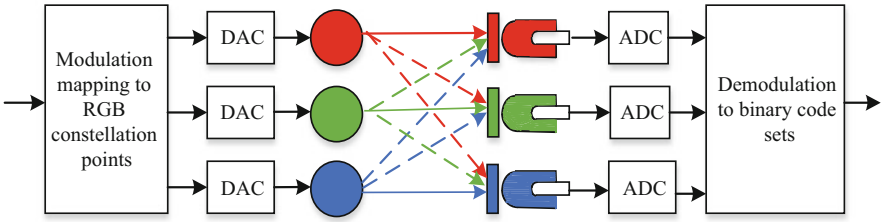

Fig. 34.5 CSK modulation system model

Orthogonal Frequency-Division Multiplexing

The OFDM modulation principle is to modulate a number of signals independent of each other onto carriers of different frequencies and combine them, enabling simultaneous transmissions in the same channel. Because a certain amount of protected band is left between the subchannels, its spectrum utilization is relatively low [85].

OFDM modulation is a type of multicarrier modulation technique, whose basic idea is to divide a given channel in the frequency domain into many orthogonal subchannels; each channel is modulated with one subcarrier to achieve parallel transmissions [85]. As a result, the OFDM spectrum can be overlapped and the original signal can be separated without distortion at the receiver. The use of OFDM is promising because it can combat the intersymbol interference caused by multipath transmissions (Fig. 34.6).

Since 2011, a series of alternative solutions have been proposed by domestic and foreign researchers to address the technical limitations of the high average-to-peak power ratio in OFDM modulation [86].

Bandwidth Extension Technology for White LED Light Sources

The modulation bandwidth of LEDs is defined as the bandwidth between the corresponding frequency point and the reference frequency point, when the output AC optical power drops to half of a certain low-frequency reference value [87]. The lower modulation bandwidth of LEDs in VLC severely limits the development and application of VLC systems.

Auxiliary techniques, such as the optimal design of driver circuits, equalization techniques, OFDM, and channel coding, can improve the system modulation bandwidth; however, the preparation of white LEDs with high luminous efficacy, good color rendering, and large modulation bandwidth can have a multiplier effect. Taking the blue GaN surface coating fluorescence to form white light as an example, the main factors limiting the bandwidth include the following:

The modulation bandwidth of the GaN chip itself.
The radiation lifetime of the phosphor.
The proportion of blue-light flux accounted for in the white spectrum [88].

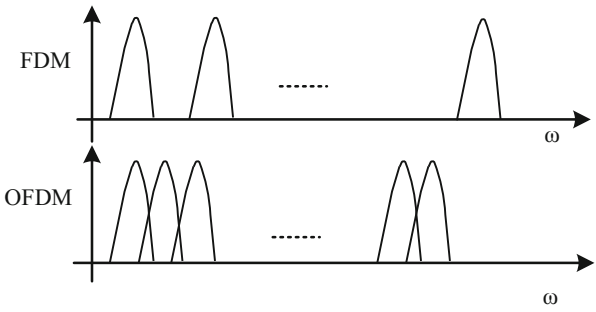

Fig. 34.6 Comparison of the spectrum structure of FDM and OFDM [85]

Pursuing the high-frequency response of white LEDs under high power output and continuously expanding the bandwidth to modulate it up to 30 MHz are the main challenges that must be researched and solved at present for high-speed white LED communication [89].

Optical Camera Communication Technology

Optical camera communication (OCC) is a VLC technique that uses an image sensor (IS) as a receiver to receive optical signals [90]. In existing research, OCC systems mostly use a single large-diameter LED as the transmitting device and a high frame rate camera as the receiving device [91]. The OCC information-sending principle is basically the same as that of VLC, and the high-speed bright and dark flickering signals of LEDs can be used to send the information. The principle of information-receiving principle is to adjust the exposure time of the monocular camera to match the flickering frequency of the LED light source, to capture a clear bright and dark stripe image [92].

The IS used at the receiving end is mainly classified into a charge-coupled device (CCD) or complementary metal oxide semiconductor (CMOS). The CCD adopts a global shutter approach, in which each row of its pixels is exposed at the same time. Only one light source state can be captured per exposure, and the communication process encodes only one bit of information, so the global shutter mode data transmission speed is limited.

CMOS uses a roll-up shutter for line-by-line scanning exposure, and the intensity of the light signals presented on different pixel lines is not the same, which means that the information obtained has a multi-bit characteristic. This property can increase the communication rate of visible light imaging [93]. Reference [93] provides a detailed analysis and comparison of modulation methods in OCC systems, which further looks at the development as well as the limitations of OCC. The working process of the two shutters is shown in Fig. 34.7.

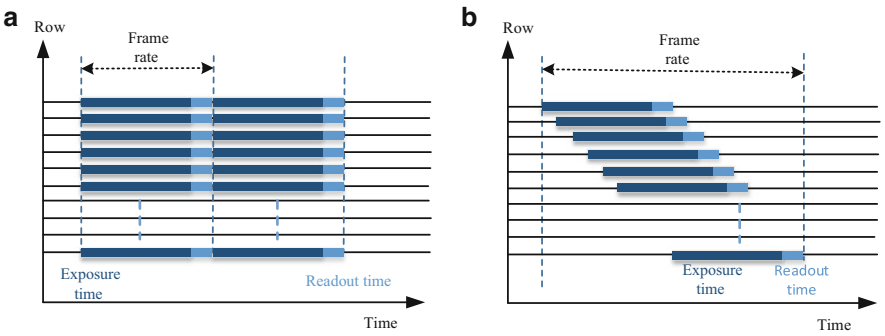

Fig. 34.7 Two types of shutter working processes. (**a**) Global shutter operation process. (**b**) Rolling shutter working process

Indoor Visible Light Communication LED Layouts

In recent years, with the further in-depth study of visible light communication systems, combined with OFDM technology and the development of a number of new schemes, the development of white LED indoor visible light communication has been strongly promoted [38].

Indoor Visible Light System Modeling

An indoor LED visible light communication system uses an LED as a signal transmitter, without affecting the lighting premise by modulating the light intensity of the LED. It relies on high-speed flashing signals that cannot be recognized by the human eye to transmit information [2].

Most current studies on LED light layouts are for 5 m × 5 m × 3 m indoor spaces. This typical indoor visible light system model is shown in Fig. 34.8 to establish an indoor coordinate system, with the LED lights fixed on the ceiling and the receiving end placed on a 0.85-m-high table [90].

Radiant power and luminous intensity are two important parameters of LED light source characteristics. When the LED light source radiation satisfies the Lambert radiation intensity model, its radiation intensity function is [94]

$$R(\varphi) = \frac{m+1}{2\pi} P_S \cos^m \varphi, \varphi \in (-\pi/2, \pi/2), \tag{34.1}$$

where $R(\phi)$ is the radiation intensity when the radiation angle is ϕ, m is the number of radiation modes, and P_S is the LED radiation power. The luminous intensity of the LED light source is

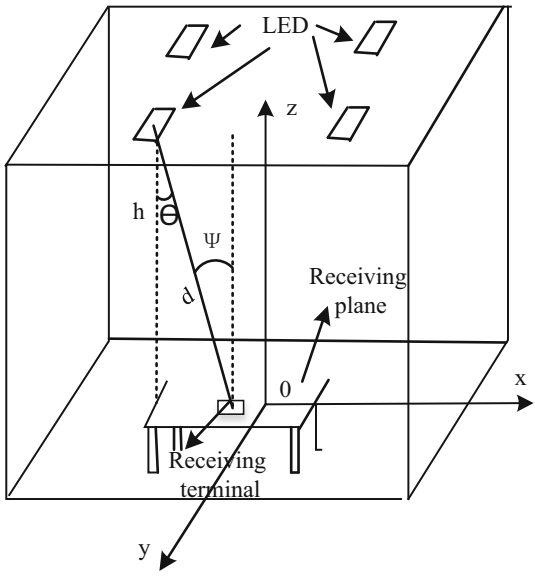

Fig. 34.8 Indoor visible light system model [94]

$$I(\varphi) = \frac{m+1}{2\pi}\varphi_s \cos^m\varphi = I(0)\cos^m\varphi, \tag{34.2}$$

where φ_s is the luminous flux and $I(0)$ is the center light intensity of the LED. The light intensity at a point on the receiving surface is

$$E_{\text{hor}} = I(0)\cos^m\varphi\cos\psi/D^2, \tag{34.3}$$

where ψ is the angle of incidence of the receiving surface and D is the distance between the LED and the receiver.

The light intensity from indoor LEDs to the tabletop is divided into two components: the LOS of the LEDs directed to the receiving end and the NLOS, which contains one or more reflections occurring from the walls or the floor, and then reaches the receiving plane, as shown in Fig. 34.9 [95]. In the non-direct line-of-sight link, the received power distribution is better than in the line-of-sight link; however, the reflections from the walls degrade the SNR [96].

Light Source Layout Design

In a typical indoor LED array layout, the received power distribution does not cover the entire receiving surface; thus, a received power interruption zone can occur, preventing the best performance of the VLC system. To overcome the shadow effect caused by light blindness, a reasonable arrangement of light sources is required.

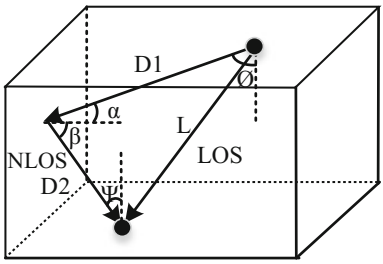

Fig. 34.9 Diagram of LOS and NLOS [95]

Table 34.5 LED light source layout solutions

Year	Layout method	Reference
2007	Four-LED rectangular layout	[97]
2012	Circular angle compensation-type layout	[98]
2012	Single LED in the center + four LEDs in the corners	[99]
2015	16-LED grid layout	[100]
2016	Elliptical layout	[101]
2017	Circular layout	[94]
2017	"4 + 1" rectangular layout program	[102]
2018	Double-nut line layout	[103]
2018	LED array + surrounding ring strip light source layout	[104]
2021	Ring angle compensation-type layout	[105]

However, different LED layout methods can cause uneven illumination and received power [94]. Table 34.5 summarizes several LED layout schemes.

Visible Light Positioning

In recent years, VLC-based positioning technology, i.e., visible light positioning (VLP), has attracted considerable attention, owing to its ability to provide high-precision positioning, based on the existing lighting infrastructure.

Visible Light Positioning Technology

Currently, common localization techniques can be grouped into four main categories: geometric measurement localization (also known as triangulation localization), scene analysis localization (also known as fingerprinting localization), proximity sensing localization, and image sensor localization [106].

In addition, reference [107] proposes a method based on relative illuminance measurements to locate the position of the center of gravity in a circular overlapping area. The illuminance ratio is used to measure the distance between the detector and the projection point of the light source, and the ranging circle equation is constructed

with the projection point as the center of the circle. The center of gravity position of the overlapping region of the triple-ranging circle is derived as an estimation of the detector's position, to achieve accurate localization [107].

The performance of the above visible light positioning methods is compared as shown in Table 34.6, and the most suitable technical solution is selected according to the required accuracy, complexity, synchronization, and other experimental requirements. VLC positioning technologies mentioned in Table 34.6 include angle of arrival (AOA), time of arrival (TOA), time of arrival (TDOA), and received signal strength (RSS).

Positioning Enablement Program

Currently, VLC positioning methods can be divided into two categories based on the type of receiver: photodetector (PD)-based and image sensor (IS)-based. This is because a positioning system with a PD as the receiver will produce large errors, owing to angle measurements, received signal strength measurements, light intensity changes, etc. The image-based method can obtain a more stable and anti-jamming signal, owing to the spatial separation characteristics of the lens in the IS [108]. Moreover, the positioning dimension can be two-dimensional or three-dimensional. The results of the work on visible light positioning in recent years are shown in Table 34.7.

Visible Light Networking

To meet the future needs of multi-user communication and to give full play to the advantages of high-capacity visible light communication, the study of networking technology is timely. Visible light networking is a practical application of visible light communication, and its networking method is one of the main problems it faces.

Networking Overview

Fundamental Principle

Indoor VLC-based networking is mainly divided into homogeneous and heterogeneous networks. Heterogeneous network convergence techniques can ensure that users make full use of network resources and maximize their utility. Therefore, the research on heterogeneous networks is more in-depth [117].

The topology of the networking system is a direct reflection of the connections between the network devices and is also the basis of the system design. Three topologies are proposed in IEEE 802.16.7 for visible optical communication networks, including [118] the peer-to-peer topology, star topology, and broadcast topology, as shown in Fig. 34.10.

Table 34.6 Comparison of visible light positioning techniques [107]

VLC positioning method		Precision	Complexity	Speed	Power consumption	Synchronization	Portability
Triangulation	AOA	Higher	Higher	Slow	High	Yes	Good
	TOA	Higher	Lower	Slow	High	Yes	Good
	TDOA	High	Low	Slow	Low	No	Good
	RSS	Low	High	Slow	High	No	Good
Scenario analysis		Lower	High	Fast	Low	No	Poor
Approximate perception		Depends on network density	Higher	Faster	Low	No	Poor
Illuminance ranging circular overlap area center of gravity positioning method		Higher	Lower	Fast	Low	No	Good

Table 34.7 Visible light positioning technology results

Average positioning accuracy (cm)	Average positioning time (ms)	Number of LEDs	Dimension	Receiver type	Positioning range (L × W × H)m^3	Reference
14.0	/	7	2D	PD	1.5 × 1.5 × 2.5	[109]
0.86	162	4	2D	IS (CMOS)	1.9 × 1.9 × 1.9	[110]
17.52	/	1	3D	IS (CMOS)	3.0 × 3.0 × 2.0	[111]
12.79	/	1	3D	IS (CMOS)	3.0 × 3.0 × 1.5	[111]
2.26	6.3/60	1	2D	IS (CMOS)	1.8 × 1.8 × 3.0	[112]
1	80	2	3D	IS (CMOS)	1.0 × 1.0 × 1.5	[113]
2.5	42	1	3D	IS (CMOS)	8.4 × 4.9 × 2.2	[114]
5.61	64,13	2	3D	IS (CMOS)	1.0 × 1.0 × 3.0	[115]
1.17	/	4	3D	PD	4.0 × 4.0 × 3.0	[116]

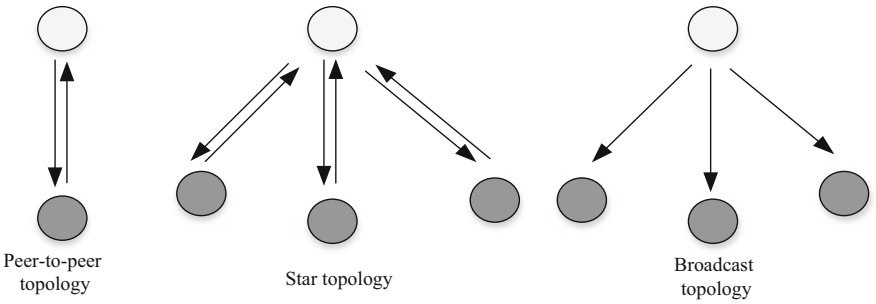

Fig. 34.10 Network topologies [118]

In the peer-to-peer topology, each device can communicate with any other device in its coverage area. A star topology consists of a master node, as well as a number of slave nodes that must pass through the master node in order to communicate. All star networks operate independently of all other star networks currently in operation. Broadcast topology communication is unidirectional: Devices in broadcast mode can transmit signals to other devices without forming a network; therefore, a broadcast network topology does not enable networking.

The star topology places higher functional requirements only on the access point (AP). To ensure low complexity under the premise, as long as rational networking protocol designs are followed, they will be suitable for a wide range of commercially available visible light networking systems.

Multiple Access Technology

Within a visible light communication networking system, multiple access technology enables signals from different users to access the local area network

according to certain rules without interfering with each other. Normally, the AP can only provide service to one terminal at a given moment. Therefore, the network needs to define the MAC layer corresponding to the access protocol to allocate the terminal to use the channel. Table 34.8 shows commonly used visible

Table 34.8 Summary of common multi-access technologies [119]

Category	Name	Principle	Advantages	Disadvantages
Non-contested multiple access	Time-division multiple access	Different terminals send and receive messages in different time slots	High average power efficiency and low realization difficulty	Requires device synchronization; high overhead
	Frequency-division multiple access	Different terminals send and receive messages in different frequency bands	Simultaneous transmission of multiple signals	The more frequency bands are divided, the slower the transmission rate on a single channel
	Code-division multiple access	Different terminal signals are distinguished using orthogonal code-word sequences	High resistance to fading and interference for bandwidth communications	With many users, the code will be too long
	Non-orthogonal multiple access	Different transmit powers are allocated to different terminals	Multi-channel signal transmissions at the same time and same frequency; large transmission rate	Higher complexity
Competition-based multiple access	Carrier listening multiple access	The terminal sends and receives data independently, listens to the channel status through the carrier, and sends data when the channel is idle	Simple to implement, as each site has the same priority and does not require centralized control	When the network load increases, more idle nodes listen to the channel at the same time, causing conflicts and leading to a reduction in network transmission efficiency
	Handshakes	Establishes communication links through request-and-response mode	Timeout retransmission is available; resources are reserved to solve the problem of high conflicts	Control command message exchange takes considerable time and overhead

light communication multiple access schemes and their advantages and disadvantages [119].

Heterogeneous Networking

VLC–Wi-Fi Networking

VLC has a small coverage area and high data rates, while Wi-Fi has the opposite characteristics. In a VLC–Wi-Fi heterogeneous network, the communication areas coexist. Compared with the traditional Wi-Fi-only and VLC-only systems, a VLC–Wi-Fi heterogeneous network provides seamless and reliable coverage and enables high-speed and flexible wireless access [120].

Figure 34.11 shows the four existing VLC–Wi-Fi heterogeneous networking schemes, where MT is a mobile terminal. The link transmitted with VLC has a high-speed transmission rate; when the visible link is interrupted, it can be switched to the same uplink or downlink Wi-Fi link to continue the transmission [121].

In indoor environments, the heterogeneous VLC–Wi-Fi network has the following characteristics:

The demand for downlink data is much greater than the demand for uplink data
The uplink optical link will become visually interfered
The line-of-sight transmission of VLC is susceptible to occlusion interference

Compared with the other three schemes, the scheme shown in Fig. 34.11d is more suitable for an indoor VLC–Wi-Fi heterogeneous network. A downlink with Wi-Fi as a complement to VLC not only provides a high-speed downlink transmission rate but also provides a seamless communication experience. An uplink with Wi-Fi data transmission solves the problems of line-of-sight transmission, as well as the visual interference in VLC uplinks [122].

VLC–PLC Networking

Power line communication (PLC) uses medium- and low-voltage power lines as a communication medium for information transmission. The advantage of PLC is that it can be used anywhere in the home, without the need for additional network wiring. By combining the two technologies, VLC and PLC, a new broadband access system can be effectively used in home networks to promote the development of indoor visible light communication [123]. Combining the two technologies using the newly defined unified MAC layer policy is more difficult. Therefore, different media can be used to maintain independent MACs, exchange information above the MAC layer, and apply unified control and management [124].

A typical fixed-point VLC combination scheme is to place the VLC dedicated transmission device under the VLC light source so that the VLC transmits at a fixed point, as shown in Fig. 34.12a. VLC uplinks and downlinks are used to communicate between the VLC light source and transceiver. The VLC light source is connected to

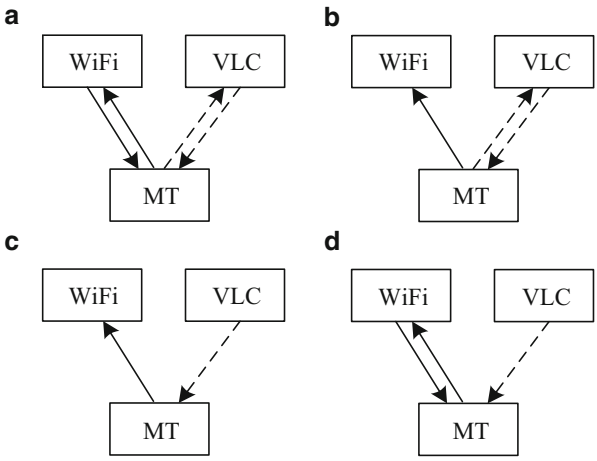

Fig. 34.11 VLC–Wi-Fi heterogeneous network transmission solutions [122]. (**a**) VLC uplink and downlink, Wi-Fi uplink and downlink. (**b**) VLC uplink and downlink, Wi-Fi uplink. (**c**) VLC downlink, Wi-Fi uplink. (**d**) VLC downlink, Wi-Fi uplink and downlink

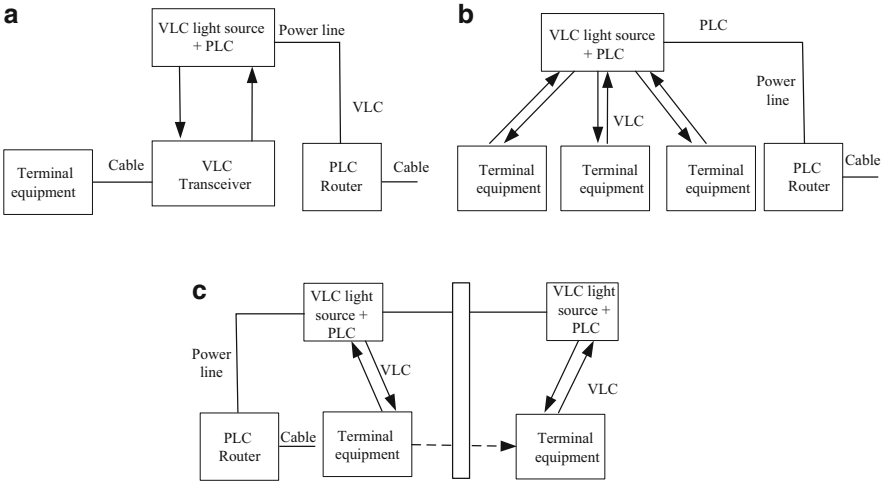

Fig. 34.12 PLC–VLC combination solutions [125]. (**a**) VLC fixed-point transmission. (**b**) Multi-terminal VLC fixed-point transmission (**c**) Multiple VLC light source transceivers

the external network port device by the PLC device, the VLC light source and PLC device are connected by the PLC power line, and both of them use PLC communication [125].

Each Internet access device in the multiple VLC device terminal scheme has a VLC transceiver. The light source is connected to the external network by a power line, and they communicate with each other by PLC, as shown in Fig. 34.12b. The scheme can also be extended to rooms with multiple light sources, where the light sources are networked directly through power lines. The communication

automatically excludes weaker light signals at a distance and communicates using VLC with the nearest light source [125].

The multiple VLC light source transceiver scheme mainly solves the problem of moving a single device from one room to another to ensure uninterrupted communication, as shown in Fig. 34.12c. Because the light source PLC is networked, the new VLC light source remembers the VLC device that is already online through the PLC, so there is no need to re-register the device after it reconnects [125].

Reference [126] provides a thorough review of several technical aspects related to PLC–VLC networking, societal applications, and the most important challenges when designing high-speed integrated PLC–VLC systems [126].

Other Heterogeneous Networking Examples

Intermixing VLC and Ethernet technology uses an optical communication medium conversion module as the core to convert signals between different media of wired network interfaces and wireless free space [127]. Clients can use white light communication to smoothly connect with Ethernet and use custom communication protocols to communicate information between servers and multiple clients and between each client on the integrated network [127].

The fusion of visible light communication and Ethernet is conducive to the construction of a converged communication network of radio, wired optical, optical wireless, and other communication modes; thus, it effectively expands the usability of the network and provides a broad application prospect for indoor short-range communication.

5G networks have always regarded network convergence as an important attribute and have been continuously enhanced and developed. Therefore, the convergence of VLC/5G networks is also an intrinsic need [128]. Reference [129] built an experimental convergence setup, which ultimately led to the successful implementation of an RGB-based VLC system using the new 5G radio standard [129].

Application Scenarios

Visible light communication has a panorama of application development in multiple fields, multiple scenes, and multiple industries. At the present stage, LED visible light communication is mainly used in indoor local area networks (LANs), intelligent traffic systems, and other fields and will develop applications in more directions in the future.

Smart Home

A smart home network is constructed by establishing a smart home integrated software and hardware system based on a visible light communication wireless

LAN. The main research and development focus is on portable visible light communication interface modules, which can be directly embedded in all types of electrical appliances and network access devices, to achieve low-cost, high-rate LAN networking technology that can match the intelligence of commonly used home appliances [130].

Health Care

VLC applications in health care include operating room lighting systems that support real-time data transmission and synchronize all monitoring devices. In the imaging department, ultrasound can be used for real-time calculations for pathology diagnoses using the VLC system. Visible light transmits data using columns of light with a very small angle of dispersion, so it can provide high-speed, high-capacity data passbands to accomplish high-definition and picture-synchronized remote transmission of dynamic medical imaging. Clinics, inpatient hospitals, and waiting areas can be decorated with Internet lights to provide high-speed Internet to attendants. This can also enable doctors to update their medical databases while away from the office [131].

Intelligent Transportation

Visible light communication technology combined with high-speed data image sensor (e.g., high-resolution, high-speed camera) technology enables the system to receive and send timely information about traffic operating conditions. This, in turn, allows traffic personnel to obtain real-time traffic light identification and road condition information, to make appropriate driving adjustments and improve traffic quality and efficiency [132].

Aviation Applications

Because RF communication produces severe electromagnetic interference, it cannot be used in aircraft. Because of the inherent characteristics of LEDs, such as security and the ability to facilitate seamless data transfers, an integrated PLC–VLC system is more suitable than Wi-Fi technology for deployment in aircraft to provide in-flight entertainment, other emergency services, etc [133]

Ship Communication

VLC provides a new type of wireless communication transmission inside a ship by modifying the lighting circuits, solving the problem of serious wireless signal blockage between cabins. By further connecting sensors, VLC can be used to

sound alarms and locate fires by using the signal attenuation caused by flames and smoke obstruction. Using the lighting equipment, the ship's personnel and key equipment can be equipped with optical receivers to localize the auxiliary management and control [134].

Intelligent Industrial Lighting

An intelligent lighting control system using visible light communication technology can not only function as an intelligent lighting management system but also be part of a fast LAN communication network and be combined with the Internet for remote control and access to large amounts of data. The use of an intelligent lighting control system combined with virtual reality technology can provide position information about items in an intelligent warehouse and analyze the detection results in an automated assembly line. Thus, it can lead to the future revolution of visual work interfaces in industrial production to meet the demand for informationization and humanized construction of smart factories [135].

Museum Environment Monitoring

An intelligent museum environmental monitoring system constructed using VLC technology transmits environmental monitoring data through LEDs. It provides the dual functions of lighting and communication, thus effectively reducing the duplication of museum-related monitoring systems and lowering operational costs. It enables the stable monitoring of museum environmental factors, while minimizing damage to museum artifacts [136].

Library Navigation

Indoor navigation in libraries can be realized using the latest visible light communication technology. Through the six steps of inputting the target resources on the mobile phone, getting the flashing information from the camera, decoding the information, obtaining the position of the LED light, locating the starting point and direction of the navigation, and finding the destination information on the path, the library indoor navigation is realized. This provides readers with a fast and efficient method of acquiring books, thus significantly improving the efficiency of book finding and service quality [137].

Underwater Applications

In underwater environments, radio-frequency (RF) transmission rates suffer severe attenuation, which makes RF unable to meet the needs of communication. Owing to

the long delay time of sound waves, the RF bandwidth is limited, and it adversely affects the life of marine organisms. In contrast, underwater visible light communication can overcome attenuation and electromagnetic interference. Research on underwater visible light communication systems has achieved preliminary results [132].

Emergency Applications

In some emergency applications, including defense, power plants, and military, it is vital to maintain great security to protect data from intruders. In addition, the effects of electromagnetic interference (EMI) must be overcome. Therefore, the deployment of integrated PLC–VLC systems has proven to be the best way to ensure secure, as well as EMI-free, communication [133].

Development Trends

To further expand the future application areas of visible light communication, improve its communication performance, and breakthrough application bottlenecks, researchers should continue to explore new technologies and methods. Future research work should focus on the following:

Research and development of new LED devices, to overcome the shortcomings of the light source itself, solve the bandwidth limitation problem, and improve the luminous efficiency. In addition, the cost, control complexity, and other issues should be considered to promote the use of large-scale VLC [138, 139].

Currently, widely used infrared photodetectors are not suitable for VLC; therefore, new high-quality photodetectors suitable for VLC need to be developed in a targeted manner to increase the transmission distance of VLC communications [132].

Transferring data from an illuminated LED light source to a device (i.e., downlinks) is very straightforward. However, transmitting data from devices (mobile terminals) to LEDs (i.e., uplinks) is quite a challenging task. To truly realize visible light dual-full-time communication, uplink implementation techniques must be further explored [132, 133].

The VLC data transmission rate is the biggest challenge for visible LEDs. The high bandwidth utilization and superior anti-interference performance of multiplexing modulation techniques should be explored in depth, while methods, such as efficient filtering techniques and novel filters, should be explored to improve the communication rate [80, 140].

In the analysis and design of VLC systems, external factors that block the channel must be fully considered; thus, it is crucial to establish a visible channel model with practical information. The model can be refined by aiding in the selection of the optimal LED light source layout and luminosity, which reduces the blind zones and minimizes intersymbol interference [132, 141].

Current research on visible light heterogeneous networking is still in its infancy. In the future, it will be necessary to explore the coexistence and compatibility of visible light with terahertz, millimeter wave, microwave wireless communication, and other communication modes [139].

Machine learning algorithms can be applied as advanced signal processing algorithms to VLC to accommodate the complex data processing needs of future systems. Although machine learning-based systems have made some progress, they are still lacking in intelligence. Therefore, more novel machine learning algorithms should be explored in the future to achieve synergy and work together to promote the intelligence of visible light systems [139].

Summary and Outlook

This chapter summarized the current status of research at home and abroad and gave a brief overview of some key technologies involved in the visible light communication system model. For the indoor application of visible light communication, several light source layouts and heterogeneous networking schemes were summarized as follows:

The light-emitting mechanism of LED devices and the basic principles of visible light communication were briefly explained.

Domestic and international research on visible light communication was summarized, and the communication rates involved in the written progress are summarized in a table.

Key visible light technologies were discussed, including link technology classification, existing uplink implementation schemes, inverse modulation techniques, equalization techniques, common information modulation techniques, limitations of light source bandwidth and the extension of its materials, and optical imaging communication schemes.

Based on an indoor visible light system model, a variety of LED layouts and visible light localization schemes were demonstrated.

Indoor visible light heterogeneous networking technologies were further introduced, including four VLC-Wi-Fi heterogeneous networking schemes and three PLC-VLC combination schemes.

The application scope of visible light communication technology covers many fields. Through continuous development, it has achieved very impressive research results, at both theoretical and application levels. It can be foreseen that, after solving the problems of LED devices and dual full-time communication, VLC communication will usher in a period of high-speed development in the future. It will form a complete visible light communication network, accelerate the rapid development of the standardization and industrialization of visible light communication, and optimize and upgrade traditional industries.

Introduction

Visible-light communication is a rapidly developing optical wireless communication technology that not only provides room lighting but also provides users with high-speed data-transmission services. Visible-light communication technology has the potential to design stable communication-network structures in terms of indoor communication systems. The heterogeneous integration of visible-light communication and existing networks enables wireless-access technologies to complement each other, thereby enhancing the network-system capacity and improving resource utilization.

This chapter introduces visible-light communication networks, power-line communication networks, wireless network communication, Ethernet, long-term evolution (LTE) networks, and radio-over-fiber system integration networks. Finally, the development of visible-light communication and heterogeneous fusion networks is discussed.

In recent years, visible-light communication (VLC) has attracted widespread attention as a new type of wireless communication technology. It directly loads the signal onto a light and uses the rapid response characteristics of light-emitting diodes (LEDs) to achieve high-speed signal transmissions while lighting a room [1].

VLC technology has the unique advantages of no spectrum authentication, strong resistance to electromagnetic interference, wide transmission bandwidth, environmental protection, and energy saving. In the future, it will be used for indoor navigation and positioning, provide high-speed information services, and provide wireless-access networks in electromagnetic-sensitive environments, such as hospitals, waiting rooms, and cabins [2]. However, currently, VLC wireless communication networks have the disadvantages of small coverage, immature uplink-transmission link technology, can easily be obscured, limited LED modulation bandwidth, and poor diffraction ability [3].

Therefore, researchers have begun to combine VLC with other wireless-communication technologies to build network systems with large capacities, high-speed information transmission, small access delay, high reliability, strong network security, and flexible structures [4]. Considering the characteristics of various wireless-access technologies, a diversified heterogeneous integrated network architecture can be built to complement all types of wireless-network access technologies. Therefore, research on heterogeneous converged network systems will be an important trend promoting the development of heterogeneous visible-light communication networks in the future.

Domestic and Foreign Research Progress

In 1999, Pang [5] of the University of Hong Kong proposed the concept of visible-light communication technology in the study of LED traffic-lighting systems. He noted that voice-broadcast and traffic-lighting monitoring could be achieved through

light-emitting diodes (LEDs). The entire system data-transmission distance reached 20 m.

In 2000, Tanaka et al. [6] combined optical communication with an LED home link, calculated the received power for the receiver, studied the influence of the size of the field of view on the performance, applied the system to a private network, and created a communication model with an indoor transmission rate of 10 Mbit/s.

In 2002, Zhongchuan Laboratory [7] intensely researched the performance, layout, and channel mode of the lighting source in a VLC system, and analyzed the influence of the signal-to-noise ratio distribution and intersymbol interference in detail, which laid an important foundation for VLC theoretical analysis.

In 2003, Komine and Nakagawa [8] from Keio University proposed a system fusing power-line communication (PLC) and VLC. They provided a specific scheme for two types of network integration, and analyzed their characteristics through simulation. Then, the channel model and noise of the PLC–VLC fusion system were analyzed.

In 2004, Komine et al. [9] studied the influence of shadow and wall multipath reflections on the system in a visible-light channel transmission. They selected a time-division multiple-access modulation method to obtain a data-transmission rate of 800 Mbit/s and effectively reduced the influence of shadows on the system.

In 2005, Komine et al. [10] analyzed a VLC channel from the perspective of line-of-sight (LOS) and non-line-of-sight (NLOS) models and reflection. The performance of the VLC system under on–off keying (OOK), two pulse-position modulation (2-PPM), 4-PPM, and 8-PPM was further studied.

In 2006, Ding et al. [11] of Xi'an University of Technology elaborated on the structure and key technologies of an indoor VLC model, discussed the key issues of light-source layout, receiver-field angle, and intersymbol interference in VLC systems, and provided the corresponding solutions.

In 2007, Ding et al. [12] studied the location deployment of an indoor VLC lighting source, conducted a detailed theoretical analysis of the receiving and light-source power at the receiving end, and simulated the optimal LED-layout scheme. Based on the above scheme, a design scheme for an indoor wireless-communication system using VLC technology was presented, and the key components were analyzed [13].

In 2008, Yun et al. [14] studied VLC modulation and demodulation methods to weaken the influence of intersymbol interference at high data-transmission speeds and proposed a modulation and demodulation scheme based on orthogonal frequency-division multiplexing (OFDM). The simulation showed that the scheme could be used for indoor lighting and high-speed data transmissions.

In 2008, the European Union established the Home Gigabit Access Network (OMEGA) project, and one of its important research areas was VLC technology [15]. Grubor [16] proposed placing a blue filter in front of a white LED, which expanded the modulation bandwidth of high-power white LEDs from 2 MHz to 20 MHz, effectively improving the transmission rate.

In 2008, Chen [17] designed an indoor VLC system-using array LEDs, diversity-reception technology, and intensity-modulation/direct-detection (IM/DD) methods.

The simulation showed that diversity-reception technology was conducive to improving the signal-to-noise ratio of the system. It effectively reduced the impact of indoor-object occlusion and personnel and receiver movement on the communication link.

In 2009, Song et al. [18] used the Monte Carlo ray-tracing algorithm to calculate the impulse response of an indoor visible-light channel. An adaptive OFDM visible-light communication system was proposed. The simulation results showed that the scheme significantly improved the utilization of the frequency-band resources and the overall performance of the system.

In 2009, Komine et al. proposed an adaptive-equalization filter to overcome the intersymbol interference (ISI) caused by multiple lighting sources in indoor VLC. Moreover, an adaptive-equalization filter designed using the least mean squares (LMS) algorithm was used to equalize the indoor VLC multipath channel, and the channel-estimation algorithm was further studied in a mobile environment. The results showed that the adaptive-equalization system more effectively reduced the influence of illumination shadows on the communication network in a mobile environment.

In 2010, Ding et al. [19] first proposed a new mathematical theoretical basic-research model of the LED luminescence mechanism and estimated the model parameters using the Gauss–Newton iterative nonlinear regression algorithm. The results showed that this model could be widely used.

In 2011, Ding et al. [20] designed a new multi-white LED-array transmitting antenna, based on a mathematical model of white LED luminescence, and successfully applied it to an indoor VLC system. They also analyzed the important effects of the number of arrays and their layout, the size of the array optical axis pole angle and the size of the optical array layer spacing in the multi-array light emitting device on the indoor optical power distribution scheme, and accordingly proposed the optimal scheme and guidelines for the configuration of relevant design parameters. Further, the scheme of controlling the optical power at the transmitter is investigated and the new multi-array antenna design with flat-topped optical power distribution is completed.

In 2011, Little et al. [21] of Boston University used WiFi as the uplink for a VLC system. In this scheme, the downlink transmission rate was 10 Mbit/s, and the uplink transmission rate was 30 Mbit/s.

In 2012, Kong et al. [22] proposed placing a number of optical cones in different directions of a hemisphere as an optical receiving antenna, using the angle-diversity receiving method to solve the intersymbol interference on the receiving antenna of a VLC system. A specific layout was designed and implemented, and the total light-intensity receiving problem in the entire hemisphere system was discussed.

In 2013, Chi et al. [23] proposed an indoor two-way communication system using the quadrature amplitude modulation–orthogonal frequency-division multiplexing (QAM-OFDM) modulation method based on red, green, and blue (RGB) LED technology. It combined pre-equalization technology with post-equalization technology. An uplink-transmission rate of 300 Mbit/s and a downlink-transmission rate of 1.15 Gbit/s were realized in the communication process.

In 2014, Zheng et al. [24] analyzed a VLC system with radio frequency (RF), visible light, and 780–950-nm-wavelength infrared light as the uplink communication link and provided a design scheme with a 1550-nm wavelength laser as the uplink communication link. In an indoor environment, a wavelength-division duplex all-optical communication link was formed with a visible-light downlink. Its uplink-transmission rate reached 1 Gbit/s.

In 2014, Tsonev et al. [25] realized a high-performance VLC system with a data-transmission rate of up to 3 Gbit/s on a single LED. They used a 60-MHz modulation-bandwidth gallium arsenide LED and OFDM modulation technology to link the pre-equalization and adaptive data loading.

In 2015, Kang et al. [26] studied 16-PPM multidimensional coding technology and built an RGB LED visible-light audio and video transmission system. The transmission rate on the 3-m communication link reached 1.5 Mbit/s; this multi-dimensional coding technology also effectively enhanced the spectrum utilization of the system and laid a theoretical foundation for high-speed VLC transmissions.

In 2015, Mossaad [27] designed a scheme to solve the problem of a high peak-to-average ratio in the OFDM modulation mode in VLC; that is, the transmitter divided the high peak-to-average ratio signal into several low peak-to-average ratio signals, and then transmitted them by LED. This reduced the influence of the nonlinearity of the LED lighting source on the high peak-to-average ratio signal.

In 2015, Song et al. [28] proposed a single-frequency network (SFN) system design for video broadcasting based on a PLC and VLC deep fusion. OFDM, pre-equalization, and system-equalization techniques were used in the PLC–VLC system. The following year, they studied the channel problem of the PLC–VLC system [29] and analyzed the channel as a whole.

In 2016, Ke et al. [30] comprehensively reviewed visible-light LED communication technology, the basic principle of LED device luminescence, optimal LED location in an indoor VLC system, the array design of the receiving end, and the three link-configuration methods of the VLC system transceiver. Moreover, the bottleneck in VLC technology research was noted.

In 2017, Zhang et al. [31] studied the application effect of user-detection technology in a multi-access VLC system to address the problem of multiple-access interference. They analyzed and understood the effect of correlation detection and blind multi-user detection on the bit-error rate, and summarized a variety of scenarios suitable for VLC applications.

In 2017, Basnayaka [32] designed an indoor VLC system by combining radio frequency and VLC technology to solve the problem of uneven signal coverage caused by uneven illumination in indoor VLC systems. The simulation results showed that the indoor VLC system could greatly reduce the coverage of blind area.

In 2017, Wang et al. [33] proposed an energy-optimal LED arrangement for indoor VLC systems. The particle-swarm optimization algorithm was used to simulate and analyze the distribution of the received power, energy loss, signal-interruption rate, and signal-to-noise ratio under various LED layouts. The simulation verified that the circular-layout scheme required fewer LED lights, optimized

the signal-to-noise ratio distribution, effectively reduced the intersymbol interference of the system, and reduced the overall energy loss of the system.

In 2018, Ke et al. [34] constructed a bidirectional VLC system with a single LED light source using reverse-modulation technology, and proposed a new scheme for constructing an uplink data-transmission link in a VLC system. The uplink and downlink data links of the control system adopted quaternary frequency-shift keying and differential quadrature phase-shift keying modulation, respectively. In the 3-m data-transmission link, the downlink transmission rate was 5 Mbit/s, and the uplink transmission rate was 2 kbit/s. This was the first report on an uplink in this field.

In 2019, Liu et al. [35] clearly proposed technology integrating VLC and Ethernet, and developed a signal-conversion module between wired and wireless media. This integration method achieved full information coverage by the network system. It had high application value in the artificial-intelligence field and other areas.

In 2020, Xue et al. [36] proposed a high spectral-efficiency dimming control scheme by combining OFDM technology and pulse-code modulation (PCM) technology. This scheme not only supported high-speed VLC but also met the requirements of user illumination-source brightness control.

In 2021, Wang et al. [37] applied four-level pulse-amplitude modulation (PAM-4) to a VLC system. An RGB LED was used at the transmitter, and an equalizer was added before the receiver. When the linear equalizer was used at the receiver, the system rate reached 75 Mbit/s.

In 2021, Zhang [38] investigated VLC networking, coding and decoding. He took the lead in building a real-time VLC-based networking-demonstration system platform.

To realize high-speed and safe VLC based on LEDs, the research topics of domestic and foreign scholars include modulation technology, LED light sources, light-source optimization layouts, and other communication systems. To overcome the influence of indoor multipaths, the system bandwidth should be expanded and the transmission rate increased.

Indoor Visible-Light Communication Systems

Visible-light communication (VLC) systems typically include three parts: visible-light transmitters, visible-light transmission systems, and visible-light receivers [39], as shown in Fig. 35.1. The visible-light emitter is mainly composed of a visible-light modulation-coding module and an emission module. The transmitter first encodes, modulates, and pre-equalizes the original data, and then adds an electrical signal to the LED drive current to make the LED glow. At the receiving end, a photodetector (PD) converts the received visible-light signal into an electrical signal, and then the initial signal is restored using demodulation [40].

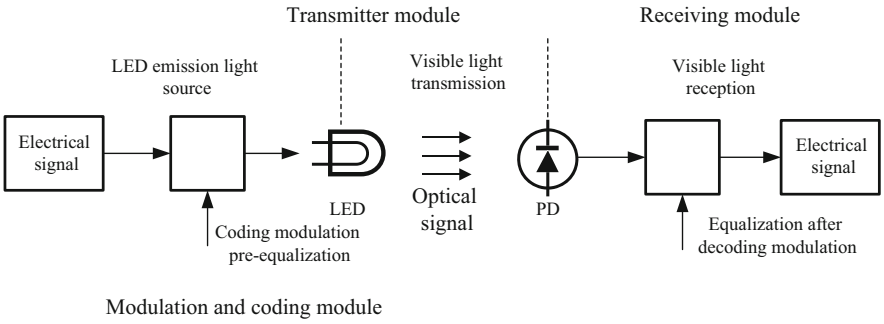

Fig. 35.1 Visible-light communication-system block diagram [40]

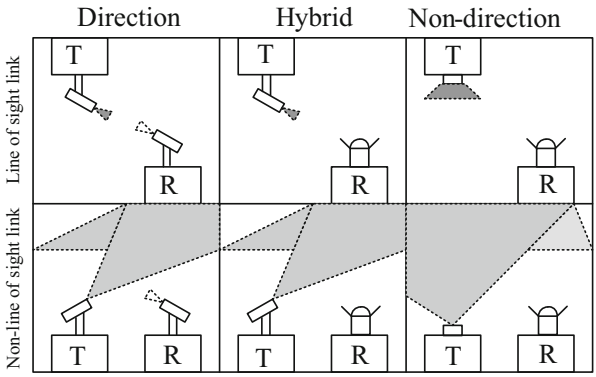

Fig. 35.2 Optical communication-link division standard [42]

Link Modes and Channel Models

Link Modes

In indoor wireless-communication systems, link modes are divided based on two standards [41]. First, the transmission and reception are directional; second, there is no line-of-sight (LOS) transmission. According to the first standard, the transmitting angle of the transmitting end and the receiving-field angle of the receiving end are both very small, and the system link is a directional link. If the sender and receiver do not meet the directional conditions, the system link is a non-directional link; when only the sender or the receiver satisfies the directional condition, it is called a hybrid link [42].

Under the second standard, if the receiver receives both the direct-looking optical signal transmitted directly in the direct-looking space and the reflected optical signal through the indoor emitter, the link is a line-of-sight (LOS) link. If the receiver contains only the reflected-light signal emitted by the indoor emitter, the link is a non-line-of-sight (non-LOS) link [42].

There are six possible link scenarios, as shown in Fig. 35.2.

VLC typically uses the direct-link mode. Following are three variations of the direct link [42].

1. Directional line-of-sight links require the transmitter and receiver to be aligned [42]. Because the optical power consumed by light scattering at the transmitting end is very small, and the angle of view at the receiving end is only focused toward the transmitting direction, the optical receiving power at the receiving end will be large, and the multipath interference will be small under this condition. This method requires a strict alignment between the transmitter and receiver. When the receiving angle is offset or the link is obscured by other obstacles, the communication quality deteriorates significantly. This method is more suitable for static point-to-point communications.
2. Two hybrid line-of-sight chains exist. First, the optical transmitter has a large emission angle and the optical receiver has a small receiving angle. Second, the optical transmitter has a small emission angle and the optical receiver has a large receiving angle. In the first case, an increase in the transmitting angle of the optical transmitter reduces the received power at the receiving end. It also increases the coverage area of the optical communication at the transmitting end to ensure that the user can still communicate with the lamp group when moving the device in a certain coverage area. Because the receiving field of view is very small, the multipath interference generated at the receiving end is significantly reduced. Thus, this scheme is more practical.

   In the second case, the information received by the transmitter is relatively concentrated, and the receiving angle of the receiver is very large. In this case, the receiver undergoes severe noise and intersymbol interference [42].
3. The nondirectional line-of-sight link increases both the transmitting and receiving angles. This method plays a beneficial role in user mobility, so that users can obtain the information sent by the light group over a large range. However, an increase in angle sometimes leads to the enhancement of multipath interference, which seriously affects the link-communication quality [42].

Channel Models

$x(t)$ represents the instantaneous optical signal generated by the LED and $y(t)$ represents the instantaneous current signal of the photodetector. The receiver determines whether data must be demodulated according to the instantaneous current value. Because the multipath signal generated between the transmitting and receiving antennas causes spectral and spatial selective fading, the spatial orientation of the transmitting and receiving antennas determines the amplitude range of the signal.

To obtain accurate results, it is necessary to model the transmission channels. The channel characteristics are represented by a baseband linear system between the input signal $x(t)$, output signal $y(t)$, and impulse response $h(t)$ [30]. The background light, detector, and circuit noise can be regarded as additive white Gaussian noise, $n(t)$, as shown in Fig. 35.3. The channel model is

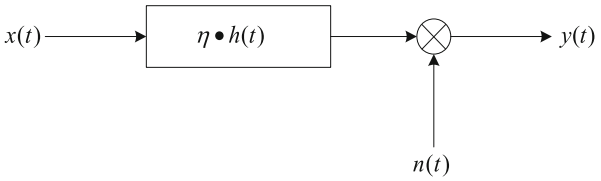

Fig. 35.3 Indoor VLC channel model [30]

$$y(t) = \eta \frac{x(t)}{d^2} \otimes h(t) + n(t), \tag{35.1}$$

where $\otimes$ represents the convolution, η is the conversion efficiency of the photodiode, and d is the distance between the transmitter and receiver. To not lose generality, $1/d^2$ factors are merged into $h(t)$, yielding

$$y(t) = \eta x(t) \otimes h(t) + n(t). \tag{35.2}$$

At present, two main research methods are used for indoor optical wireless channels: the analytical method and the ray-tracing method. Gfeller [43] proposed dividing an indoor surface into several small areas, each of which has Lambert reflection characteristics, and the optical power received by the receiver is the sum of the reflected surfaces. Based on Lambert radiation, Barry [44] proposed a recursive method for solving the transfer function of an indoor channel. The running time of this method increases exponentially with the number of reflections.

The Monte Carlo ray-tracing method is an effective method for studying wireless channels. It studies the channel impulse response, path loss, and time-delay expansion by tracking the path of each ray until the ray reaches the receiving end or exceeds the maximum simulation time. Generally, the probability of a light being received by the detector is very small; therefore, to obtain a reliable simulation result, a large amount of light must be generated, generally between 10^8 and 10^{11} rays. Compared with the analytical method, the ray-tracing method is closer to the actual channel characteristics, and the results are more reliable. However, the reliability is at the expense of a large number of operations.

Rodríguez et al. [45, 46] improved the reflection-propagation model by dividing it into diffuse reflection and specular reflection, and proposed a multiple-reflection model based on the Phong model. An indoor optical wireless channel transmission was modeled using the ray-tracing method, and the error of the impulse response was analyzed.

To obtain better lighting effects, several white LEDs are generally required in a room. Because the LED layout mode is associated with the channel-transmission mode, studying the channel model and its relationship with the location of the lighting source is extremely useful. The LOS link plays a major role in the VLC network, and some necessary measures must be taken to reduce or completely remove the interference of the diffuse optical signal on the system bandwidth. Research on channel models provides an important basis for this.

Uplink Communication Links

In recent years, domestic and foreign research on indoor VLC has mostly focused on key technologies, such as channel modeling, light-source location deployment, modulation methods, coding-method design, and application-system integration development [47]. With the progress of the communication era, the requirements for high-speed and two-way communication in rooms are becoming increasingly urgent.

At present, the technologies for creating communication transmission uplinks mainly include radio frequency, infrared light, lasers, and visible light [48]. Most light-source structures are relatively complex, and damage to the human eye during the movement of the light source is also a problem to be considered.

To address the problems encountered in the design of communication uplinks, researchers have attempted to study reverse-modulation technology. However, current research on reverse-modulation optical communication-system technology is more biased toward basic theory and transmission-link simulations, and reverse-modulation technology is typically used in indoor VLC systems. However, actual cases are rare.

Cat's Eye Reverse Modulator (MRR) is a common reverse modulator that consists of a cat's-eye system and an electro-optic modulator. A modulator is placed at the focal plane of the cat's-eye reverse reflector, and the reflected light intensity is controlled by changing the defocus amount of the transmitting surface to achieve the reverse modulation [49].

In 2017, Ke et al. built an uplink in an indoor VLC system using a defocused cat's-eye MRR and successfully realized full-duplex communication with one-way light sources, simplifying the uplink light source and significantly reducing the complexity of the system implementation. The stability of the network-system transmission was verified experimentally. There was no interference between the uplink and downlink, and the data-return problem of indoor VLC network systems was effectively solved [50].

The link from the reverse end to the active end is the uplink. In [51], the author used the cat's-eye reverse modulation system as the core of the transmission link of the reverse communication system. Figure 35.4 shows the reverse communication-system structure diagram.

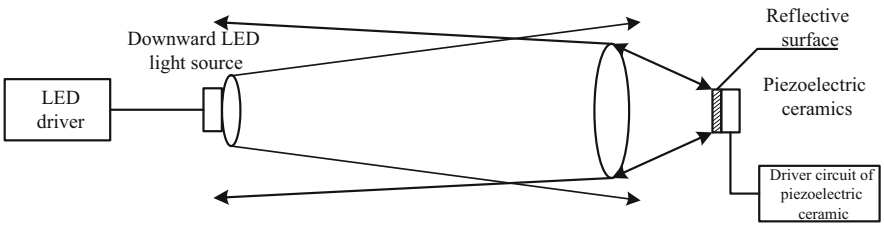

Fig. 35.4 Structure of the reverse communication system [51]

During the system operation, the active end sends the modulated beam directly to the reverse end. The beam-divergence angle of the LED light source is relatively large. The receiving focusing lens located at the reverse end should be discharged side by side with the cat's-eye MRR, and both must be within the effective illumination range of the LED.

The reverse end uses a reverse modulator to modulate the information on the downlink secondary, modulates the signal on the communication uplink to the communication downlink, and then reflects it to the active end. After the receiver at the active end receives the optical signal, the uplink-modulation information is automatically separated and demodulated to realize a duplex-communication link.

The main devices in the uplink hardware include the cat's-eye reverse modulator, drive circuit unit, and signal-receiving and processing circuit unit [52]. The active side must separate the uplink-modulation information from the background light and the information from the downlink high-frequency component. When the modulation rates and modes of the communication uplinks and downlinks are different, the frequencies generated by the two signals passing through the receiver are also different. A band-pass filter is used to separate the uplink signal from the received information, and then the uplink signal is demodulated to restore its uplink baseband-data information. Figure 35.5 shows the uplink-principle block diagram.

In [51], the authors detected the reverse-modulator characteristics using the carrier frequency of the most suitable frequency-shift keying (FSK) modulation method. Based on a preliminary experimental platform, a white LED lamp was used as the lighting source to load the sine-wave signal with different frequencies into the driving circuit of the piezoelectric ceramic sheet. The light intensity of the return signal of the active end was observed using a photoelectric detector when the piezoelectric ceramic sheet had different carrier frequencies. The experimental results are listed in Table 35.1.

From Table 35.1, it can be seen that the light intensity of the return signal is not the same, after a sine-wave signal of different frequencies is input. As the piezoelectric-ceramic plate resonates at a 3-kHz frequency, the piezoelectric-ceramic plate peaks at this frequency. The peak value decreases slowly as the

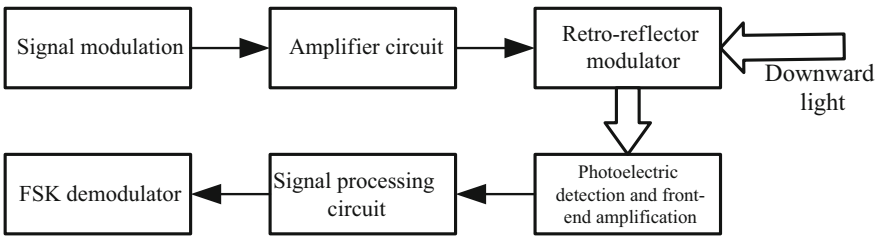

Fig. 35.5 Uplink-principle block diagram [51]

Table 35.1 Peak-to-peak values of return light-intensity signal driven by different frequency signals [51]

Signal frequency (kHz)	1	2	3	12	16	20	Greater frequency
Reflected light-amplitude peak-to-peak value (mV)	10	15	30	10	10	5	Submerged by noise

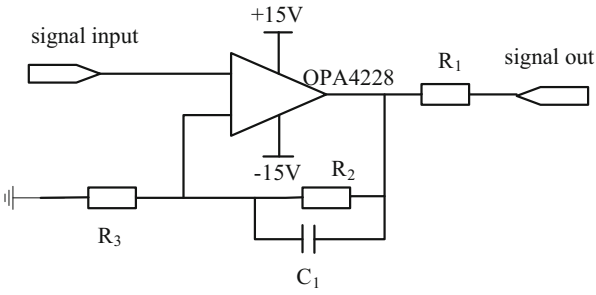

Fig. 35.6 Drive-amplifier circuit module [51]

input frequency of the optical signal gradually deviates from the resonance frequency.

Because the uplink uses a defocused cat's-eye MRR, the defocus amount is proportional to the variation range of the reflected light power. The larger the defocus amount, the greater the change in the return-signal light power, and the better the modulation effect. The defocusing amount depends on the amplitude of the piezoelectric-ceramic sheet, which is proportional to the driving voltage of the modulator [53]. To provide a better modulation effect, the driving circuit must have a wider range of driving-signal outputs. The author chose driving voltages of −15 V–15 V.

The circuit is shown in Fig. 35.6. Because the modulation signal of the digital-to-analog converter (DAC) output is far from sufficient to drive the piezoelectric-ceramic sheet, the signal amplitude must be increased to ensure that the piezoelectric-ceramic sheet operates normally. The OPA4248 amplifier used in the circuit has the advantages of low noise, strong driving force, and large bandwidth; thus, it is used as the driving chip for the piezoelectric-ceramic sheet.

The receiver separates the uplink information from the photodetector after reverse modulation and demodulates it. The reflected light is converted into an electrical signal by a photodetector, but is first amplified to eliminate the influence of background light. Then, a band-pass filter is used to filter out the interference of the communication downlink to extract the uplink information. Finally, the uplink information is amplified and sent to the field-programmable gate array (FPGA) for demodulation [51].

Visible-Light Communication Heterogeneous-Fusion Networks

VLC and Power-Line Communication Integration

VLC uses LEDs as the access points to access indoor broadband data; however, VLC equipment requires power when working, and indoor visible light cannot be directly used as an information source [54]. It must be connected to the backbone network to avoid becoming an information island. Power-line communication (PLC) couples the message to be transmitted to a low-voltage (or medium-voltage) power line through digital modulation, and uses the power line as the transmission medium to complete the transmission.

Because of its good characteristics and lack of additional wiring, it has been widely used in power-line communication systems, the Internet of Things, and smart homes [55]. If PLC technology is integrated into VLC, it will make indoor VLC more convenient for accessing other networks.

Fusion Scheme

Visible-light communication is closely related to power lines and has various applications. Many scholars have closely investigated the combination of PLC and VLC technology and proposed various specific combination schemes [56–58].

VLC is combined with PLC as a wireless technology. It is difficult to define a new unified strategy for the medium-access control (MAC) layer. Therefore, different media are used to exchange information above the MAC layer and establish a unified control-management system [59].

Scheme 1 Fixed-position VLC. This scheme is a classic combination of PLC and VLC. Its feature is that a special VLC transceiver is installed under the VLC light source so that VLC data transmissions can be completed from a fixed position. As shown in Fig. 35.7, Internet-access devices are connected to the VLC transceiver with an Ethernet cable, and the VLC uplink and downlink communicate between the VLC light source and the transceiver. The VLC light source is connected to the external-network port device through the PLC device and connected to the PLC device through the PLC power line; they communicate with each other by PLC. The advantage of this scheme is that the Internet device does not need any modification to connect to the Internet [59].

Scheme 2 Fixed-point transmission VLC. The feature of this scheme is that multiple VLC devices have built-in VLC transceivers, which can simultaneously communicate with VLC light sources. As shown in Fig. 35.8, multiple VLC devices can share a VLC light source in a room, and the VLC light source uses the VLC power line to access the external network through the PLC device, and the VLC light source communicates with the PLC device through the power line. The scheme can also be extended to indoor occasions with multiple VLC lighting sources. These VLC light sources are also connected by power lines, and users can use the nearest VLC light source to access the Internet [59].

Scheme 3 VLC downlink, PLC uplink. To reduce the interference caused by the simultaneous luminescence of multiple VLC devices, each VLC device can be

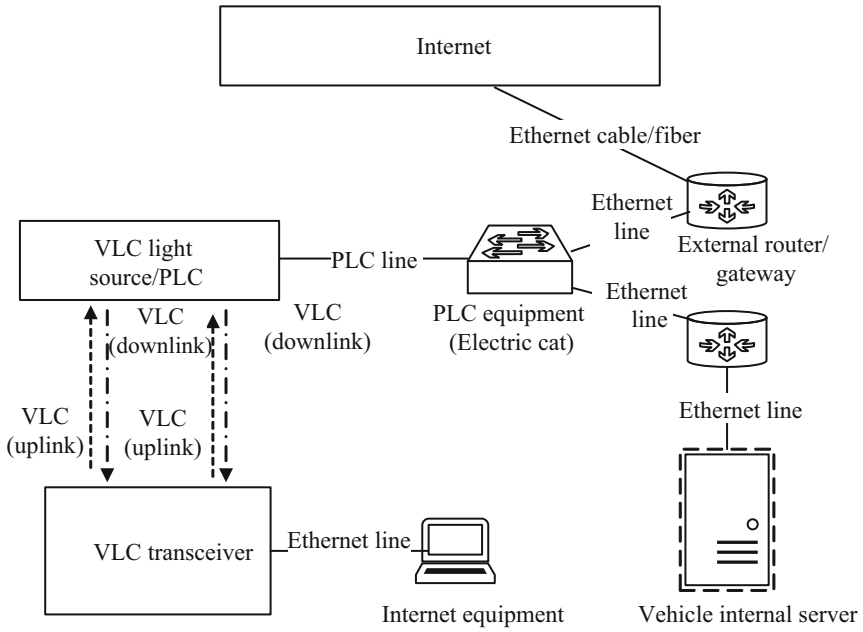

Fig. 35.7 Scheme 1: Fixed-position VLC [59]

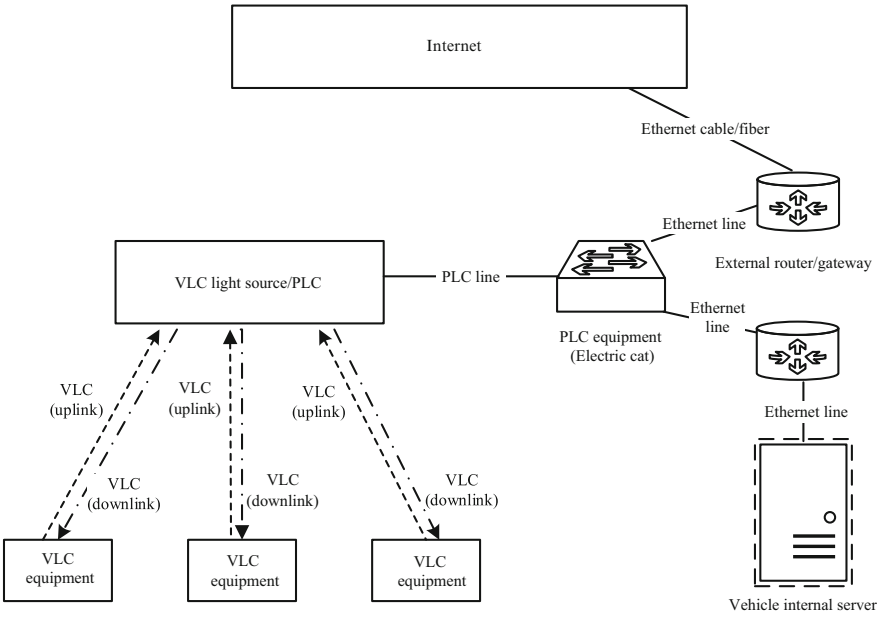

Fig. 35.8 Scheme 2: Fixed-point transmission VLC [59]

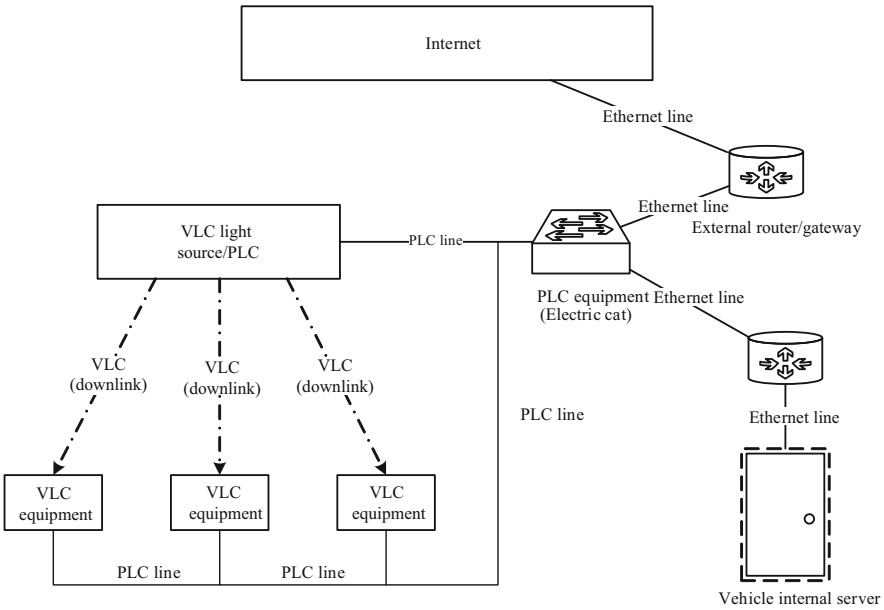

Fig. 35.9 Scheme 3: VLC downlink, PLC uplink [59]

transmitted back by PLC. As shown in Fig. 35.9, the VLC device receives the downlink information from the VLC light source, the power line transmits the uplink information of the VLC light source, and finally connects with the Internet. In addition, the scheme states that to prevent power-line crosstalk between VLC devices, all VLC devices must be connected in parallel on the power line [59].

Fusion-Network Structure

For PLC and VLC fusion systems, the fusion technology is mainly divided into two categories. One demodulates and amplifies the information loaded on the power line, and then loads the LED. The processing method uses a decode-and-forward (DF)/amplify-and-forward (AF) mode [60, 61]. The other loads the LED directly without demodulating the PLC information, which is a deep-fusion method. The principle of the first type of fusion method is shown in Fig. 35.10.

The deep integration of PLC and VLC technology loads power-line information into the LED without modulation and demodulation and uses PLC with visible light as the transmitting point. The PLC signal uses an existing power line to transmit the information and sends a signal to the LED. In addition, no modem is required between the power line and LED [63, 64], as shown in Fig. 35.11.

The above two fusion methods were analyzed, and a general model of the PLC–VLC system was obtained, as shown in Fig. 35.12. PLC/VLC represents the conversion of a PLC signal to a VLC signal.

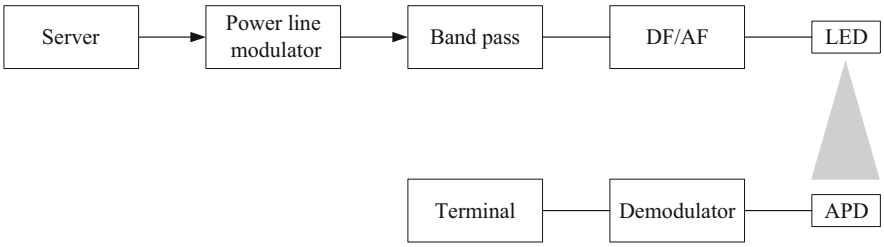

Fig. 35.10 DF/AF fusion mode of a PLC–VLC system [62]

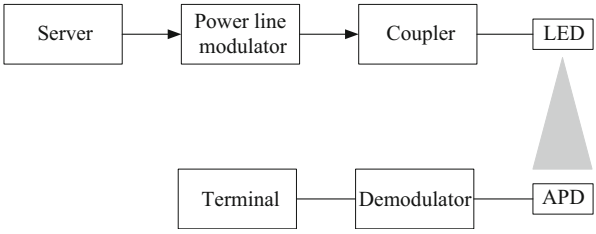
Fig. 35.11 PLC–VLC deep-fusion system [62]



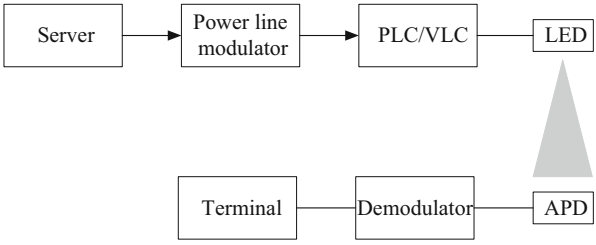


Fig. 35.12 General model of a PLC–VLC system [62]

Channel Model of the Fusion System

The integrated network channels mainly include the PLC channel, LED-lamp channel, VLC channel, and avalanche photodiode (APD) converter. At present, there are two main viewpoints on researching the PLC and VLC fusion-channel characteristics: top-down and bottom-up [65]. In the top-down method, the fusion-channel system is regarded as a black box. Through large-scale test analyses and statistics of certain parameters in the PLC–VLC fusion channel and simulation of the data, a channel model of the PLC–VLC network can be obtained.

The bottom-up method starts with functions that are easier to implement in the network system, gradually analyzes the components that affect the fusion channel from simple to complex, and then uses the two-port network to obtain the channel model of the fusion system, as shown in Fig. 35.13.

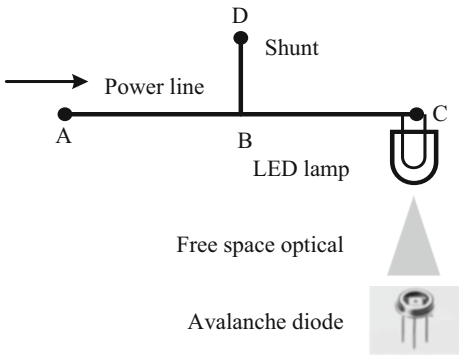

Fig. 35.13 Fusion-system channel model [66]

Heterogeneous Integration of VLC and WiFi

At present, WiFi technology is relatively mature; however, owing to its limited spectrum resources, a single WiFi hotspot cannot meet the requirements of multi-user high-speed Internet access, and the deployment of multiple WiFi hotspots produces co-channel interference [67]. These problems have a serious impact on users' Internet experience. VLC can use light to propagate in a very small space and transmit data to many user devices at a high rate, whereas WiFi can communicate at a relatively low rate in a larger space. Therefore, the combination of VLC and WiFi technologies can complement each other and provide indoor wireless high-speed communication and seamless coverage.

Indoor VLC–WiFi Heterogeneous Networking Scheme

In practical applications, many difficulties exist on the user-demand side when designing VLC transmitter systems, such as the difficulty of integrating the transmitter with an existing intelligent terminal and the limitation of the transmitter's directivity. In addition, because each user may have different transmission requirements for uplinks and downlinks in actual use, other uplink-transmission schemes can also be considered. The WiFi communication rate can reach 300 Mbit/s, and the transmission distance is approximately 100–300 m. The data-transmission distance and rate satisfy the requirements for uplink data transmissions in an indoor-environment network.

A change in the indoor user's location or building pattern may lead to a decrease in VLC signal quality or a disconnection. In [68], the authors used WiFi to assist VLC; that is, the VLC signal was converted to WiFi to transmit data when the VLC signal was interrupted. Four heterogeneous networking transmission schemes are introduced below.

Scheme 1 simultaneously uses visible light and WiFi for uplink and downlink data transmissions [69] and can achieve higher uplink and downlink transmission rates. When visible-light uplink or downlink transmissions are interrupted, the system switches to WiFi to continue the data transmission [68].

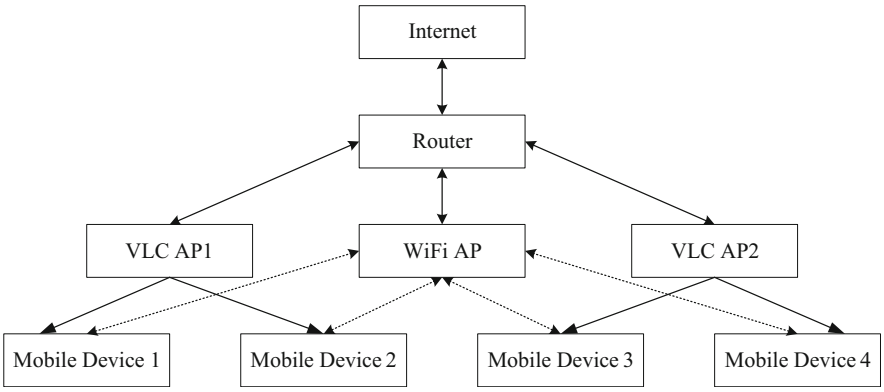

Fig. 35.14 VLC–WiFi topology [68]

In Scheme 2, visible light is used for uplink and downlink transmissions, but WiFi performs uplink transmissions, which can provide high-speed uplink and downlink transmission rates. When the visible-light uplink transmission is interrupted, it can switch to WiFi to continue the transmission [68].

Scheme 3 uses visible light for downlink transmissions and Wi-Fi for uplink transmissions, which provides a high-speed downlink transmission rate [68].

Scheme 4 uses visible light for downlink data transmissions, while WiFi performs uplink and downlink data transmissions, thereby achieving high-speed downlink transmissions. If a visible-light downlink transmission is interrupted, it can be converted to WiFi to continue the data transmission [68]. The topology is shown in Fig. 35.14.

Characteristics of Indoor VLC–WiFi Heterogeneous Networking

Currently, the uplink schemes of indoor VLC–RF heterogeneous networks include visible light, infrared, and WiFi. There are two drawbacks of using visible light as an uplink-transmission signal. First, it is necessary to configure a visible-light-transmitting device at the photodetector (PD) end. Current technology is far from being able to miniaturize visible-light transmitting devices for integrating with other mobile devices. Second, visible light requires a large transmission power and can only be transmitted by an LOS link.

For the terminal PD, it is necessary to solve the problems of power, volume limitation, and location interference to the LOS link [26]. When infrared is used for uplink communication, its half-power angle is very small, usually between 15° and 30°. In addition, the human eye is sensitive to infrared (IR) light. Users usually control their output power in practical applications, and the working range is usually approximately 1 m.

In [70], the author achieved an infrared optical-link transmission rate of 1.152 Mbit/s; however, it could only provide a single service as the communication downlink of a heterogeneous network. This makes it very difficult to offload traffic from visible-light communication.

WiFi has low power consumption, low cost, good compatibility, reliable transmission, and strong networking flexibility. Its radiation distance is approximately 100 m, and the transmission power is 100–200 mW. It can easily achieve stable data transmission in indoor environments. The transmission rate is 300–600 Mbit/s, which meets the requirements of system-uplink transmissions.

In an indoor VLC–WiFi heterogeneous network, the VLC access point provides a very high rate for the downlink transmission of indoor VLC with the advantages of high transmission power and large bandwidth. In addition, the WiFi access point uses its technical characteristics of large coverage area, strong anti-occlusion interference ability, and controllable uplink-transmission ability to realize uplink transmissions in heterogeneous networks [71].

In a WiFi cellular network system, the downlink data traffic far exceeds the uplink data traffic, and the two are asymmetric. In this system, the communication uplinks and downlinks do not interfere with each other during data transmission; that is, they are decoupled. Therefore, the communication uplinks and downlinks of the indoor VLC–WiFi heterogeneous network are also decoupled.

Indoor VLC–WiFi Heterogeneous Network AP Layout

The design scheme of an indoor VLC–WiFi network usually depends on the deployment of the VLC. When planning and deploying indoor lights, the actual lighting needs of the indoor users should be fully considered at the beginning of the design of the whole house. Moreover, the indoor-light intensity must meet the international lighting standard, 300 lx–1500 lx; otherwise, the indoor light will be too strong or too weak to have an impact on human-eye health.

In [72], the author studied the load balancing and power control of VLC–RF heterogeneous networks in a 10 m × 10 m × 3 m room. As shown in Fig. 35.15, the VLC–RF heterogeneous network consists of 16 LED lights and an RF access point. The RF access point (AP) is located in the center of the ceiling, each LED is 2.5 m apart, and the dotted circle indicates the range of visible-light communication LOS when the field of view is 45°. There is no communication-blind area in this regular layout.

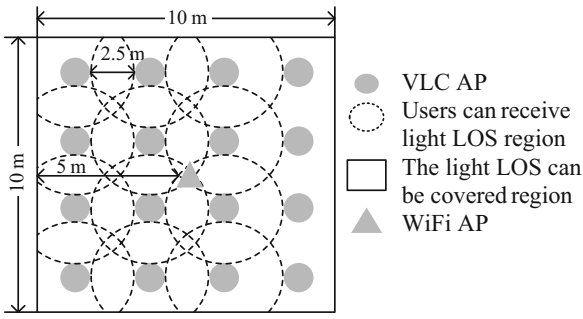

Fig. 35.15 Rectangular uniform AP layout of a VLC–WiFi [73]

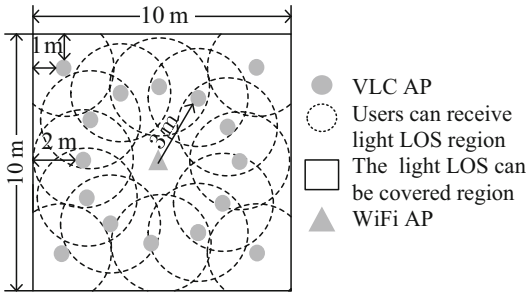

Fig. 35.16 Irregular AP layout in VLC–WiFi [73]

In [73], the author introduced an irregular AP-location deployment scheme to solve the VLC–RF network-access selection problem. As shown in Fig. 35.16, the VLC–RF heterogeneous network consists of 16 LED lights and an RF access point; the RF access point is located at the center of the ceiling. Twelve LED lights are evenly distributed in the central area of the room to form a circle with a 3-m radius, and an LED light source was placed 1 m from the wall at the edge position to supplement the light.

In this scheme, when the LED-emission half-power angle and the user's field angle are both 60°, there are communication blind spots at the center and edge of the room. When the user is in these positions, the communication will be interrupted.

From the above analysis, it can be seen that a reasonable light-source layout will fully meet the lighting needs of the users in the room; however, it is still possible to generate communication blind spots. Therefore, to achieve seamless coverage of indoor communication, an RF access point must be installed in the room.

VLC and Ethernet System Integration

Combining a VLC system with Ethernet technology [74, 75], which has perfect and reliable underlying protocols and standards, will increase the use of indoor-communication access technology in the future. The fusion of VLC and Ethernet technologies accelerates the integration of various communication technologies, such as radio, wired light, and wireless light, and further improves the performance of communication networks.

Two-Way Communication Systems

The client uses white optical communication to transmit messages, as shown in Fig. 35.17. The system communication downlink uses LED visible light, the communication uplink uses a semiconductor laser, and both the communication uplinks and downlinks are equipped with optical transmitters and receivers to facilitate the successful completion of two-way communication [35].

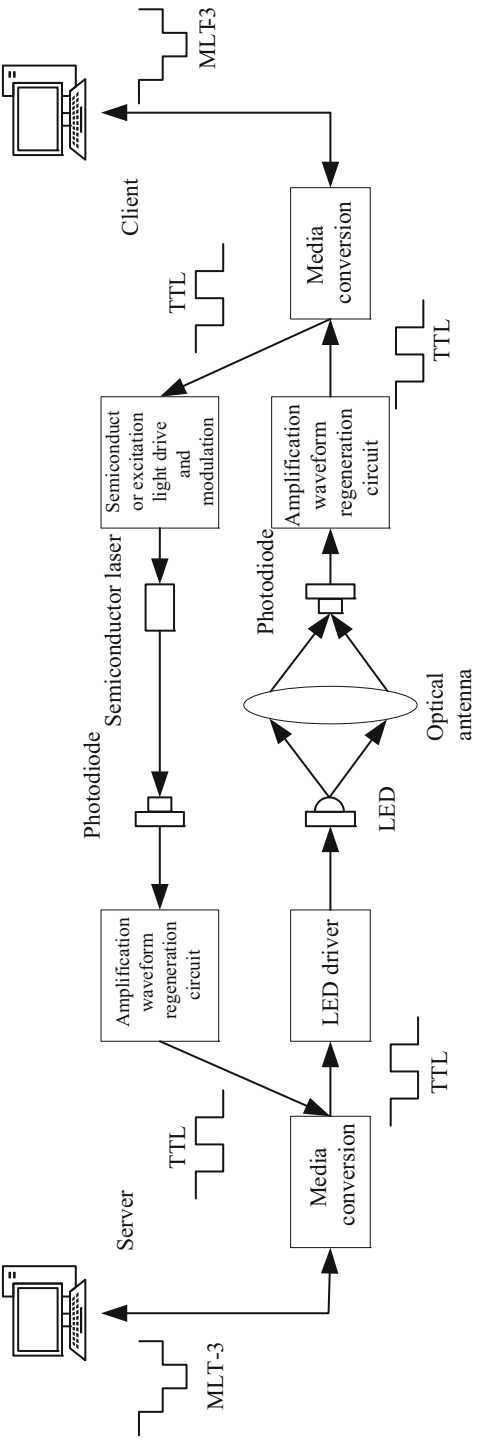

Fig. 35.17 Communication system diagram [76]

The working process of the visible-light downlink is as follows:

1. The server sends the Ethernet multi-level transmit 3 (MLT-3) tri-state bipolar data to the RJ-45 interface-circuit data-processing module and transmits it to the optical-communication medium-conversion module after filtering and coupling.
2. The MLT-3 three-state bipolar level in the network data information is converted to a unipolar TTL level suitable for adjusting the LED through the optical-communication medium-conversion module and transmitted to the LED drive-modulation module.
3. The LED drive-modulation circuit module provides the LED drive current and loads it onto the LED lamp.
4. The optical-communication medium-conversion module converts the electrical signal into network data and transmits it to the client through a twisted-pair cable [76].

Optical Communication Medium-Conversion Module

Network-Interface Circuit

A network-interface circuit generally includes a network control unit and a main processor. The ENC28J60 network control-unit chip, manufactured by Microchip, includes the MAC and PHY layers and supports full-duplex, half-duplex, and other modes. It integrates the physical layer internally and uses a packet-filtering mechanism to constrain the packets sent [77]. Using the industry-standard serial peripheral interface (SPI) [78], the function of the ENC28J60 chip is to pack, unpack, or transform the Ethernet data-frame format.

The network-interface circuit is shown in Fig. 35.18, and a 1:1 pulse transformer is connected to the differential pins (TPIN+/TPIN-) and (TPOUT+/TPOUT-). The

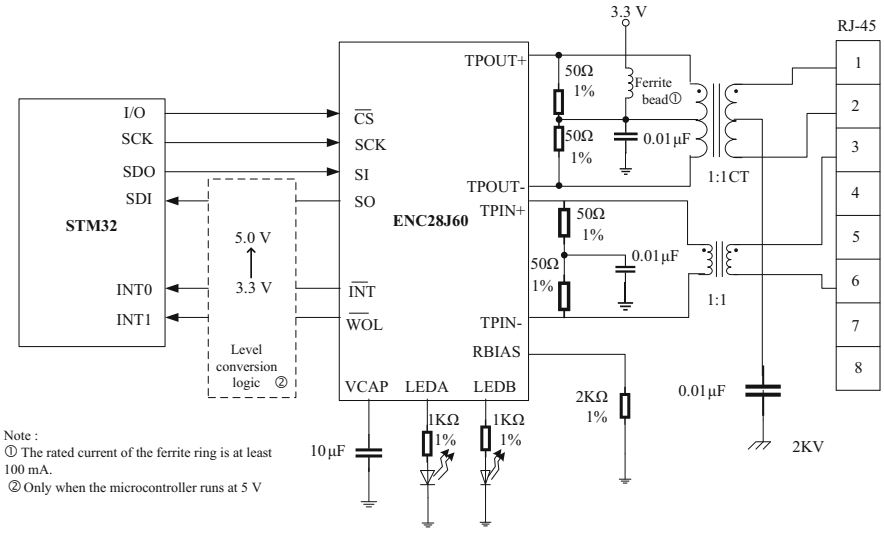

Fig. 35.18 Network-interface circuit [76]

former operates with 10BASE-T without a central tap, and the latter has a central tap. To prevent electrostatic interference, the transformer needs a more than 2-kV voltage isolation, but also must connect to a 50-Ω resistor and 0.01-μF capacitor. The resistance between the RBIAS pin and the ground is 2 kΩ, which meets the requirements of the ENC28J60 ethernet-controller internal analog-circuit design. A 10 μF capacitor is connected between the VCAP pin and the ground to ensure that the regulator works stably.

All the power pins in the interface circuit are connected to a 3.3-V external power supply. In addition, all the reference ground pins are connected to the same external grounding point. The purpose of this design is to drive an external load that the internal 2.5-V regulator of the ENC28J60 cannot directly drive. The LEDA and LEDB pins are connected in series with an LED to display the working state of the circuit.

The optical-communication medium-conversion module uses an STM32F103RBT6 main processor. The main function of the STM32 is to drive the ENC28J60 Ethernet controller to switch the format of the Ethernet data and send and receive Ethernet data information [76].

Protocol Conversion

In an Ethernet system, the signal-coding method is generally the MLT-3 multi-order baseband digital coding method. MLT-3 is a bipolar code with a positive level "+1," zero level "0," and negative level "–1." The information in the VLC is transmitted in space by the change in the TTL level, modulated by the LED, relative to the brightness of the light. The main function of the optical-communication medium-switching module is to switch the polarity level between the two transmission media in the mutual-integration network system and convert the protocol between the communication means [76].

The main functions of the protocol-conversion software given in Reference [76] are hardware and protocol stack initialization, application setting, and packet-format conversion. The working process of the protocol conversion is shown in Fig. 35.19. The Ethernet-frame data packets pass through the data-link, Internet Protocol (IP),

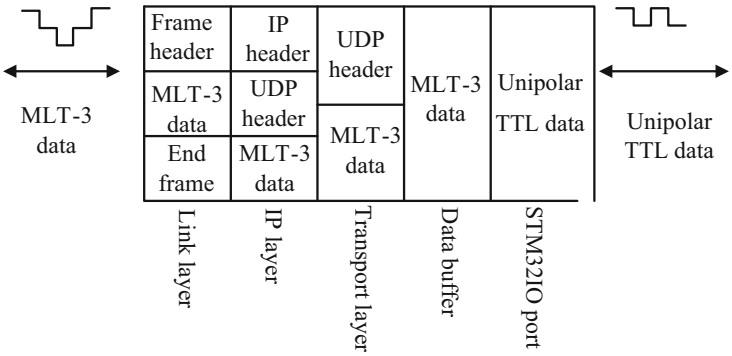

Fig. 35.19 Protocol-conversion workflow [76]

and data-transmission layers, and the frame header, frame tail, IP header, and user datagram protocol (UDP) header are all removed. Subsequently, all the remaining MLT-3 data information is stored in the Ethernet data-cache area, and all of them are converted into unipolar data information through the medium-conversion module [76].

Mutual Fusion of Local Area Networks

The types of network topology are stars, rings, buses, and hybrids [79]. Owing to the common characteristics of VLC and broadcast communication, the star-topology network structure is more suitable for research on interworking network technologies. As shown in Fig. 35.20, this is a common inter-integrated local-area network structure [76]. The network structure includes several clients and a server. Communication between the clients depends on the server, but the server can communicate directly with the clients.

In the Windows system environment, the typical UDP working process is as follows: after starting the server program, the server is loaded into a socket database, and the socket function is established. The local network address must call the Bind function to create a connection. When the server successfully connects to the client, it can call the Sendto and Recvfrom functions for data transmission and reception, respectively. After the transmissions and receptions are completed, both parties call the Close function to close the socket [76].

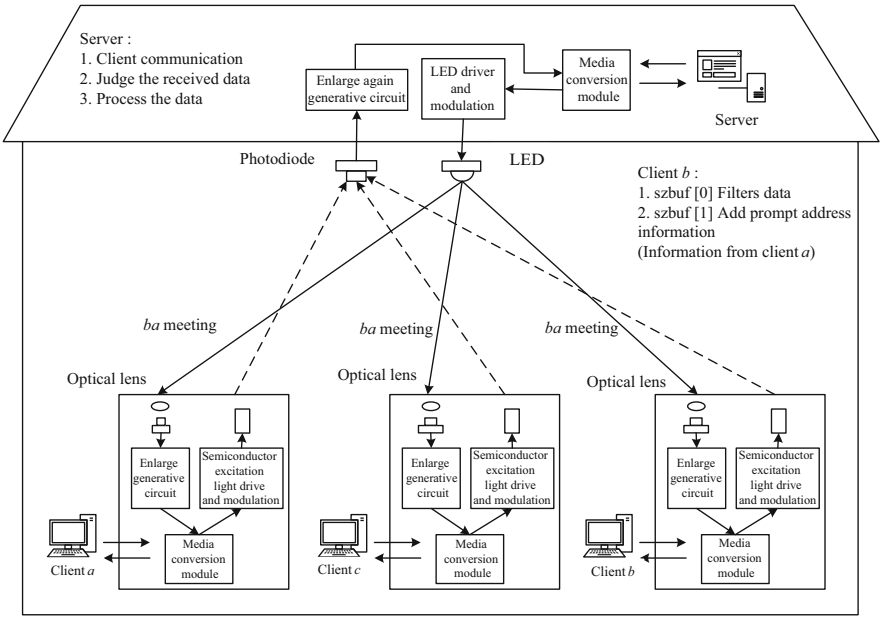

Fig. 35.20 Interconnected network structure [76]

In [35], the author integrates VLC technology and Ethernet technology through an optical-communication medium-conversion module system and makes the two communication technologies complementary to a greater extent; this solves some problems existing in traditional communication technology.

VLC and LTE Network Interconnections

At the Toronto, Canada, Conference in December 2004, the Third Generation Partnership Project (3GPP) officially proposed the long-term evolution (LTE) project [80]. The key technologies of multiple-input multiple-output (MIMO) and OFDM were introduced into the LTE system, which significantly improved the data-transmission rate and system spectrum efficiency. The LTE network supports various bandwidth-allocation schemes, such as 20 MHz, 15 MHz, 10 MHz, 5 MHz, 3 MHz, and 1.4 MHz. It supports the current global mainstream 2G/3G network-frequency bands and new network-frequency bands. The method for allocating spectrum resources is also more flexible.

In terms of network architecture and design, an LTE network has a flatter and more compact network structure. When the number of network nodes is small, the delay is small, and the deployment and maintenance costs of the network are lower. Classic LTE systems include the frequency-division duplexing (FDD)-LTE system and the time-division duplexing (TDD)-LTE system.

At present, many types of wireless communication technologies provide diverse types of services. Bandwidth resources, information-transmission rates, service support, and user mobility have different priorities. Table 35.2 lists the advantages and disadvantages of some representative wireless communication technologies, such as the Global System for Mobile Communications (GSM), wireless local-area networks (WLAN), LTE, and femto-to-femto (F2F).

The future development direction of mobile-communication technology should be to integrate all types of wireless or wired communication technologies so that they can work together to bring seamless coverage and more diversified network services to the majority of users, and fully meet their diverse Internet needs. Based on this concept, some scholars have proposed a heterogeneous network-architecture scheme that combines a VLC network system with other network technologies [81–84]. In [85], the author analyzed the resource-management scheme in a VLC–LTE heterogeneous network based on a virtual cell.

Network Architecture

The positions of the visible-light access points are evenly deployed in the indoor VLC so that the visible-light signal can spread throughout the indoor area. However, when the visible-light transmission channel system is affected by other ambient-light interference, the signal transmission is shielded, network resources are missing, or the access point (AP) is damaged, the VLC system may not work. To ensure that user services are not affected within a certain range, LTE base stations are deployed

Table 35.2 Advantages and disadvantages of different network communication technologies

Communications technology	GSM	WLAN	LTE	F2F
Advantage	The interface standard is universal, and supports encrypted information transmission and multiple services.	The configuration methods are diverse, easy to install and expand, and the cost of network deployment and transformation is low.	The spectrum bandwidth configuration is flexible, cell-edge transmissions are improved, the delay is low, and the rate is fast.	It can make up for the holes in macro cellular networks, improve the signal-coverage quality, enhance the user experience, and reduce the network operation costs.
Disadvantage	The system capacity and data rate are limited, the coding quality is low, and the switching function is poor.	Poor security, information may be stolen, the signal is greatly affected by the environment, and the connection is unstable.	Signaling design is complex, signal penetration is poor, high-frequency signals decay rapidly, and inter-cell interference is difficult to control.	It needs fixed-line broadband resource support, a perfect end-to-end service quality-assurance strategy, and requires users to pay higher fees.

outdoors and all indoor areas can communicate to achieve seamless network switching [85].

In [85], the design scheme of the VLC–LTE heterogeneous network is to evenly arrange several visible-light access points on a 20 m × 20 m × 3 m indoor ceiling, forming a VLC cellular network composed of multiple visible-light access points. The LTE base station is placed outdoors, and the communication range covers the entire indoor area so that indoor users can receive LTE signals.

There is only one access point in the LTE network. According to the actual use of the users, the bandwidth of each AP is set to 20 MHz, and the VLC system has no subchannel-division operation. It uses cooperative transmission and time-division multiplexing technology to provide services to the users. The bandwidth of the LTE network is set to 20 MHz to divide the subchannels. The bandwidth of each subchannel is $B_L = 20/L$ MHz, where L is the number of subchannels. An LTE network uses OFDM technology to provide services to users.

The user can only access one network at a time. $S_N = \{a, b\}$ represents the allowed network set, a represents the VLC network, and b represents the LTE network. $U_k^a = 1$ means that user k accesses network a, and $\delta_k^{am} = 1$ means that user k accesses the mth AP of the VLC network, where $\delta_k^{am} \in \{0, 1\}$. $U_k^b = 1$ indicates that user k accesses network b. To avoid co-channel interference, each LTE network

subchannel is only provided to one user, and user k selects the first subchannel in the LTE network; $\delta_k^{bl} = 1$ and $\delta_k^{bl} \in \{0, 1\}$.

p_k^1 indicates that user k selects the transmission power of subchannel 1 in the LTE network. p_k^a denotes the received signal power of user k in the VLC network, where the received signal power is the power of each AP in the virtual cell received by the user. $B_k^a = 20\text{MHz}$ denotes the bandwidth of user k for each AP. N_0^b is the channel-noise power-spectral density of the LTE network downlink, N_0^a is the channel-noise power-spectral density of the VLC network downlink, and g_k^b represents the channel gain of user k on the LTE network downlink channel 1.

NUM_k^{AP} represents the number of APs in the virtual cell constructed by user k accessing the VLC network and $\text{NUM}_k^{\text{USER}}$ represents the number of users in the virtual cell constructed by user k accessing the VLC network. $\text{NUM}_{\text{VLC}}^{\text{CELL}}$ represents the number of indoor virtual cells.

The signal-transmission rate of user k in the VLC network is

$$C_{\text{cell}}^a = \sum\nolimits_{m=1}^{M=64} \delta_k^{am} B_k^a \log_2\left(1 + \frac{p_k^a}{N_0^a * B_k^a}\right) / \text{NUM}_k^{\text{USER}}. \tag{35.3}$$

The data-transmission rate of a user in the cell cannot be accurately calculated because of joint transmissions and time-division multiplexing in the virtual cell. Therefore, the data-transmission rate of all users in the cell must be calculated and used as the data-transmission rate of the cell.

$$C_{\text{cell}}^a = \sum\nolimits_{\text{num}=1}^{\text{NUM}_{\text{num}}^{\text{USER}}} \sum\nolimits_{m=1}^{M=64} \delta_{\text{num}}^{am} B_{\text{num}}^a \log_2\left(1 + \frac{p_{\text{num}}^a}{N_0^a * B_{\text{num}}^a}\right) \tag{35.4}$$

The signal-transmission rate of user k in the LTE network is

$$C_k^b = \sum\nolimits_{K=1}^{L} \delta_k^{bl} B_L \log_2\left(1 + \frac{p_k^b g_k^b}{N_0^b * B_L}\right). \tag{35.5}$$

The total throughput of the heterogeneous networks is

$$C = \sum\nolimits_{K=1}^{\text{NUM}_{\text{VLC}}^{\text{CELL}}} C_{\text{cell}}^a + \sum\nolimits_{k=1}^{N} U_k^b C_k^b. \tag{35.6}$$

Compared with traditional LTE communication networks, the data-transmission rate of a VLC network is faster, and the bandwidth resources are more abundant. Therefore, when indoors, users may prioritize the VLC network to obtain high-speed and reliable communication services. However, in some special cases, users may also choose to access a traditional LTE network using a vertical handover.

Ideally, users should preferentially access networks with sufficient idle resources, low interference, and low switching costs. However, in practical applications, owing to the limitations of the user's location, the actual occupancy of network resources cannot be fully understood to access the network that meets the requirements.

Therefore, user-terminal access is managed uniformly through the controller of the VLC–LTE heterogeneous network.

Indoor VLC and LTE Network-Interconnection Model

In [86], the authors proposed a method for integrating LTE and VLC networks. As shown in Fig. 35.21, the LTE and VLC network-interconnection system consists of several LTE base stations, VLC access points, service gateways (SGW), and mobility-management entities (MME). The LTE network base stations are connected through the X2 interface. The MME and SGW connect to the entire LTE network base station.

The dual-mode terminal can communicate with the VLC network through its access point and with the LTE network base station through the wireless interface. This system also includes a VLC network scheduler, which is responsible for coordinating the connections between the MME/SGW, LTE network base stations, and VLC access points.

The role of the VLC network scheduler differs on different sides of the system. The LTE base-station side can complete some work closer to the LTE base station; the VLC side is an important device for configuring and managing the entire system. In addition, as an important interface between the LTE network and VLC network equipment, it has a data-information caching function and an exchange-management function. The VLC network scheduler uses the S1 and S2 interfaces to connect the MME and SGW, respectively, and is connected to all the LTE base stations through the X2 interface.

As shown in Fig. 35.22, the terminal is converted from an LTE network to a VLC network. The main steps are as follows:

1. The VLC access-point information is detected when the terminal accesses the LTE base-station network, and the detection report is automatically sent to the LTE base station. The information in the detection report must strictly follow the measurement specifications agreed with the base station, such as the measured

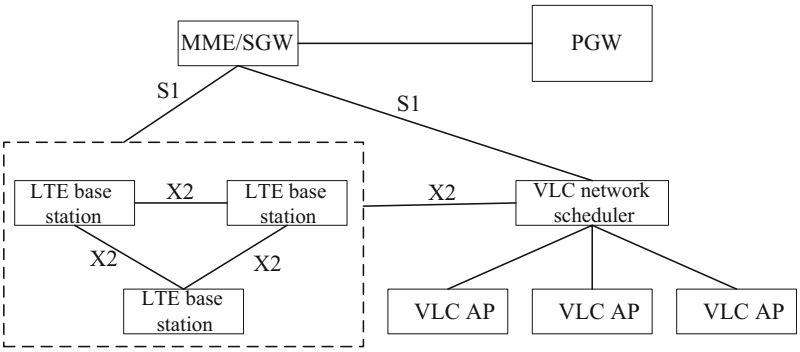

Fig. 35.21 Functional module diagram of the LTE and VLC interconnection system [86]

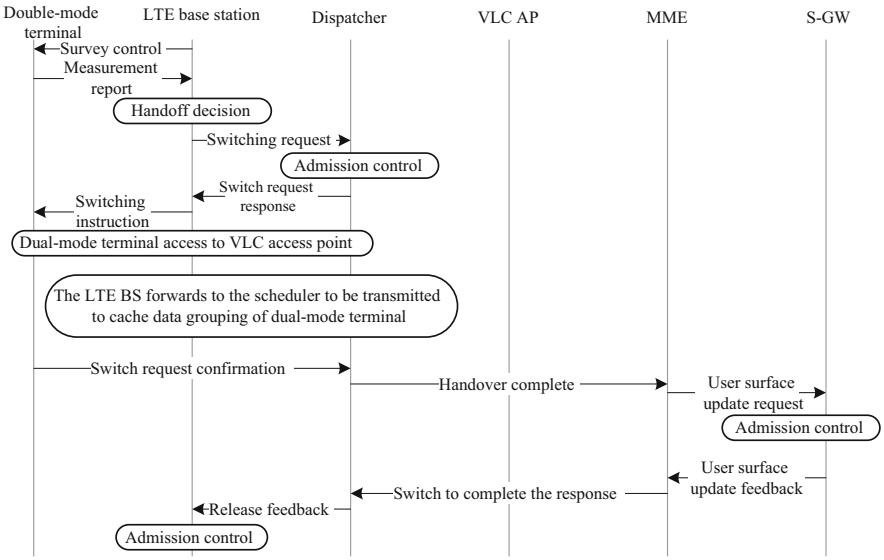

Fig. 35.22 Signaling process for dual-mode terminal switching from LTE to VLC [86]

trigger signal, cycle, and other contents containing cell-identification information and signal-quality requirements.

2. The base station must analyze the data information after receiving the switching signal reported by the user terminal and then determine whether to switch. If the system confirms that it should not switch, it terminates without waiting for the return information; if the base station decides to switch, it sends a switching instruction to the scheduler and enters step 3.
3. When the scheduler receives a handover request, the VLC connects to each VLC access point detected in step 1. After the connection is successful, the scheduler controls the access point and obtains information from it in real time, such as the available resources and load balancing.
4. The scheduler parses the received information related to the access point, determines the admission-control result, and returns the corresponding handover-response information to the base station. The base station sends corresponding instructions to the terminal, and the terminal then determines whether to switch.
5. If the terminal wants to switch, it must access the access point through the handover protocol, which is negotiated by both sides. In addition, the base-station system will be ready, at any time during the entire network-switching process, to save all the data to be sent to the terminal, transmit a copy to the network scheduler, and cache a copy of the local database.
6. After the terminal successfully accesses the VLC, it applies to the scheduler for confirmation and the scheduler sends a corresponding response, according to the current specific state.

7. After the terminal handover, the dispatcher receives the signal at the end of execution and sends it to the MME, which reports it to the SGW, and switches the downlink-transmission signal through the user surface update. When the switching operation is completed, the SGW sends a complete-switching signal to the MME and the MME sends the complete-switching signal to the scheduler.
8. The scheduler requests the base station to release the dual-mode terminal-related information resources after receiving the switching-end signal of step 7. The scheduler then sends the cached data information to the terminal through the access point to ensure a smooth output of the data information.

The process of switching from a VLC network to an LTE network is shown in Fig. 35.23.

The VLC is connected to the LTE through the scheduler. On the LTE base-station side, the scheduler remains completely transparent and has all the characteristics of an ordinary LTE base station. On the VLC network side, all VLC network access points are uniformly managed by the scheduler. The VLC network scheduler also controls the conversion between the LTE and VLC networks.

This scheme has obvious advantages for the LTE system. The conversion process meets the existing LTE requirements and has little impact on the performance of the existing LTE scheme. The VLC network is connected to the LTE network in a tightly coupled manner, which meets the needs of users to a greater extent and reduces the delay caused by system switching, thus ensuring good system performance.

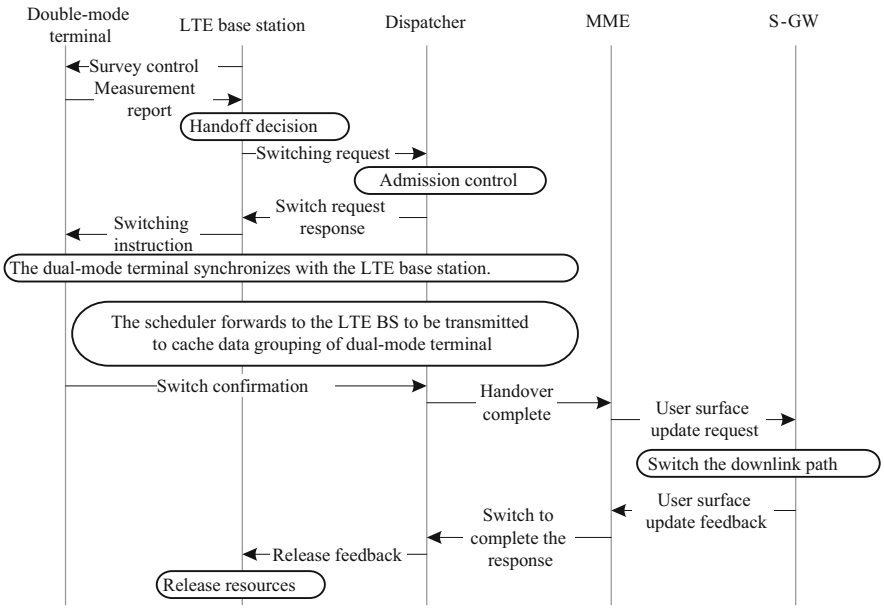

Fig. 35.23 Signaling process for dual-mode terminal switching from VLC to LTE [86]

Interconnection of a VLC and Radio-over-Fiber (RoF) System

The use of white LEDs in lighting systems will become increasingly widespread, and LED-based VLC network technology will also be widely used in the industry. White light sources can be divided into the following two categories:

1. Blue LED light covered with a phosphor layer
2. Mixed red, green, and blue (RGB) light

Comparing the above two types of light sources, the disadvantage of the former is that the bandwidth is small, which is due to the phosphor; for the latter, because the light is filtered, the optical power is reduced. Therefore, the RGB scheme has more advantages for practical applications. However, to achieve high-speed transmissions, modulation techniques, such as discrete multitone (DMT) and OFDM, must be used. In addition, RoF technology can provide a high transmission bandwidth and is more flexible than wired access. If these two technologies are combined, the gains will be different.

When using the mature WiFi IEEE 802.11 g protocol and existing components on the market, RoF and VLC technologies can be integrated. The RoF–VLC system achieves 54 Mbit/s information transmissions. The system is suitable for two-way transmissions, and its performance meets the WiFi standard specifications. Especially for the VLC sublink, the brightness level of the receiver is 15 lx, which is much lower than the standard-lighting brightness level of an indoor office environment.

Summary

With the vigorous development of wireless communication technology, VLC has achieved significant results in basic theory and application fields, which has promoted the rapid development of wireless communication and accelerated the practical application of VLC. The heterogeneous integration of visible-light communication and other communication methods is an indispensable step to meet the needs of future wireless communication. In the future, a major technical challenge for VLC will be successfully integrating existing networks with VLC systems, giving full play to its advantages, and supporting indoor multi-user large-capacity communication. Combined with the evolution and development trends of current visible-light communication systems, the following observations are made:

1. VLC bandwidth resources are very rich; however, the bandwidth of commercial LED devices for modulation is only tens of MHz, which greatly restricts the VLC transmission rate. Therefore, the development of high-speed, high-bandwidth LED devices is a future research and development trend.
2. The visible-light channel-mode selection must be based on the specific light-field distribution and spatial characteristics of the LED component itself. However, in

practical applications, other things must be considered, such as receiver frequency-response characteristics, optical antenna systems, the spatial light-field distribution, atmospheric turbulence, background-light noise, scattering, diffraction, and reflection in the visible-light transmission channel. Integrating this data information to establish a visible-light channel model provides important theoretical guidance for the future development of high-speed VLC technology in China. Moreover, it is of great significance for space and underwater wireless visible-light communication.

3. VLC bidirectional transmission is difficult. Information transmission requires both uplinks and downlinks. It is difficult for a VLC with a commercial LED as the carrier to transmit data upward. It is necessary to increase the LED lamp through a dedicated network card for upward data transmissions, and to add a detector for the downlink-transmission LED to receive the uplink signal. Therefore, using Wiener InGaN/GaN multiple quantum-well LED components to achieve full-duplex communication will become a research hotspot in the future.
4. Currently, VLC heterogeneous networking is still in the primary research stage. The coexistence and compatibility of visible light and terahertz, millimeter wave, and microwave wireless communications will be an inevitable trend in future VLC development.
5. VLC will be a reliable B5G/6G communication method in the future. It can be combined with other communication methods to form a full spectrum network, providing large capacity, high speed, and stable and reliable wireless transmissions for specific scenarios. Examples include intelligent visible-light positioning systems, indoor visible light, and millimeter-wave wireless hybrid networks. To meet the needs of future systems to process complex data, intelligent algorithms based on machine learning should be the focus of attention. They can be used as advanced signal-processing algorithms in VLC systems.
6. In terms of VLC systems, RGB LEDs can provide ultrahigh spectral bandwidth, and wavelength-division multiplexing technology can be used to increase the channel capacity. However, if the color ratio is not well controlled, the human eye will live for a long time in a space that deviates from natural color, which could lead to unforeseen vision problems.

Abstract

Optical-camera communication (OCC), a rapidly developing and emerging optical wireless imaging communication technology, has broad application prospects, owing to its low cost and highly popular optical-camera receivers. However, the received images have problems, such as perspective distortion, tilt distortion, halo effects, and optical noise, making threshold detection in image processing difficult. Implementing an OCC system that improves the data rate and transmission distance remains a problem. An image-optimization demodulation scheme is proposed. In the decoding process, the region of interest (ROI) is first used to extract the image matrix to reduce the impact of halo effects. Distortions in the image must be detected and corrected. We designed an improved center/surround retinex image-enhancement scheme, based on fast-scale adaptive bilateral texture filtering, which can efficiently eliminate the fluctuation of grayscale values both globally and locally. Subsequently, a simple threshold assessment is

performed. The stripe width of the received pixel is used for symbol judgment to complete subsequent demodulation and decoding; then, the original transmission data are obtained. In an experimental analysis, the improved center/surround retinex algorithm proposed in this study solved the problem of fluctuating grayscale values. Compared with other algorithms, it had the highest decoding efficiency, whether with an increase in communication rate from 3.5 kbps to 6.5 kbps or a change in communication distance. It had an average decrease in bit-error rate of about one order of magnitude and the best decoding performance.

Optical camera communication · Halo effect · Distortion correction · Center/surround retinex

Introduction

Visible-light communication (VLC) technology, one of the most promising wireless communication technologies in the 6G blueprint, has attracted widespread attention, owing to its rich spectral resources, fast transmission speed, ultra-high bandwidth, excellent security, and lack of electromagnetic radiation [1]. Currently, VLC, as an integrated green lighting and communication function, plays an important role in short-range communication [2]. Optical-camera communication (OCC), an important branch of low-power and broad-spectrum VLC, has become more popular, owing to the widespread development of complementary metal-oxide semiconductor (CMOS) cameras at the receiving end.

Optical-camera communication encodes and modulates the transmission data to be input at the sending end; the coding prevents as much as possible the occurrence of a stroboscopic light-emitting diode (LED) light-source effect [3]. If people's eyes are exposed to a stroboscopic environment for a long time, it can affect their mood, causing boredom, anxiety, etc. It may result in eye fatigue, distraction, and in serious cases, migraine headaches, blurred vision, epilepsy, and possibly neurological diseases.

The CMOS optical camera at the receiving end is equipped with a high-resolution CMOS image sensor [4], and its rolling-shutter effect greatly improves the data rate, compared to the global-shutter effect. The optical signal at the sending end is recorded as bright and dark stripes representing "1" and "0" [5, 6].

Although the shutter mode improves the data-transmission speed, it introduces a series of problems. One problem is that the data between two imaging frames cannot be captured. In the design process, it should be ensured that each captured image frame contains at least one complete data packet. Another issue is the correction of image perspective and tilt distortion caused by the offset of the receiving angle at the receiving end and jitter during shooting. A third issue is the halo effect, which is caused by the overflow of charges from saturated pixels to adjacent pixels. The light-

overflow effect and optical noise make threshold decisions in image processing difficult, which can reduce the decoding efficiency.

To solve the above problems, we designed correction methods for the tilt and perspective distortion caused by unstable receiver equipment and different angles. Moreover, we proposed an improved center/surround retinex algorithm based on fast-scale adaptive bilateral smooth filtering to eliminate the global and local fluctuations of gray values. A simple threshold decision can efficiently decode the original data. We tested the bit-error rate under different transmission rates and distances and concluded that our algorithm could efficiently decode the sent data in both cases.

Domestic and Foreign Research Progress

In 2000, Japanese scholar Tanaka et al. [7] proposed the use of white LEDs to simultaneously provide indoor lighting and wireless data transmission using light, designed a wireless home-link communication system, and simulated and analyzed the system. In 2006, Ding and Ke [8] from Xi'an University of Technology first introduced the concept of visible-light communication into China. With the continuous advances in key technologies in the field of visible-light communication, breakthroughs have been made in many applications.

In 2011, the IEEE released the IEEE Standard 802.15.7-2011 visible-light communication standard to ensure standardized research for VLC systems. Its full name was the visible-light short-range optical wireless communication standard, which was the first standard related to VLC. Although the IEEE 802.15.7 standard originally developed by the IEEE did not include optical wireless communication based on optical cameras, it was included in the 2014 IEEE 802.15.7r1 revised standard. After OCC was included in the revised standard, the standard was managed by a TG7m organization composed of academic researchers from multiple countries, such as China, the United States, and South Korea. The initial draft of IEEE 802.15.7-2018 was completed in 2018 [9].

In 2012, Danakis et al. [10] proposed a CMOS-camera data-reception scheme using visible-light communication, using a cubic-polynomial fitting method to distinguish the LED status, achieving a data rate far higher than the camera frame rate for visible-light imaging communication systems.

In 2013, Takai et al. [11] proposed a fast LED detection technology and integrated communication pixels, ordinary image pixels, and fast LED detection-technology circuits in optical-communication image sensors to produce a special CMOS image sensor. They designed a new optical wireless communication system using LEDs and CMOS technology for automotive applications.

In 2014, Chen et al. [12] proposed and demonstrated a novel filterless VLC system based on RGB light-emitting diodes and mobile-phone cameras. The system utilized a feature-matching method based on a scale-invariant feature-transformation algorithm for the received grayscale images. The experiment showed that the proposed method was simple and reduced the computational complexity.

In 2015, Chow et al. [13] proposed a link for visible-light imaging communication using CMOS cameras, which had a data rate higher than the frame rate of CMOS image sensors. At the receiving end, histogram equalization and Sobel filters were used to enhance the VLC signal performance, which alleviated the impact of halo effects. However, a significant bit-error rate occurred when the communication rate increased.

In the same year, Chow et al. [14] proposed using second-order polynomial fitting at the receiving end of visible-light imaging communication systems to reduce the halo effect of CMOS sensors. They used histogram equalization and Sobel filters to enhance the VLC signal performance, and third-order polynomial fitting to determine the threshold. The experimental results showed that, under different illuminances, the error rate could be improved by approximately an order of magnitude.

In 2016, Liu et al. [15] proposed and experimented with three threshold schemes, namely third-order polynomial curve fitting, iterative schemes, and fast-adaptive schemes, to evaluate them. In the same year, Liu et al. [16] proposed a visible-light imaging communication scheme using devices with LED and CMOS sensors for optical encrypted transmissions. They proposed and demonstrated the use of the Otsu threshold to define the data logic in shutter mode, and reduced the problem of fluctuating grayscale values using smoothing schemes.

In the same year, Liu et al. [17] proposed and demonstrated the use of a second-order polynomial-enhanced extinction-ratio scheme and an iterative and improved fast adaptive-threshold scheme to demodulate the obtained shutter mode. The experimental results showed that by using this enhancement scheme, the error rate could be improved by two orders of magnitude.

In 2016, Liang et al. [18] studied the performance of visible-light imaging communication systems when light sources moved to different parts of an image frame, and proposed and demonstrated the use of region-growth algorithms to track light sources. The extinction-ratio problem was reduced through selecting a grayscale-column pixel matrix, second-order polynomial smoothing, and Sobel filtering.

In the same year, Liang et al. [19] studied the effective thresholding problem in the experimental demodulation process of visible-light imaging communication systems. They proposed and demonstrated the maximum-entropy and minimum cross-entropy threshold algorithms. The demodulation error rates of the two algorithms were equivalent; however, the maximum-entropy threshold algorithm had a lower latency and was more advantageous.

In 2016, Li et al. [20] proposed a digital image-processing scheme for visible-light imaging communication using mobile-phone cameras as receivers. The scheme utilized grayscale conversion to remove low-grayscale and LED light spots and histogram equalization and high-pass filters to process the image. The resulting bright and dark stripes were clearer and easier to decode. The experimental results demonstrated that the VLC system could resist interference and extend its transmission distance.

In 2017, Dai et al. [21] proposed a non-line-of-sight channel communication scheme to solve the halo effect caused by light sources in optical-camera

communication and the communication-discontinuity problem between multiple frames. The experimental results showed that the synchronization accuracy and communication speed were improved through high-precision synchronization algorithms and multi-column signal accumulation.

In the same year, Chen et al. [22] proposed an effective demodulation scheme to synchronize and demodulate the shutter mode of visible-light imaging communication systems. First, linear interpolation was used to increase the number of effective sampling points, and then a new threshold scheme using extreme-value averaging was proposed. The experimental results showed that the proposed scheme significantly improved the processing latency and reduced the bit-error rate.

In the same year, Wang et al. [23] proposed a long-distance non-direct-view link communication system that used improved rolling-shutter mode demodulation algorithms, such as background-compensated floodlight mitigation, extinction-ratio enhancement, and the Bradley adaptive threshold, which could receive and demodulate 1.5-m non-direct-view link communication under a low illumination of 145 lx.

In the same year, Zhang et al. [24] proposed a scheme to enhance the performance of visible-light imaging communication using a moving-exponential averaging algorithm. This scheme first sorted the elements of each row of the grayscale values of the pixel matrix in descending order and then selected an appropriate pixel array to reduce random noise interference. The moving-exponential averaging algorithm reduced the impact of extinction-ratio fluctuations on the decoding performance.

In 2018, Lee et al. [25] proposed a method for suppressing the noise interference in visible-light imaging communication systems. The proposed scheme used "signal averaging" to reduce additive white Gaussian noise, and reduced background noise through an adaptive window threshold and normalization. Experiments showed that this scheme improved the transmission performance of visible-light imaging communication systems.

In the same year, Shi et al. [26] proposed using a dynamic-column matrix-selection algorithm to avoid halo effects and experimented with optical-camera communication that supported user mobility. The results showed that the bit-error rate performance was inversely proportional to the movement speed and lateral distance, and decreased with a corresponding increase. In the same year, Guan et al. [27] proposed the use of contrast-constrained adaptive histogram equalization to extend the transmission distance and reduce the effect of background noise.

In the same year, Sun [28] investigated the visible-light communication system of smartphones, designed a signal-reception scheme based on mobile cameras and mobile light sensors, and determined the practical value of the mobile-camera scheme. This system effectively reduced the hardware requirements of traditional VLC systems for docking with the receiving users. In the same year, Zhang et al. [29] proposed a threshold algorithm based on stripe-boundary pixels to improve the performance of visible-light imaging communication systems. The results showed that this algorithm had advantages in terms of transmission distance and data rate, compared with traditional third-order-polynomial fitting schemes.

In 2019, Zhang et al. [30] proposed three threshold algorithms to improve the performance of VLC systems based on the CMOS-camera shutter effect. The

threshold schemes were based on equal-weight, fractional-weight, and ratio-weight moving averages. Compared with traditional threshold schemes based on polynomial fitting, the proposed threshold scheme had significant advantages in terms of both system performance and computational complexity. The threshold scheme based on the fractional-weight moving average was the best.

In the same year, Li et al. [31] proposed an efficient thresholding method to increase the transmission distance in optical-camera communication. This method utilized a nonlinear transformation of the average grayscale values of each column to increase the contrast between the light and dark bands. The experimental results demonstrated that this method was superior to polynomial regression.

In the same year, Zhang et al. [32] proposed an information-decoding scheme for visible-light imaging communication systems that effectively suppressed the halo effect of received images by utilizing synchronous dynamic-compensation technology and introducing histogram equalization, least-squares fitting, and other technologies. The results demonstrated that this decoding scheme effectively improved the reliability of information transmission.

In the same year, Zhong et al. [33] designed an algorithm based on back-propagation neural networks to decode images received by lens-less optical-camera communications. This algorithm effectively recognized blurred image patterns and used an adaptive training-sequence adjustment mechanism to adapt to time-varying environments. Simulation results showed that the proposed image-decoding algorithm had a good bit-error rate.

In the same year, Zhu et al. [34] proposed a frame-synchronization mechanism for a rolling shutter based on the imaging principle of optical cameras, applied visible-light imaging communication to directional transmission characteristics, and designed a sensor-node debugging information-security transmission scheme based on optical-camera communication.

In 2020, Liu et al. [35] proposed an adaptive contrast-enhancement algorithm to solve the problem of high-extinction-ratio images in visible-light imaging communication systems. This scheme was suitable for high-fluctuation data modes; however, when the transmission distance increased, the decoding error rate exceeded the forward error-correction threshold limit of 7%. In the same year, Meng et al. [36] used a feature grayscale matrix to alleviate the impact of the halo effect but did not fundamentally eliminate the grayscale-value fluctuation problem.

In 2021, Li et al. [37] proposed a novel demodulation scheme for visible-light imaging communication systems that utilized an adaptive image-enhancement algorithm based on dilation and corrosion to solve the problem of fluctuations in grayscale values. However, it occasionally deformed pixel objects and could lead to information loss. In the same year, Bai et al. [38] designed a new data-frame structure suitable for optical-camera communication links, effectively solving the data-loss problem in optical-camera communication links caused by asynchronous receiving and sending ends and camera-frame spacing.

In 2022, Wu et al. [39] proposed a multilevel modulation scheme using a pilot-assisted K-means algorithm that obtained the stripe-propagation state in optical

channels under different environments and improved the data rate and performance of visible-light imaging communication.

In the same year, Dong et al. [40] proposed a simple channel-equalization method that utilized the spatiotemporal relationship of spatial-delay pulse-width modulation waveforms transmitted by multiple light sources to effectively alleviate the uncertain sampling problem caused by the asynchronous nature of optical-camera communication. They analyzed the equalization error rates caused by undersampling and overexposure under different duty cycles and exposure times.

In the same year, Zhang et al. [41] proposed introducing visible-light imaging communication into subway-train positioning, using LED light sources in tunnels as the information-sending end of the positioning system and optical cameras as the information-receiving end. Visible-light imaging communication technology was used to obtain the coordinates and shape information of the LED light sources to determine precise train positions.

In the same year, Chen et al. [42] proposed an exponentially-weighted filtering algorithm to suppress the interference of grayscale fluctuations, ensuring the influence of adjacent pixel rows. This algorithm, combined with reference-stripe judgment, rapidly demodulated and decoded the data of visible-light imaging communication systems, reduced the problem of high error rates caused by grayscale fluctuations in optical-camera communication, and had lower algorithm complexity.

In the same year, Jiang et al. [43] proposed a pilot-based strip-area-estimation decoding algorithm and designed pixel-rearrangement schemes and stripe-separation decision-making methods that improved the decoding performance under receiver sway or position shifts in visible-light imaging communication. The effectiveness of the proposed decoding algorithm was experimentally verified.

In 2023, Zhang et al. [44] proposed a train-positioning algorithm based on the combination of a backpropagation (BP) neural network and visible-light imaging communication. This method used an LED light source in the tunnel as the communication transmitter, introduced feature variables in the light-stripe-code modulation process, and used a BP neural network to classify and recognize the information sent by the light source. This increased the communication distance and improved the timing and accuracy of train positioning.

System Model

The system model of optical-camera communication is shown in Fig. 36.1. The computer inputs the data to be transmitted. The signal light source at the sending end adopts Manchester encoding, which can continuously provide up to two identical bits, preventing the stroboscopy problem caused by a large number of consecutive 1 or 0 bits. Using binary amplitude on–off keying (OOK) modulation, the 01 code of the transmitted data is represented by a unipolar non-return-to-zero code. After the data are encoded and modulated, the microcontroller controls the LED driver circuit to send the data to the LED light source for transmission.

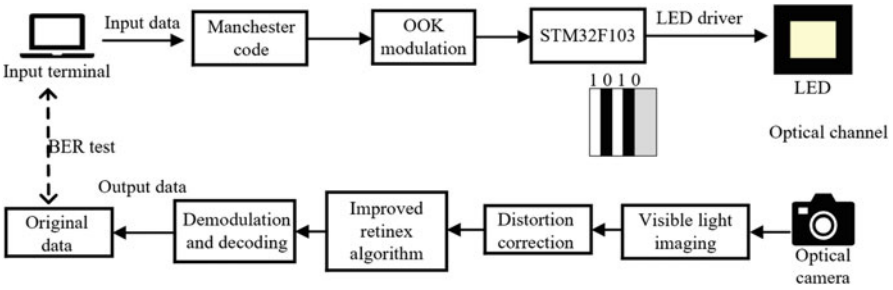

Fig. 36.1 Overall block diagram of an optical-camera communication system

After transmission through the optical channel, it reaches the receiving end and is received by an optical camera with a CMOS image sensor, forming an image with light and dark stripes. The received image is optimized and processed, including correcting for distortion and eliminating overall and local grayscale fluctuations in the image, to achieve efficient demodulation and decoding. Finally, the original transmission data are obtained.

Working Principle of CMOS Image Sensors in Optical-Camera Communication

Optical-camera communication uses optical cameras as receivers of optical signals, and is a new type of visible-light wireless communication. The light source at the transmission end performs the dual tasks of lighting and communication.

CMOS optical cameras have become one of the most promising receiving platforms for optical-camera communication because CMOS image sensors use a rolling-shutter exposure mode. Specifically, the light signals sent by LED light sources are captured by the camera in the form of images; the signal-capturing process is shown in Fig. 36.2. Compared with the global-exposure mode of CCD imaging, the rolling-shutter exposure mode improves the transmission rate of optical-camera communication [45].

The CMOS image sensor performs row-by-row exposure under shutter-mode control. When the LED is turned on, the pixels are exposed to form bright stripes; when the LED is turned off, the pixels form dark stripes. The received light signal is converted into an electrical signal and recorded to obtain a strip image with alternating light and dark stripes. The transmitted data can be obtained by analyzing the light and dark stripes [45].

The frame rate R_i of a camera is generally expressed as the reciprocal of the sum of the frame-reading time T_R and the interframe interval T_G, as shown in Eq. (36.1).

$$R_i = \frac{1}{T_R + T_G} \tag{36.1}$$

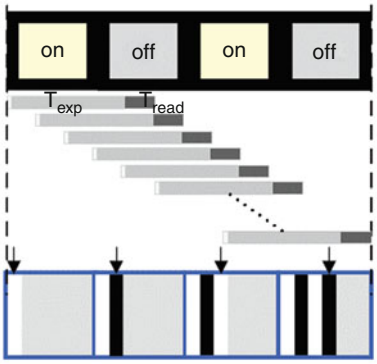

Fig. 36.2 Rolling-shutter exposure mode of a CMOS image sensor

The frame-readout time is $T_R = T_{\text{exp}} + (Y - 1) \times T_{\text{read}}$, where T_{exp} is the pixel-row exposure time of the CMOS image sensor, T_{read} is the reading time of the CMOS image sensor, and Y is the total number of pixel rows in the image.

To ensure correct data reception, it is necessary to consider the problem of matching the visible-light transmission rate and the shooting frame rate of the camera, as shown in Eq. (36.2). This means that the transmitted data rate R_r should simultaneously be higher than the shooting frame rate R_i of the camera and lower than the row pixel-scanning rate R_s of the CMOS image sensor. The shutter time of the CMOS image sensor determines the rate range of the visible-light information.

$$R_i \leq R_r \leq R_s \tag{36.2}$$

The row pixel-scanning rate R_s of CMOS image sensors can be estimated from the total number of pixel rows in the image and the frame rate of the camera; it is represented as

$$R_s = Y \times R_i \approx Y \times \frac{1}{T_R} \tag{36.3}$$

The frequency of LED flashing must be set within an appropriate range, ensuring that the frequency exceeds the human-eye limit and that normal lighting functions are achieved, as well as correct reception by CMOS image sensors. The maximum allowed data-transmission rate can be expressed as

$$R_{r\,\max} = \frac{1}{t_{\min}} \tag{36.4}$$

where t represents the exposure time of the camera in seconds and $t_{\min}$ represents the shortest exposure time. Although the parameter values of optical cameras vary among different models, the shorter the exposure time, the higher the system communication rate.

After the data rate R_r transmitted by the system is determined, the bit resolution of an image frame can be further determined at a specific receiving end. The bit resolution is expressed as

$$r = \frac{R_i \times Y}{R_r} \tag{36.5}$$

The number of information bits that can be carried in an image is represented as

$$N_r = \frac{Y}{r} \approx \frac{R_r}{R_i} \tag{36.6}$$

It can be seen that the number of bits transmitted in an image frame is closely related to the transmission rate of the system and the frame rate of the camera.

Design of Data Frames for the OCC Sending End

The data-frame design should not only ensure the correct reception of data information but also consider the issue of synchronous reception at the receiving end. In this experiment, the frame header of the data frame adopts an identifier with a length of eight bits, designed as 01111101, to ensure that the receiving end recognizes the frame header to achieve a synchronous reception. This frame flag can serve as both the start flag of one data frame and the end flag of the previous data frame, distinguishing between the two data frames. The 01 code in the frame identifier can also serve as a reference for the subsequent decoding.

Then, an eight-bit sequence identifier is designed to ensure that the receiving end decodes the data and reorders them correctly. A data frame can transmit 16 or more bits of data. In the data-frame design, the sequential identifier and data were encoded using Manchester encoding, as shown in Fig. 36.3.

Equation (36.1) shows a frame gap T_G between two consecutive images captured by the camera, $T_G = \frac{1}{R_i} - T_R$, which can lead to incomplete data information at the receiving end. The sending rate of the LED can be adjusted to ensure that at least two identical data frames are recorded in one frame of the image at the receiving end.

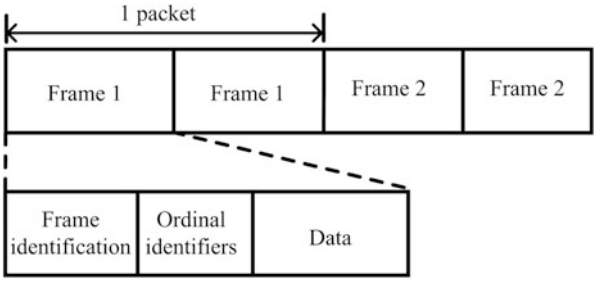

Fig. 36.3 One packet containing two data frames

Including two data frames in one packet can solve the problem of data loss caused by inter-frame intervals, thereby ensuring that complete data are obtained when decoding the received images.

Design of the Demodulation Algorithm

There are several basic problems in experimental research on optical-camera communication. Problems with perspective and tilt distortions in imaging are caused by the shooting angle and shaking during the shooting. Because of the interference of ambient light, the received signal is polluted by additive white Gaussian noise. Severe fluctuations affect grayscale image values. These issues cause serious errors in the subsequent decoding, and the receiving end will not receive the correct transmission data.

To solve the problems with receiving in optical-camera communication, this study designed corresponding solutions. Corresponding fast-correction methods were designed for the two types of distortion problem. An improved center/surround retinex algorithm was designed to address the interference of light noise in the environment and the fluctuation of grayscale values in the images. Changing the kernel function of the center/surround retinex algorithm enabled it to solve the problems of overall and local grayscale fluctuations in the received image, thereby ensuring correct decoding of the transmitted data stream. Because optical-camera communication uses simplex communication, reducing the error rate is a key factor in achieving correct communication.

Selection of ROI

To reduce the halo effect and improve the timeliness of subsequent decoding, the region of interest (ROI) was selected according to the method described in [46], as shown in Fig. 36.4. By selecting an image matrix with a smaller halo effect, the grayscale feature curve shown in Fig. 36.5 can be obtained. However, there is still a serious fluctuation in the grayscale values in the selected ROI, which affects the subsequent decoding.

Distortion Correction for Visible-Light Imaging

During the experiment, the receiving end may be in different situations. In one situation, different shooting angles at the receiving end can change the stripe width of the image, which is a perspective distortion. In another situation, the shaking of the device at the receiving end can cause the image to have skewed stripes, which is known as tilt distortion. In both cases, the image at the receiving end is distorted and cannot be recognized. This seriously affects the visible-light imaging communication and is unacceptable.

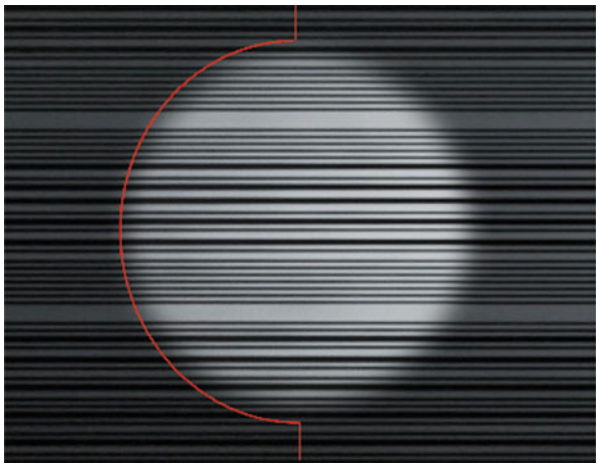

Fig. 36.4 Selection of ROI image matrix with a low halo effect

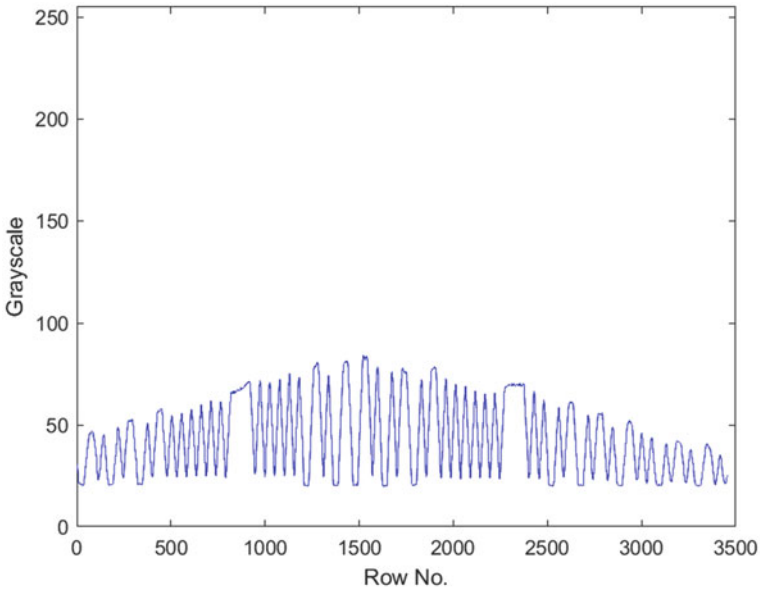

Fig. 36.5 Grayscale-feature curve of ROI region

Therefore, correcting the distortion of the received image is crucial for ensuring correct reception at the receiving end of an OCC system. Considering the different characteristics of these two types of distortion, two different correction methods have been proposed.

Correction of Perspective Distortions

During the experiment, there may be situations in which the receiving end does not directly face the light source. For example, when shooting from the left or right, the received image features may differ, which can lead to perspective distortion.

The imaging results obtained when shooting from the right side of the light source are shown in Fig. 36.6. The dashed line represents the original image size, and the solid line represents the distorted shape. The perspective distortion is due to the imaging characteristics of the optical-camera equipment itself, which is "near large, far small."

The specific phenomenon of perspective distortion is that the stripe width of the receiving-end image on the side near the camera is significantly greater than that on the side away from the camera. Perspective distortion changes the original width of the image stripes. Eliminating perspective distortion restores an image to its actual size. A perspective-transformation method was proposed to solve the problem of perspective distortion caused by the camera.

Perspective transformation is the process of projecting an image onto a new visual plane for correction [47]. The process involves finding the four corners of the image and converting them into equal widths, based on the perspective transformation. In this study, four preset corner points were used to resolve the perspective distortion caused by the imaging characteristics of the camera. The advantage of this perspective-transformation correction method is that it has lower computational complexity and faster processing, making it a very effective transformation method.

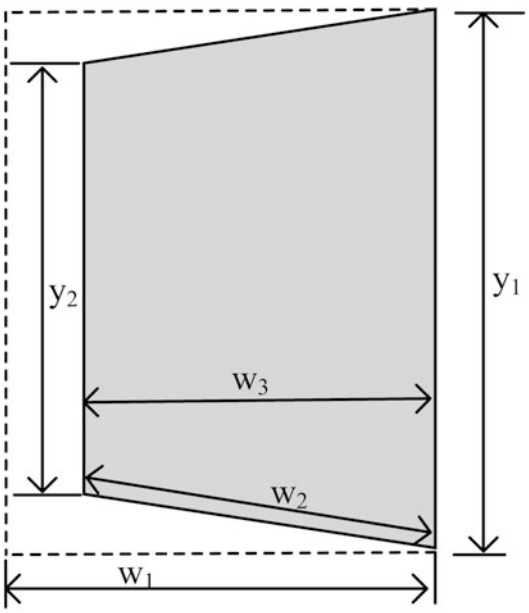

Fig. 36.6 Schematic diagram of perspective distortion

Based on the characteristics of visible-light imaging perspective distortion, this study vertically divided the distorted pixels into three small pixel parts. These three parts included the distortion on the side near the camera, the distortion far from the camera, and the portion in the middle. The segmented small pixels were stretched separately and recombined to obtain the original image.

Segmentation correction can obtain the corner coordinates of the segmented image, thereby accelerating the subsequent calculation process. The specific correction process is as follows: The perspective transformation projects the image onto a new viewing plane. The transformation formula is shown in Eq. (36.7), where (x, y, z) are the coordinates of the original image pixel, (X, Y, Z) are the coordinates of the transformed image pixel, and A is the perspective-transformation matrix.

$$\begin{bmatrix} X \\ Y \\ Z \end{bmatrix} = A \begin{bmatrix} x \\ y \\ z \end{bmatrix} = \begin{pmatrix} a_{11} & a_{12} & a_{13} \\ a_{21} & a_{22} & a_{23} \\ a_{31} & a_{32} & a_{33} \end{pmatrix} \begin{bmatrix} x \\ y \\ z \end{bmatrix} \tag{36.7}$$

The image is then converted into a two-dimensional image. $Z = 1$ and $a_{33} = 1$. The coordinates of the transformed image can be obtained as

$$\begin{cases} a = \dfrac{X}{Z} = \dfrac{xa_{11} + ya_{21} + a_{31}}{xa_{13} + ya_{23} + a_{33}} \\ b = \dfrac{Y}{Z} = \dfrac{xa_{12} + ya_{22} + a_{32}}{xa_{13} + ya_{23} + a_{33}} \end{cases} \tag{36.8}$$

To correct a perspective distortion, four original coordinates and four destination coordinates must be known. The distorted image is divided into three uniform parts. After the segmentation, the pixel coordinates of the four corners of each part can be obtained. The pixel coordinates of the four corner points are $I(x_1, y_1)$, $I(x_2, y_2)$, $I(x_3, y_3)$, and $I(x_4, y_4)$. The destination coordinates are the known coordinates of the specified rectangle for the new view. The pixel coordinates of the four corner points are (a_1, b_1), (a_1, b_2), (a_2, b_1), and (a_2, b_2).

Subsequently, by substituting these eight pairs of coordinates into Eq. (36.8), the remaining eight parameter values in the parameter-transformation matrix A, excluding $a_{33} = 1$, can be calculated. Thus, the distorted image can be corrected to obtain a normal image, and further demodulation and decoding can be completed.

The perspective-distortion correction process is shown in Fig. 36.7. Figure 36.7a shows the image captured when turning the camera angle to the right, Fig. 36.7b shows the pixel coordinates of the four corner points obtained by segmenting and labeling the distorted-perspective image, and Fig. 36.7c shows the corrected image.

Correction of Tilt Distortions

At the receiving end, a tilt distortion may occur, which differs from a perspective distortion. When the receiving device is unstable and sways during the shooting

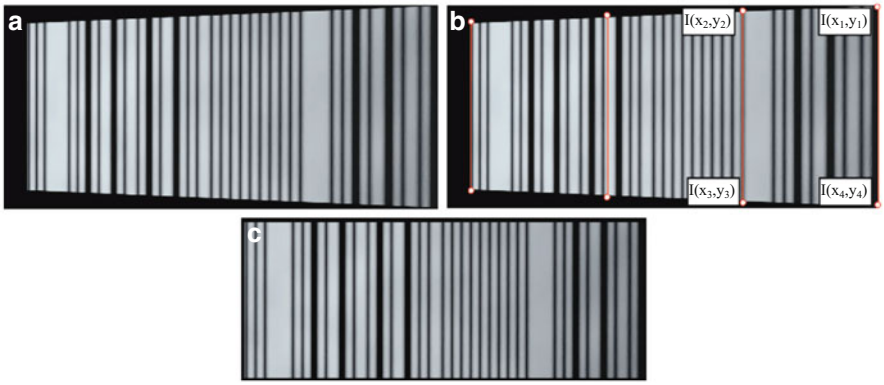

Fig. 36.7 Perspective-distortion correction process: (**a**) Picture taken from the right side, (**b**) marked segmented image, and (**c**) corrected image

process, it can cause the received image to tilt and shift, which is known as tilt distortion. As shown in Fig. 36.9a, the overall stripes in the image are tilted; however, the width of the stripes remains unchanged, which affects the ability to proceed with subsequent work.

According to the characteristics of visible-light imaging, the resulting image is a bright–dark-striped image. A random Hough transform (RHT) can be used to quickly correct the tilt problems caused by the shaking of the receiving optical camera. The Hough transform utilizes the transformation between the space in which the image is located and the parameter space for calculations [48]. The random Hough transform uses two points in Cartesian coordinates to obtain any parameter point in the parameter space; it has low computational complexity and high accuracy.

The random Hough transform is exceptionally well-suited for correcting tilt distortions, owing to its robust resistance to interference, small storage requirements, rapid straight-line detection capabilities, and precise correction of image-tilting issues.

The transformation relationship of the RHT is shown in Fig. 36.8, and the slope-intercept parameter equation for the straight line in the image is

$$f(x, y) = y - kx - b = 0 \tag{36.9}$$

where k represents the slope of the line and b represents the y-intercept. Taking k as the independent variable and b as a function, we obtain the expression in the parameter space:

$$b = -kx + y \tag{36.10}$$

The visible-light imaging tilt-correction process projects the tilted image onto a new visual plane. In the process of correcting tilted images, the angle size of the

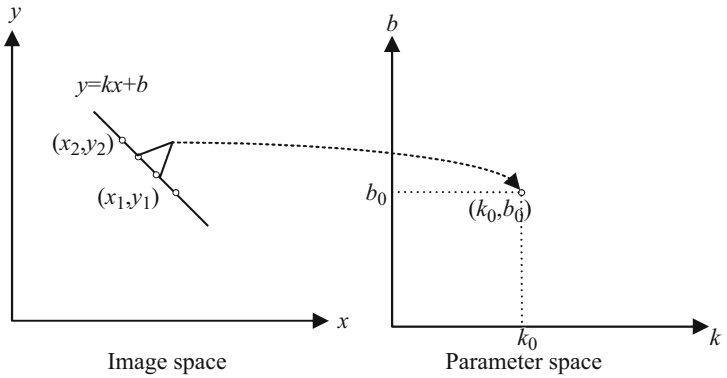

Fig. 36.8 RHT conversion relationship

image tilting can be determined, based on the frame-flag header, which improves the speed of correcting the tilted image. The tilt-correction process is as follows:

1. Because at least one data frame is present in the image, that is, at least one frame flag header, the position of the image-frame flag header is stored in dataset D.
2. Two pixel points, (x_1, y_1) and (x_2, y_2), are randomly selected from dataset D of the frame flag header.
3. From Eq. (36.10), the two pixel points, (x_1, y_1) and (x_2, y_2), selected in Step (2) can be mapped to a point (k, b) in the parameter space, and then the point (k, b) is placed in parameter set P.
4. After repeating steps (2) and (3) a few times, a parameter $y = k_1x + b_1$ in the image space can be obtained. At this point, a certain number of parameters have accumulated in parameter set P. By searching for these parameter points in P, the lines in the frame-flag header can be detected.
5. The image is corrected, based on the inclination angle of the straight line.

Figure 36.9 shows the process of correcting the tilted image angle. Figure 36.9a shows the tilted image, and Fig. 36.9b shows the image with the tilt corrected. However, the corrected image is incomplete, with missing pixels, as shown in Fig. 36.9b, and subsequent processing cannot be performed at this time.

In this study, a method was designed to fill in the missing pixels by scanning each column of pixels in the corrected image, based on the image characteristics. During this correction process, the size of the image pixels, namely, the width and height, were also calibrated; thus, the pixel size of the filled image remained unchanged, resulting in a complete image, as shown in Fig. 36.9c, which could be used for subsequent processing experiments.

When perspective or tilt distortions exist, the image at the receiving end cannot be recognized and subsequent work cannot be carried out. In this study, different correction methods were adopted, based on the different phenomena caused by these two types of distortion.

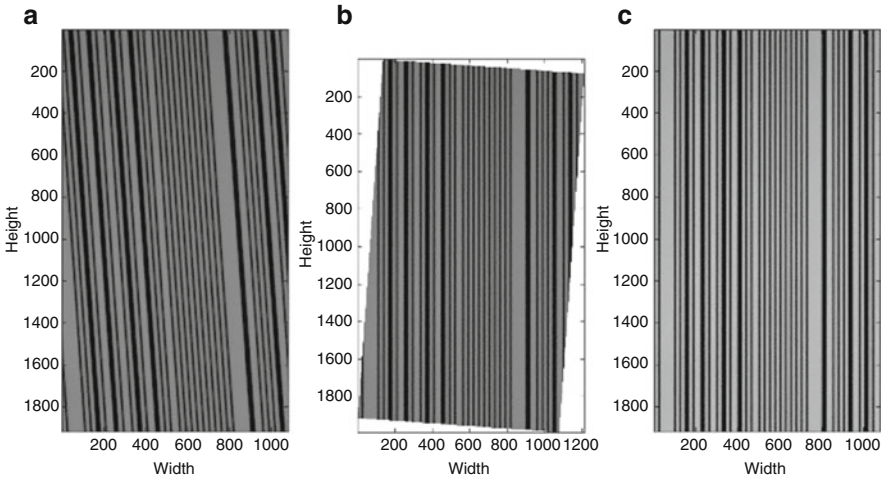

Fig. 36.9 Tilt-distortion correction process: (**a**) Tilted image, (**b**) corrected tilted image, and (**c**) complete image

Although a perspective transformation can be used to detect straight lines, in this design, it mainly addresses the perspective distortion caused by the shooting angle. The perspective-transformation method is used for correcting perspective distortion. If there is only tilt distortion caused by simple jitter, it is more suitable to use a random Hough transform because it has a lower computational complexity and higher speed.

Improved Center/Surround Retinex Image-Processing Algorithm

Center/Surround Retinex Theory

The retinex theory suggests that an image $S(x, y)$ is composed of an illumination component $L(x, y)$ and a reflection component $R(x, y)$ [49]. Its relationship is expressed in logarithmic form, as shown in Eq. (36.11). The illumination component represents the low-frequency part of the image and determines its dynamic range. The reflection component corresponds to the high-frequency part of the image and represents its essential characteristics.

The basic idea of the retinex theory in image enhancement is to remove the influence of the environment illumination component on the image and obtain the reflection component, which is the enhanced image.

$$\log S(x,y) = \log L(x,y) + \log R(x,y) \tag{36.11}$$

The real-number field formula after image enhancement is

$$\begin{aligned} r(x,y) &= \exp[\log R(x,y)] = \exp[\log S(x,y) - \log L(x,y)] \\ &= \exp\{\log S(x,y) - \log[G(x,y)^{*} S(x,y)]\} \end{aligned} \tag{36.12}$$

where $G(x, y)$ represents the surround function. The grayscale values of the pixels in an image are calculated by weighting the pixel values in the area centered on the selected pixel. The weight ratio is determined by the surround function $G(x, y)$. It is used as a filter function to calculate the illumination component in the image; a Gaussian function is generally used as the surround function. $*$ represents the convolution operation between the surround function and the original image. To expedite the computation during image processing, the convolution operation in the time domain was converted to a multiplication operation in the frequency domain.

Improved Center/Surround Retinex Algorithm

When the Gaussian function is used as the surround function to calculate the illumination component, the edge information in the image cannot be well preserved, resulting in unclear details at the image edge, which significantly affects the final image enhancement.

Accordingly, this study proposes an improved center/surround retinex algorithm to enhance the image of an optical-camera communication receiver. The specific implementation replaces the convolutional surround function with a fast scale-adaptive bilateral texture-smoothing filter. The algorithm implementation process is illustrated in Fig. 36.10. The algorithm is as follows:

1. A Gaussian function is used to extract the gradient information of the original image. The extracted gradient information is used as the information basis of the spatial-kernel box filter in the surround function to adaptively adjust the spatial-kernel width at each pixel.
2. A fast scale-adaptive bilateral texture-smoothing filter is convolved with the original image to obtain the illumination component.
3. The reflection component in the logarithmic domain is obtained from the original image and illumination components.

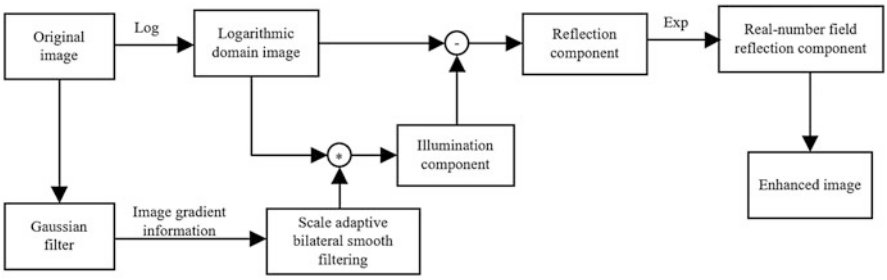

Fig. 36.10 Implementation process of the improved center/surround retinex algorithm

4. The reflection component is then converted into a real-number field and adjusted to obtain an enhanced image.

The processed image removes the influence of light noise in the environment, preserves the edge information of the image, and solves the problem of grayscale-value fluctuation to the maximum extent, both globally and locally.

An image can be decomposed into structural and textural components, in which the structural components are composed of smooth regions and significant geometric edges, whereas the texture is composed of small-scale changes. The non-uniformity of the texture components can lead to the loss of structural information, excessive smoothing, and blurring of edge information [50].

The bilateral filter uses a range kernel and spatial kernel to preserve the image-edge information while achieving a good smooth denoising effect; however, it cannot be directly used to smooth the rough texture while preserving the edge information. The scale-adaptive bilateral texture-smoothing filter can preserve the fine details and clarity of the structural components while smoothing out noise; it also clarifies the details at the edges.

The convolutional surround function $G(x, y)$ is a scale-adaptive bilateral texture-smoothing filter, and its gradient-based rules can adaptively adjust the spatial kernel at each pixel to obtain better filtering results. The range kernel provides the intensity differences in the image, preventing edge blurring and pixel mixing from both sides of the edge, which are beneficial for preserving the structure.

The formula for the scale-adaptive bilateral filter of the input image f is as follows:

$$S(i) = \frac{\sum_{j \in \Omega_i} \omega(j-i)\varphi(f(j)-f(i))f(j)}{\sum_{j \in \Omega_i} \omega(j-i)\varphi(f(j)-f(i))} \tag{36.13}$$

where $S(i)$ is the output value at pixel i, and $\omega(l)$ and $\varphi(t)$ are the spatial and range kernels, respectively.

The Gaussian range kernel is

$$\varphi(t) = \exp\left(-\frac{t^2}{2\sigma^2}\right) \tag{36.14}$$

where σ is the standard deviation of the Gaussian kernel, which determines the width of the range kernel. In the experiment, we found that when the data-transmission rate was higher, the value of σ should be correspondingly reduced to ensure that the structural edges are not blurry and the imaging is clear.

The innovation, compared with the classic bilateral filter, is that the spatial kernel uses a box filter. The window Ω_i of the spatial kernel is centered on pixel i; $|\Omega_i| = (2w_i + 1) * (2w_i + 1)$, where i is the pixel belonging to Ω_i, and w_i represents the proportion of the spatial kernel at pixel i. By adjusting the width of the spatial kernel to locally enhance smoothness, the algorithm can adaptively adjust the width of the spatial kernel at each pixel by effectively calculating the pixel scale of the input image. If pixel i is on or near the edge, a small w_i is used. If pixel i is in a uniform or textured area, a larger w_i is used.

To adaptively adjust the size of the spatial kernel for each pixel, we used a Gaussian filter to obtain the local image information:

$$G(x) = \text{gaussian}_{y \in n} \nabla f(x - y) \tag{36.15}$$

where n represents a 3×3 window and ∇ represents the gradient. Figure 36.11 shows the gradient information of the image. The filtered output image was normalized to rescale it to the range of [0, 1].

$$m(x) = \begin{cases} \min\left(0 \le G(x) \le \frac{1}{3}\right) & \forall G(x) \in \left[0, \frac{1}{3}\right] \\ \max\left(\frac{1}{3} \le G(x) \le \frac{2}{3}\right) & \forall G(x) \in \left[\frac{1}{3}, \frac{2}{3}\right] \\ \max\left(\frac{2}{3} \le G(x) \le 1\right) & \forall G(x) \in \left[\frac{2}{3}, 1\right] \end{cases} \tag{36.16}$$

From Eq. (36.17), the specific size of the proportion w_i of the spatial kernel at pixel i can be obtained, and then the size of the window Ω_i of the spatial kernel can be obtained.

$$w_i = (w_{\max} - w_{\min}) \exp\left[-\lambda m(x)^2\right] + w_{\min} \quad \lambda > 0 \tag{36.17}$$

A Fourier-expansion acceleration algorithm was adopted to implement the scale-adaptive bilateral texture filtering and raw-image convolution. The error of the approximate values of the discrete points should be within the tolerance range. Figure 36.12 shows a comparison of the image effects on the OCC receiver using the improved center/surround retinex algorithm. Figure 36.13 shows a comparison of the characteristic grayscale-value curves for processing the imaging effects using the improved center/surround retinex algorithm.

Figure 36.12a shows the original image obtained using OCC. The overall grayscale value fluctuates greatly and the image appears dark. The local

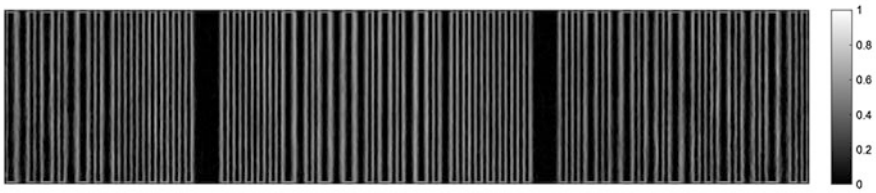

Fig. 36.11 Image gradient information

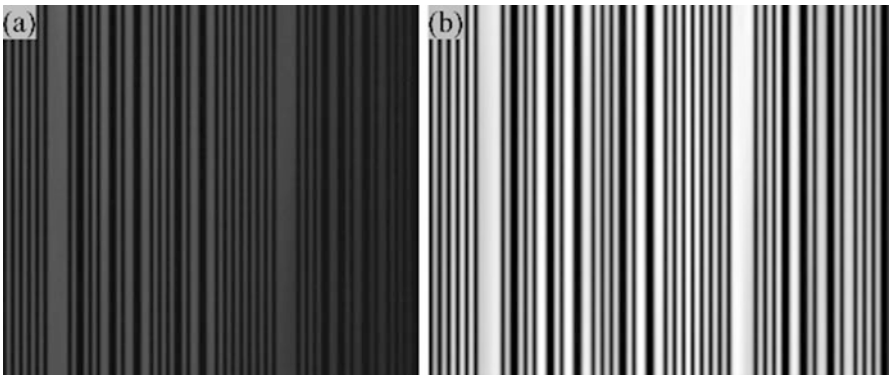

Fig. 36.12 Comparison of the image-processing effects using the improved center/surround retinex algorithm: (**a**) Before image processing and (**b**) after image-enhancement processing

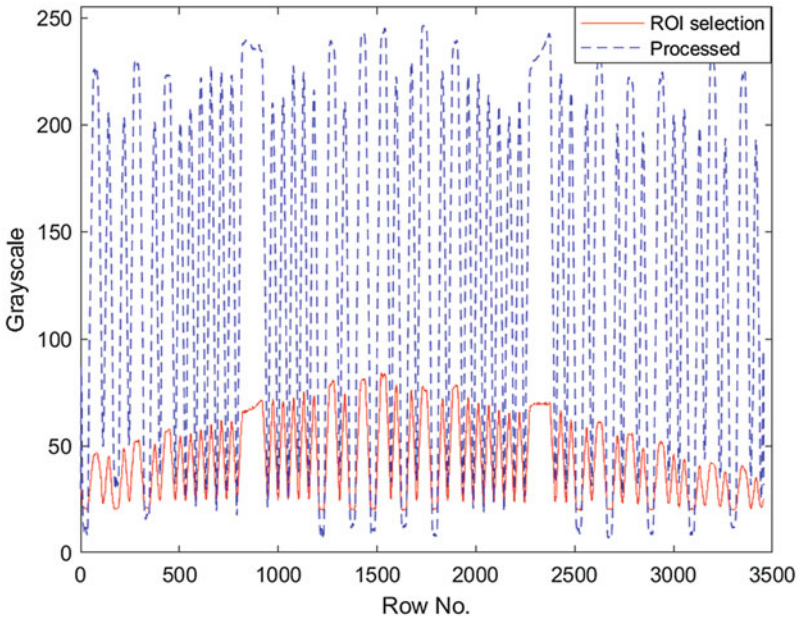

Fig. 36.13 Comparison of grayscale characteristic curves before and after image processing

grayscale values also fluctuate severely, owing to the halo effect. The blurry edges and low contrast of the bright and dark stripes seriously affect subsequent threshold decision processing.

The grayscale characteristic curve of the original image in Fig. 36.12a corresponds to the solid red curve shown in Fig. 36.13. The range of curve changes is extremely small, making it difficult to obtain accurate information using the threshold criterion. Figure 36.12b shows an image processed using the improved center/surround retinex algorithm. It is evident that the problem of fluctuations in the overall and local grayscale values of the image is resolved. The edge information of the bright and dark stripes is preserved, and the details of dark areas in the image are clearly visible.

The grayscale characteristic curve in Fig. 36.12b corresponds to the dashed blue line in Fig. 36.13. It can be seen that the distribution range and contrast of the grayscale characteristic curve processed by the algorithm in this study have significantly increased. The stripe information with smaller gray values on both sides of the image has also been improved, making subsequent decision decoding easier.

Decoding Data

A grayscale feature curve can be obtained by scanning the processed grayscale image. A simple threshold can be selected for judgment, based on the grayscale feature curve. The average of the maximum-point mean $\overline{T}_{\max}$ and minimum-point mean $\overline{T}_{\min}$ was used as the threshold for the decision to obtain a binary image, as shown in Eq. (36.18).

$$T = \frac{\overline{T}_{\max} + \overline{T}_{\min}}{2} \tag{36.18}$$

The flag-frame header should be detected to achieve synchronous reception. The bit resolution can be obtained using Eq. (36.5). The corresponding sliding window was set, based on the bit resolution, to determine the frame header. The widths of 0 and 1 of the one bit measured by the flag-frame header are W_0 and W_1, respectively, and a series of 01 is decoded according to Eq. (36.19). Then, it is decoded according to the Manchester encoding rules. Finally, the original decoded data are obtained, according to the sorting results.

$$W = \begin{cases} 0 & 0.8W_0 < W < 1.2W_0 \\ 1 & 0.8W_1 < W < 1.2W_1 \end{cases} \tag{36.19}$$

The range of W was set to $0.8W_0 < W < 1.2W_0$ and $0.8W_1 < W < 1.2W_1$ to prevent the actual measured stripe width from being poor in certain frequency bands, which could lead to a decrease in accuracy.

Experimental Results and Analysis

The bit-error rate is the most commonly used indicator of data-communication transmission quality and is influenced by various factors. As a near-field communication system, the bit-error rate of a visible-light imaging communication system is closely related to the distance and data rate of the light source.

In this part of the experiment, tilt was not characterized during the experimental phase, which means it was not a factor affecting the bit-error rate in this part of the experiment. The experiment analyzed and verified the superior performance of the improved center/surround retinex algorithm proposed in this study in eliminating global and local grayscale fluctuations, compared with other algorithms.

The experimental parameters are listed in Table 36.1. The experimental procedure is illustrated in Fig. 36.14, and the optical camera remained stable. In the experiment, the optical camera operated in the positive viewing-angle direction, and no shaking phenomena were observed. The experiment focused on two aspects:

Table 36.1 Experimental parameters

Parameter	Value			
Microcontroller	STM32F103C8T6			
Camera frame rate	30 fps			
Camera resolution	3456 × 4608			
Camera sensitivity	400			
Data cycle per bit (μs)	285	222	181	153
Data rate (kbps)	3.5	4.5	5.5	6.5
Payload bit length (bit/frame)	116	150	183	216

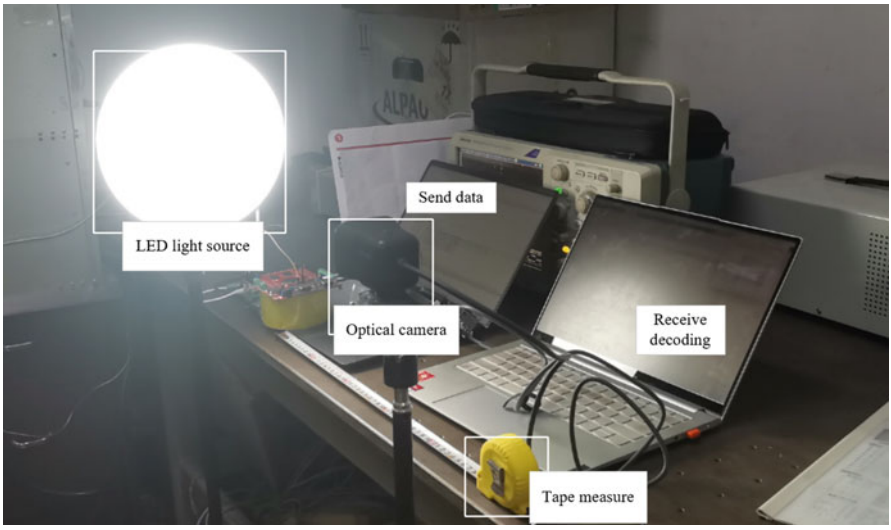

Fig. 36.14 Optical-camera communication experiment diagram

1. Different data-transmission rates at the same communication distance.
2. Different communication distances between the receiving end and the light source at the same transmission rate.

Finally, the reason why the improved center/surround retinex algorithm proposed in this study achieved good experimental results was analyzed.

Bit-Error Rate Testing

As the communication rate increases, the duty cycle of the dark stripes becomes blurred, exacerbating the extinction-ratio problem and seriously affecting the decoding. In the experiment, the transmission rate was set to 3.5–6.5 kbps, with a fixed distance of 45 cm.

The bit-error rates of the different decoding algorithms were tested, as shown in Fig. 36.15. The improved center/surround retinex algorithm proposed in this study was compared with the adaptive-contrast enhancement (ACE) algorithm [35], boundary pixels based piecewise linear function thresholding (BPBPLFT) [29],

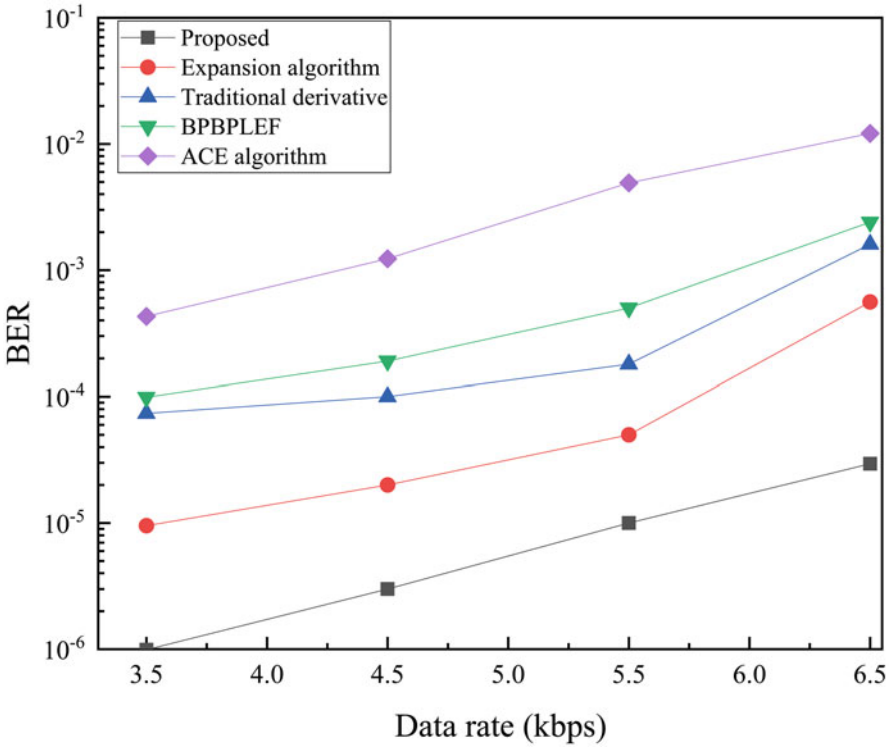

Fig. 36.15 Bit-error rates at different data rates

traditional derivative algorithm [36], and expansion algorithm [37]. The use of the adaptive-contrast enhancement algorithm and segmented linear-function threshold based on boundary pixels was limited and the traditional derivative algorithm could not obtain clear stripes when the transmission rate increased. The expansion algorithm could handle situations involving poor image quality.

As the transmission rate in the experiment gradually increased, the bit-error rate of each algorithm also increased; however, the bit-error rate of the improved center/surround retinex algorithm was always the lowest. When the communication rate was 6.5 kbps, the bit-error rate of the proposed algorithm was 2.9×10^{-5}, which is approximately one order of magnitude lower than that of the expansion algorithm.

The data rate was fixed at 5.5 kbps and the bit-error rate of each algorithm was tested within a range of 15–60 cm from the light source, as shown in Fig. 36.16. In close-range communication, as the communication distance increases, the illumination decreases, resulting in a decrease in the visible-light signal entering the CMOS sensor. Fluctuations in the overall and local grayscale values of the image received by the camera increase accordingly. The inability to obtain clear

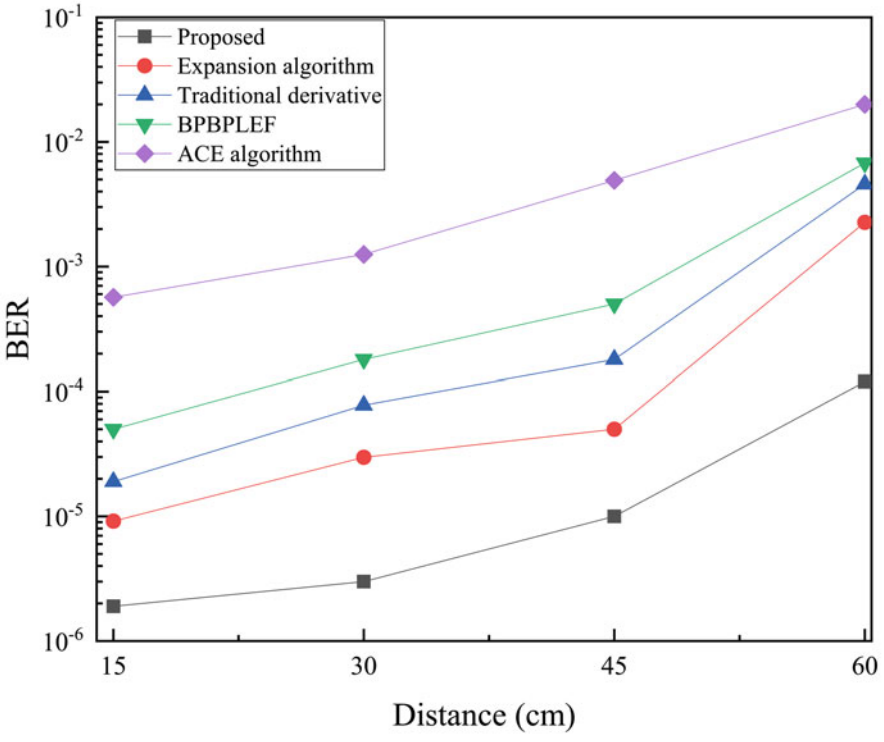

Fig. 36.16 Bit-error rates at different transmission distances

images leads to an increase in the bit-error rate, which seriously affects the decoding performance.

Based on the analysis shown in Fig. 36.16, with an increase in communication distance, the bit-error rate of each algorithm decoding increases. However, the improved center/surround retinex algorithm proposed in this study is consistently superior to the adaptive contrast-enhancement algorithm [35], segmented linear-function threshold of boundary pixels [29], traditional derivative algorithm [36], and expansion algorithm [37]. The proposed center/surround retinex algorithm has a bit-error rate of 1.2×10^{-4} at a transmission distance of 60 cm, indicating significant decoding-performance advantages.

Analysis of Experimental Results

Based on the improved center/surround retinex algorithm, the overall fluctuation of the grayscale values can be removed. Its kernel-scale adaptive bilateral texture-smoothing filter uses small spatial kernels at the edges, whereas other regions use large spatial kernels. Local smoothing removes the influence of noise, while preserving the local edge information of the image. This eliminates the problem of gray-

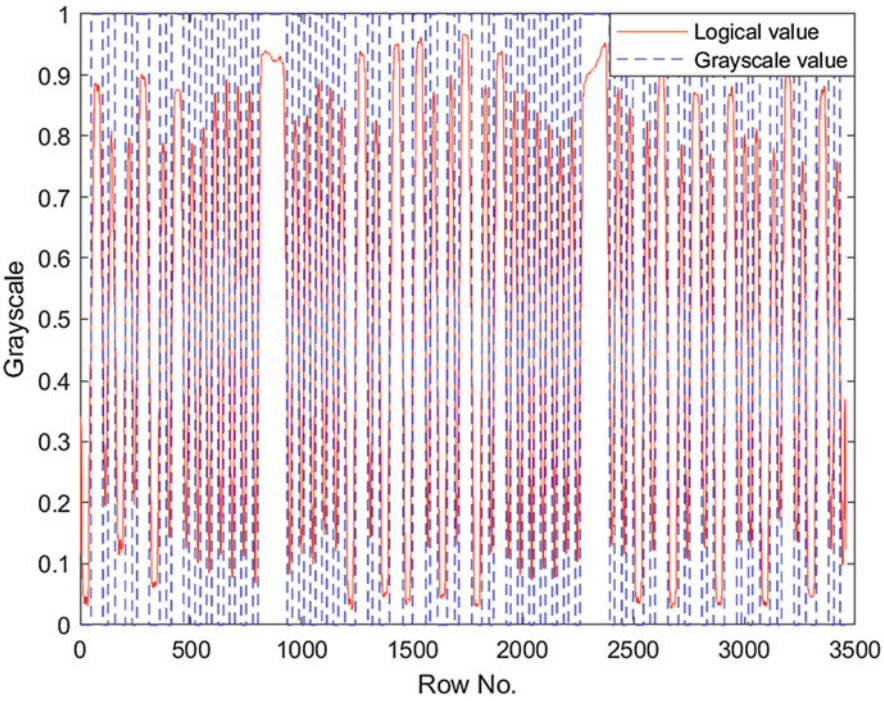

Fig. 36.17 Comparison of normalized gray values and logical values

level fluctuations caused by the halo effect and obtains an original image closest to the original transmitted data.

Subsequently, a simple threshold decision was made. The normalized grayscale values obtained using the proposed algorithm matched the corresponding logical values, and the matching effect is shown in Fig. 36.17. After obtaining a series of 01 codes, the pixel sizes of symbols 0 and 1 in the image were obtained using the frame-flag header and a decision was made. Finally, decoding and sorting produced the original transmission data.

The solid red curve in Fig. 36.17 represents the grayscale value curve processed by the improved center/surround retinex algorithm proposed in this study. The dashed blue line represents the logical value obtained from the logical-value judgment of the solid red line. It can be observed that the grayscale values correctly match the logical values. Information with smaller gray values on both sides of the image is also improved. The proposed algorithm can obtain the correct logical values to decode the data.

Conclusion

In optical-camera communication, as the system data-transmission rate increases, the number of pixel columns corresponding to the image stripes at the receiving end decreases. The traditional OCC demodulation algorithm has the disadvantage of increasing the fluctuation of the average value of grayscale pixel column with the increase of communication rate. Therefore, traditional image-processing methods produce significant errors.

At higher communication rates, the system has a higher bit-error rate, which seriously affects the communication quality. The aim of this study was to minimize the fluctuation of the grayscale values. The original data could be effectively decoded, even when the bit resolution was very small. The following conclusions were drawn from this study.

1. In response to the problems of tilt and perspective distortions, respectively caused by shaking and different receiving angles during imaging at the receiving end, corresponding correction methods were designed, based on the image characteristics, which could quickly correct the distortion problems.
2. The improved center/surround retinex algorithm simultaneously solved the problem of grayscale fluctuations in images from both global and local perspectives. The proposed algorithm eliminated the halo effect and the influence of light noise in the environment, greatly reducing the bit-error rate.
3. In the experimental verification, the improved center/surround retinex algorithm enabled the system to have a lower bit-error rate, even at higher communication rates, and was suitable for low-quality stripe images with different stripe widths, significantly improving the quality and adaptability of optical-camera communication.

Abstract

Visible light positioning (VLP) uses LED lamps for lighting to achieve indoor high-precision positioning, which has the preferences of cost-effective, no electromagnetic intermeddling, high security, and convenient deployment. In this paper, firstly, the indoor positioning system and routine visible light positioning algorithms are retrospected, and the current development status is acquainted. Then, some pivotal technologies to embellish the performance of the overall positioning system are discussed, which provides a footing for further research on the white LED indoor location system. Finally, on account of the subsisting research results, the future research direction of indoor visible light positioning technology is put forward.

Visible light communication · Visible light positioning · Indoor positioning

Introduction

At present, indoor locations mostly adopt Bluetooth, infrared, ultrasonic, radio-frequency (RF), etc., for wireless communication. Most wireless location technology is affected by the sheltering and multipath effects of buildings, and the positioning accuracy is very low in indoor environments. Thus, it cannot meet the demands of indoor location services.

Visible light light-emitting diode (LED) indoor location technology is superior. It only requires the transformation of lamps and lanterns and the addition of chips, to both light an area and provide location services. Visible light positioning technology has the advantages of low cost, green environment protection, and strong resistance to electromagnetic interference. It is very suitable for complex indoor environments, especially for obtaining accurate positions in places such as mines, hospitals, and nuclear power plants [1].

In this chapter, the key technologies to enhance the performance of indoor positioning systems are discussed because the positioning systems used in different application scenarios must meet different standard requirements, such as cost and reliability.

Visible Light Positioning Systems

A visible light LED-based indoor positioning system has the same system architecture as other positioning technologies, such as WiFi-based or Bluetooth-based systems. A typical prototype of the system is shown in Fig. 37.1.

A visible light indoor positioning system consists of two parts: one or more transmitters and one receiver [2]. Depending on the terminal location, they are divided into a photodiode (PD)-based non-imaging location system and an image sensor (IS)-based imaging location system. The system block diagram is shown in Fig. 37.2.

According to the different location methods, visible light location algorithms can be divided into geometric ranging, scene analysis (fingerprint location), proximity sensing, and image sensor imaging methods.

Geometric Ranging

By measuring the distance between the reference point and the target to be measured, the position coordinates of the object to be measured can be estimated using the geometric relation between the reference point and the target. It includes four

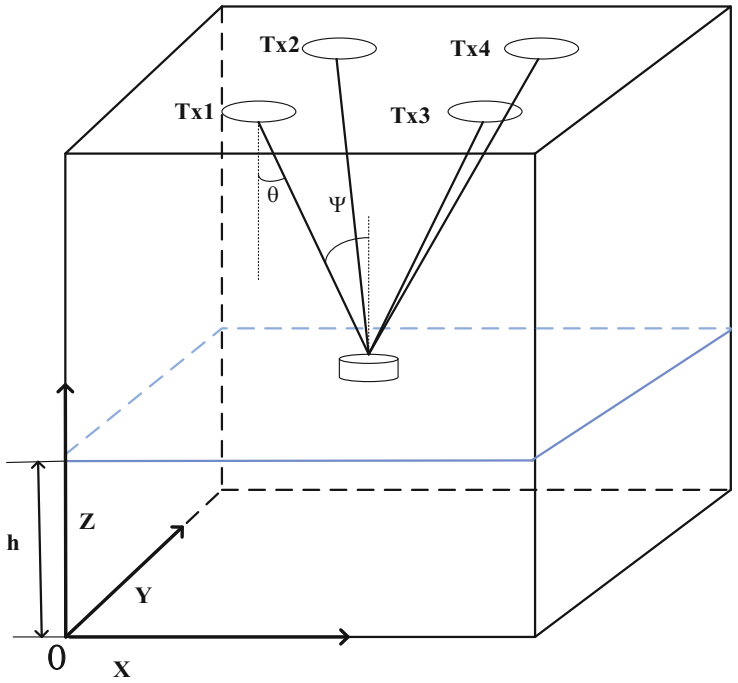

Fig. 37.1 Indoor positioning system based on LEDs

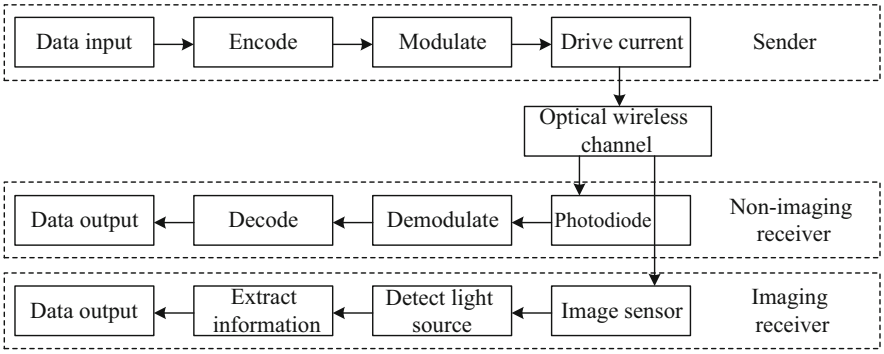

Fig. 37.2 Location system block diagram

methods: time of arrival (TOA), time difference of arrival (TDOA), angle of arrival (AOA), and received signal strength (RSS).

The TOA estimates the distance between the LED and the target, based on the signal arrival time. For visible light, the distance between the transmitter and receiver is calculated by multiplying the signal propagation delay by the speed of light [3]. The TDOA-based positioning system estimates the position of the receiver based on

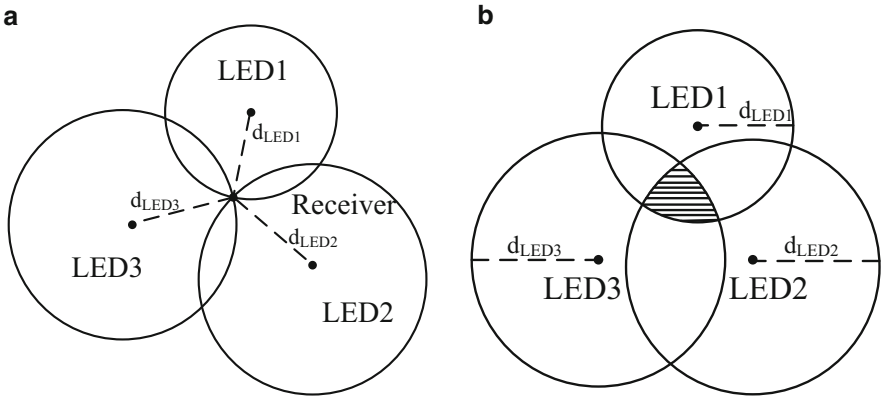

Fig. 37.3 Intersection of three-sided measurements. (**a**) Triangulation using only one intersection. (**b**) Triangulation intersecting one surface

the time difference of the arrival of signals from multiple LEDs and only requires time synchronization between the LEDs.

AOA uses known LED coordinates and the angle between the target and LED to determine the position, which requires at least two LED lights. The positioning accuracy is high for indoor locations. This method eliminates time synchronization without path loss or interference caused by the background or reflection; however, measuring the angle requires additional hardware, which is an important drawback.

RSS-based distancing typically uses direct detection in the receiver while measuring at least three known transmitter position coordinates to determine the unknown receiver location. In general, RSS follows the Lambert model. The receiver measures the strength of the transmitted signal, calculates the distance to each transmitter, and draws the possible location region based on the radius. The position is at the intersection of the three circles, as shown in Fig. 37.3a.

Owing to quantization and measurement errors, in most cases, the circles do not intersect perfectly, and the points of intersection are at the edges of the overlapping areas, as shown by the shadows in Fig. 37.3b. This intersection with a plane requires at least four LED emitters to determine unknown position coordinates [4].

Scene Analysis

Scene analysis, also known as fingerprint identification, is a non-ranging location algorithm that includes online and offline stages, as shown in Fig. 37.4. In the offline-investigation stage, specific information about the indoor environment is collected and processed. The fingerprint features include the light intensity [5], pulse response time [6], and extinction ratio [7].

In the online stage, the location of the unlocated point is estimated using a matching model, which includes three main algorithms: deterministic localization

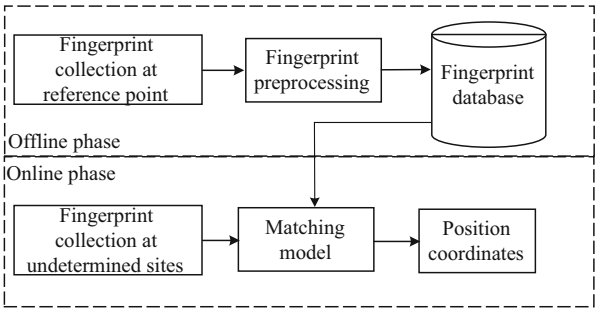

Fig. 37.4 Principle of fingerprint localization [12]

(nearest neighbor [8]), probabilistic localization (naive Bayes [9]), and neural network localization (backpropagation (BP) neural network [10]). In addition, correlation is a new fingerprint-matching technique proposed in the literature [11]; when a mobile device is closer to a specific base station, the correlation between the mix of received signals from all base stations and the transmitted signal from that base station is higher.

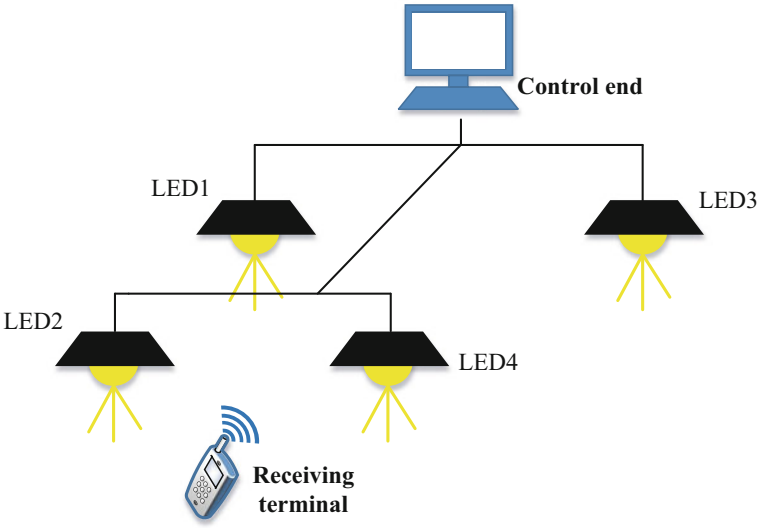
The key to the fingerprint location method is to establish a fingerprint database. The location accuracy depends on the size of the area and the degree of feature identification; however, the portability of the system is an unavoidable drawback.

Proximity Sensing

The proximity sensing method, also known as the LED method, is a rough localization method, as shown in Fig. 37.5. Each LED lamp is controlled by a terminal that emits light with unique characteristics. By comparing the light intensity of the specific signal at the receiver, the approximate position of the target can be determined according to the signal intensity [13]. This method has a simple system structure and is easy to realize, in terms of coding and modulation. This is a rough location, and its location precision is closely related to the distribution density of the transmitter.

Image Sensor Imaging

The image sensor imaging method is based on the theory of aperture imaging, with the help of image sensor parameters, and object and image point coordinates of the relative position relationship, to obtain the image sensor position information. The current receiver can use single or multiple image sensors. As shown in Fig. 37.6, the monocular camera image positioning system uses a single camera to capture images of multiple LEDs at the receiving end of the system. The position of the image sensor is determined by identifying the positions of multiple LEDs.



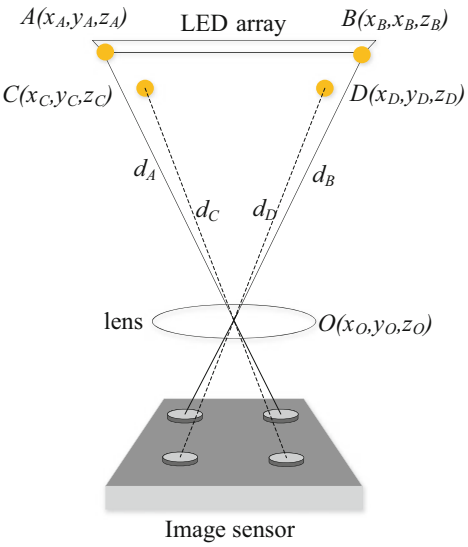


Fig. 37.5 Schematic of the LED positioning method [14]

Fig. 37.6 Location system using a monocular camera

Owing to the angle error caused by a single image sensor, some researchers use two image sensors, such as in Fig. 37.7, to determine the position, effectively reducing the angle error. The positioning accuracy is higher and more flexible; however, this method requires complex equipment and has a high cost. Some

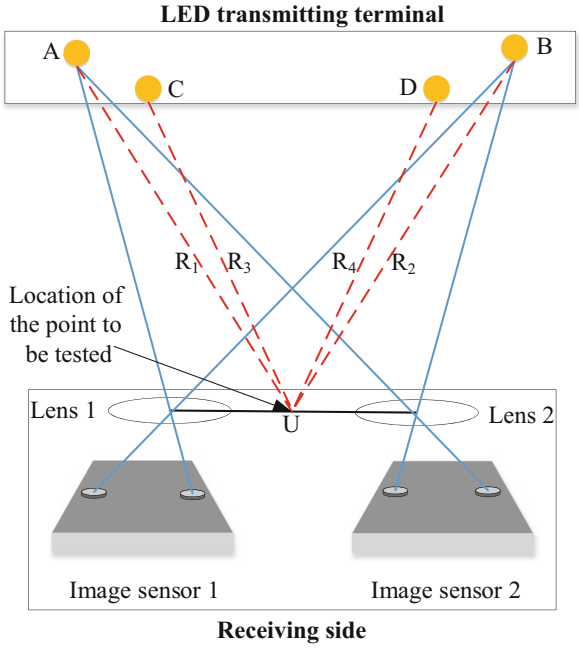

Fig. 37.7 Location system using a binocular camera [15]

researchers also use inertial sensors and other auxiliary hardware to reduce the angle error of a single image sensor.

The above discussion is for 2D positioning. It is assumed that all LEDs are installed at the same height and that the z coordinates of the receiver are known. It should be noted that when the installation error exceeds 5%, the positioning accuracy is affected; there is an error of 20 cm higher in [16]. The principles of the visible light localization algorithms are briefly described above, and the performances of these algorithms are compared and summarized in Table 37.1.

Domestic and Foreign Research Progress on Indoor Visible Light Localization

Foreign Research Progress

Since the introduction of the E-911 positioning standard by the Communications Commission in 1996, indoor positioning technology has rapidly developed [18]. In 1999, Pang [19] first proposed the theory of visible light communication (VLC) technology based on light-emitting diodes (LEDs). In 2007, the Japanese Electronics and Information Technology Industries Association (JEITA) developed the CP-1221 (VLC system) and CP-1222 (visible light ID system) standards; CP-1222 is the standard in the field of visible light positioning (VLP) [20].

Table 37.1 Performance comparison of visible light localization algorithms [17]

Method	Precision	Coverage	Cost	Multipath interference	Extra hardware	Advantage	Disadvantage
LED	Depends on the light spacing	Good	Low	Yes	No	Low cost	Low accuracy
AOA	Medium	Good	High	Yes	Yes	No bandwidth required	(1) High cost; (2) complex; (3) requires antenna arrays
TOA/ TDOA	High	High	High	Yes	Yes	High precision	(1) High cost; (2) requires precise time synchronization
RSS	Medium	Good	Medium	Yes	No	Low cost	(1) Low precision; (2) susceptible to multipath fading
Fingerprinting	Depends on the grid-partition density	Good	Medium	No	No	Low cost	(1) Requires extensive calibration; (2) map maintenance is complex
Image method	High	Good	High	No	Yes	Strong anti-interference	(1) Complex algorithm; (2) high cost

In 2010, when researchers began focusing on visible light-based localization techniques, Sertthin used a single photodiode (PD) for localization, experimented with different field-of-view (FOV) angles at the receiver, and obtained an inverse relation between the precision and FOV [21]. In 2012, Prince et al. implemented a hybrid system using the RSS and AOA algorithms that used several PDs with different FOVs between 70° and 100°. The results showed that the optimal angle was 90°, and the positioning error was 13.5 cm [22]. Thus, in VLP system design, the choice of FOV needs to be weighed against the specific model. The same is true with respect to the image sensor resolution, as shown in Figs. 37.8 and 37.9.

In 2011, Giulio Cossu implemented short-distance communication using orthogonal frequency division multiplexing (OFDM) technology, combined with a triangulation algorithm, to achieve a communication rate of 300 Mbit/s at a close range, and the feasibility of localization was presented [23]. Information systems (IS) combined with smartphones to move VLC location technology from the lab to the commercial market.

In 2013, South Korea's Renaissance Laboratory developed emart, an app for supermarkets, that provided in-store navigation for consumers. Panasonic has 200 optical transmitters on the third floor; visitors wear special receivers in their ears and connect to their phones via Bluetooth to reach their destinations, according to the arrows provided by the location app. In 2013, Sekercioglu analyzed the accuracy of VLC using the arrival time algorithm. The theoretical limit of the estimation accuracy, calculated using the Cramer–Rao lower bound (CRB), showed that the error range was 2–6 cm [24].

In complex environments, multipath reflection is an important factor affecting the accuracy of indoor positioning. In 2016, Aminikashani et al. used a deterministic and

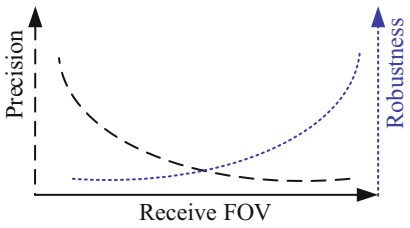

Fig. 37.8 Tradeoffs with respect to the FOV at the receiving end [11]

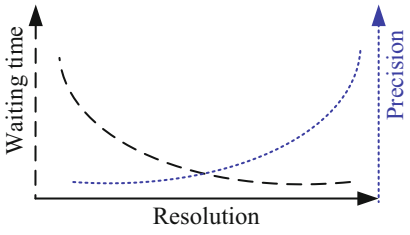

Fig. 37.9 Tradeoffs with respect to the image sensor resolution [11]

improved Monte Carlo method to calculate the impulse response to the multipath reflection effect. The accuracy of the system reached 0.558 m [25], using the calibration method to reduce the positioning error. However, the combination of very high reflectivity and thermal noise with shot noise may result in the highest signal being received as a diffuse signal in some locations. In 2019, Tran de-noised the signal and eliminated the low-intensity reflective signal using machine-learning (ML) classification and regression to improve the VLP, improving the positioning accuracy by 52.55% [26].

With the development of big-data processing technology, intelligent optimization algorithms have been widely used. In 2018, Hsu et al. first applied a neural network in a localization experiment in a visible light chamber and demonstrated continuous target tracking. The distance between the LED lamp and receiver was 2.5 m, and the average position error reached 3.65 cm [27].

In 2020, Yu-Chun proposed and demonstrated a VLP system using sigmoid data preprocessing and applied it to two regression-based ML algorithms with an average experimental positioning error of 2 cm [28]. The optimization algorithm improved the indoor location accuracy and the data-utilization rate. In 2023, Ahmed's proposed location system verified that support vector regression (SVR) was 46% better than a one-neuron neural network and 0.65% better than a 10-neuron neural network in terms of location error. They determined that it was appropriate to integrate it into mobile devices and apply it to real-life problems [29] (Table 37.2).

Domestic Research Status

In 2006, Ding et al. from Xi'an University of Technology first proposed the use of OFDM to reduce intersymbol interference (ISI) in indoor location systems based on VLC. In 2007, Koh et al. began to study LED light source layouts with minimal light-power fluctuations [30], providing a basis for visible light positioning. The LED luminescence model was important for VLP design. In 2010, a mathematical luminescence model of a general white LED was proposed. The similarity coefficient between the model and manufacturer data was more than 95%, and the model precision was high [31].

In 2014, Zhang theorized the CRB expression of the received signal strength index (RSSI) algorithm for evaluating the positioning error performance and considered the effect of multipath reflection on the positioning accuracy [32]. In 2015, Wu et al. proposed an improved RSS-based triangulation algorithm that achieved very low error fluctuations with or without occlusion, with a positioning accuracy of less than 3.5 cm [33].

In 2016, Guan applied code-division multiple access (CDMA) to indoor visible light communication, using the orthogonality of the spread-spectrum code and diversity receiver technology. The algorithm verified that more than 88% of the system positioning accuracy was within 5 cm [34]. In 2018, Ye et al. proposed the use of wavelet denoising and a cross-correlation function detection method to extract useful signals at the receiving end because of the large RSS error in measuring the

Table 37.2 Foreign research status of indoor visible light localization

Year	Researcher/ Organization	Research progress	Precision	Receiving end
1999	Grantham Pang	The theory of visible light communication based on LEDs was presented for the first time		
2007	JEITA	The CP-1221 and CP-1222 standards were established		
2010	Sertthin	The relationship between accuracy and FOV was obtained		PD
2011	Giulio Cossu	The feasibility of short-distance communication and location was proposed		PD
2012	Prince	The RSS and AOA positioning systems found the best FOV value	13.5 cm	PD
2013	Sekercioglu	Analyzed the TOA algorithm using the CRB	2–6 cm	PD
2016	Aminikashani	The Monte Carlo method calculated and calibrated the impulse response	0.558 m	PD
2018	Hsu	Neural networks first applied to VLP and tracking is realized		PD
2019	Tran	Used ML classification and regression to improve VLP	Positioning accuracy improved by 52.55%	PD
2020	Chow	Developed a sigmoid function data preprocessing VLP system	2 cm	PD
2023	Ahmed	Machine-learning approach is used in conjunction with RSS	The SVR location error was 46% better than that of a neural network	PD

distance between the receiving end and the sending end. The positioning error could be stabilized within 1 cm, and the accuracy was 10 times higher than that without treatment [35].

At present, the dynamic-location problem is seldom involved in imaging locations based on VLC. In 2017, Fang achieved an average positioning time of 22 ms by designing a lightweight image-processing algorithm that supported 5 Mbit/s real-time navigation with both positioning accuracy and real-time performance [36].

One of the biggest problems when using a camera is lens distortion, which can occur with any lens, as shown in Fig. 37.10. In 2018, Wang used camera calibration, monocular vision, and location technology to partition an indoor environment and applied a calibration process to solve the distortion problem. They achieved an average point-of-view location time of less than 5 s and a positioning accuracy of

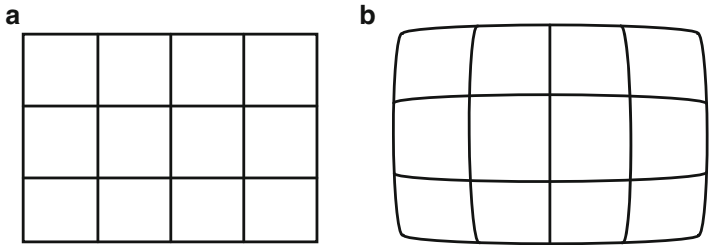

Fig. 37.10 Effect of lens distortion on an image. (**a**) Original image (**b**) Distorted image

less than 0.5 m [37]. Wang combined the advantages and disadvantages of photodetectors and camera receivers, using the photodetector to receive ID information and the camera to receive visual information; it achieved 3D positioning at the decimeter level [38] (Table 37.3).

At present, most studies on VLP systems only focus on positioning accuracy; however, robustness and real-time performance are often neglected. In 2019, Chen proposed an improved extreme learning machine (ELM) algorithm based on fingerprints, which had fast-localization and fast-learning abilities. In 2020, Chen introduced the K-means++ clustering algorithm to cluster fingerprints with similar signal strengths into one class and then used a weighted k-nearest neighbor (WKNN) algorithm to calculate the location error, to solve the problem of large errors in most indoor locations.

In 2021, Zhang proposed a clustering fingerprint location algorithm to screen out the edge area and enlarge it effectively; the edge-region error was reduced [40]. In 2022, Qin proposed to use two fingerprint databases to train two Elman neural networks to calibrate predictions. An average positioning error of 7.13 cm and average positioning time of 0.24 s were obtained [41].

Research Progress on Key Technologies

Indoor visible light localization is easy to realize; however, it is easily influenced by the outside environment, which leads to large positioning errors, including multipath reflection, inter-cell interference, and the presence of ambient light. Many researchers have focused on developing VLP systems with high precision, reliability, and reasonable costs. Next, we discuss the four main VLP technologies: LED layout, modulation, intelligent optimization algorithms, and multifeature fusion location.

LED Layout

Compared with other indoor wireless location technologies, indoor locations based on visible light must include reliable lighting to obtain an accurate location. The LED light source layout is the basis of information transmission. The LED layout

Table 37.3 Domestic research status of indoor visible light localization

Year	Researcher/ Organization	Research progress	Precision	Receiving end
2006	Ding Deqiang	VLC uses OFDM to reduce intersymbol interference (ISI)		
2014	Zhang	The CRB expression of the RSSI algorithm is derived theoretically		
2015	Wu Nan	The trilateral location method is improved, considering the LED topology	3.5 cm	PD
2016	Guan Weipeng	Applied CDMA to indoor VLC	5 cm	PD
2017	Fang Junbin	Designed a lightweight image-processing algorithm	5 Mbit/s real-time navigation	IS
2018	Wang Yong	Partitioned and applied calibration to solve the distortion problem	0.5 m	IS
2018	Wang	The PD received the ID information, and the camera received the visual information	Minutes and seconds	PD and IS
2018	Wei Yezi	Wavelet denoising and cross-correlation function detection used to extract useful signals	1 cm	PD
2019	Chen	Proposed an improved ELM algorithm based on fingerprints	0.07 m	PD
2020	Chen	Introduced K-means++ clustering algorithm		PD
2021	Zhang Rui	Filtered out and enlarged the edge area	Overall accuracy improved by 9.4%	PD
2022	Qin Ling	Trained two Elman neural networks using a fingerprint database	7.13 cm	PD

can also affect the positioning error, and the average positioning error can be reduced by increasing the LED coverage area.

In most cases, a single LED light source cannot meet the international requirements of 300 lx–1500 lx indoor illumination. Reference [42] states that the total number of LED emitters and PDs must be greater than three. If the number of used LED transmitters is greater than the number of PD receivers, a better positioning performance can be obtained. Multi-LED light sources are widely used in indoor lighting; hence, the illumination uniformity, power consumption, and communication reliability must be considered when designing LED arrays.

In the past, a large number of studies only considered the influence of a single layout model on the overall accuracy. They did not fully consider the relationship between the layout model and positioning accuracy. The signal strength of the receiver fluctuates significantly, which affects the positioning accuracy. Ding et al.

of Xi'an University of Technology [1] determined the receiving surface layout with the least optical power fluctuation in a $5 \times 5 \times 3$ m^3 room configuration. The average value was 1.5 dBm and the variance was a minimum of 0.02 dBm. Most current VLP experiments use this layout.

To meet the basic indoor illumination requirements, Shen et al. [43] determined the LED positions corresponding to the minimum positioning error of the CRB on the surface to be measured. Zhao [44] designed the $4 + 1$ LED illumination-compensation distribution mode and constructed an optimization function considering the illuminance mean-square deviation and the average bit-error rate. They obtained an illuminance uniformity of 93.23% under the optimal point and an average bit-error rate of 6.45×10^{-7}.

Guan used a new algorithm to verify that the location accuracy of an isosceles triangle was better than that of a right triangle, because the LEDs were more evenly distributed. Guan [45] compared the precision-stability interval and limit mean error of different models for the basic and dense layout models of a multilight source in a VLP system. However, it was not significant, which meant that the stability of the positioning system could be improved using an appropriate LED layout.

Compared with multiple LED layouts, LED-array layouts often achieve better positioning performance, and uniform and symmetrical light sources can provide a more stable illumination environment; however, the improvement of the positioning performance of the entire system is limited.

Light Source Modulation Modes

Light-emitting diodes are used for lighting and communication purposes; therefore, appropriate light source modulation should be used to modulate the signal containing the information to switch LEDs at the desired frequency. This means that VLC modulation methods must not only achieve data rates but also meet lighting requirements [46]. The modulation modes commonly used in visible light communication include on–off keying (OOK) [47], pulse-position modulation (PPM) [48], OFDM [49], carrierless amplitude and phase (CAP) modulation, and color-shift keying (CSK) [50]. OOK and PPM have simple structures and are easy to implement, whereas OFDM has better performance in improving spectrum utilization and overcoming the multipath effect.

In 2004, Komine et al. used the OOK scheme, but two important issues were not considered: dimming control and flicker control. On this basis, some studies combined OOK with the Manchester code, which effectively avoids continuous signals and affects normal lighting. An indoor positioning system based on PD requires multiple light sources to transmit position information; the transmitting signals overlap in the time and frequency domains, which affects the positioning performance. Therefore, the advantages of multiplexing in non-imaging VLP systems have been demonstrated.

One paper [51] proposed to use asymmetric limiting optical OFDM (ACO-OFDM), DC biasing optical OFDM (DCO-OFDM), and asymmetric limiting

Table 37.4 Performance comparison of different modulation modes

Modulation mode	Rate	Dimmer	Flicker problem	Anti-interference	Complexity
OOK	Low	Supported	High	Low	Low
PPM	Medium	Supported	Low	Medium	Medium
OFDM	High	Not supported	Low	High	High
FSK	Medium	Not supported	Low	Medium	Lower
CAP	Medium	Supported	Low	High	High
CSK	Medium	Supported	Low	High	Low

DC biasing optical OFDM (ADO-OFDM) to solve the localization error caused by multipath effects. In 2015, Xiang Yang proposed a visible light localization scheme based on an ACO-OFDM pilot signal. The positioning accuracy was improved, compared with OOK [52]. A comparison of the performances of different modulation modes is presented in Table 37.4.

Intelligent Optimization Algorithms

Research has shown that combining VLP and intelligent optimization algorithms can improve the location performance in 2D and 3D locations. Reference [53] divides the maximum-likelihood technique into four types: supervised learning, unsupervised learning, reinforcement learning, and deep learning, as shown in Fig. 37.11.

The supervised learning model with classification and regression functions is very suitable for improving positioning accuracy and reducing the computing time to meet the real-time requirements of practical applications. In the supervised learning model, common algorithms include artificial neural networks (ANNs), k-nearest neighbor (KNN), decision tree (DT), random forest (RF), and support vector regression (SVR). It has been proven that the supervised learning method is more accurate and stable than the traditional method.

The intelligent algorithms used in localization are summarized in Table 37.5. The algorithm optimization process needs to be further explored.

Multifeature Fusion Localization

In an indoor environment, a single positioning technology cannot cover all the areas, and the positioning accuracy is limited. In addition to parameter estimation using only a single attribute of the received VLC signal (e.g., TOA, RSS, or AOA), there are hybrid schemes that combine several signal attributes to estimate location-dependent parameters. Compared with traditional techniques, this hybrid approach

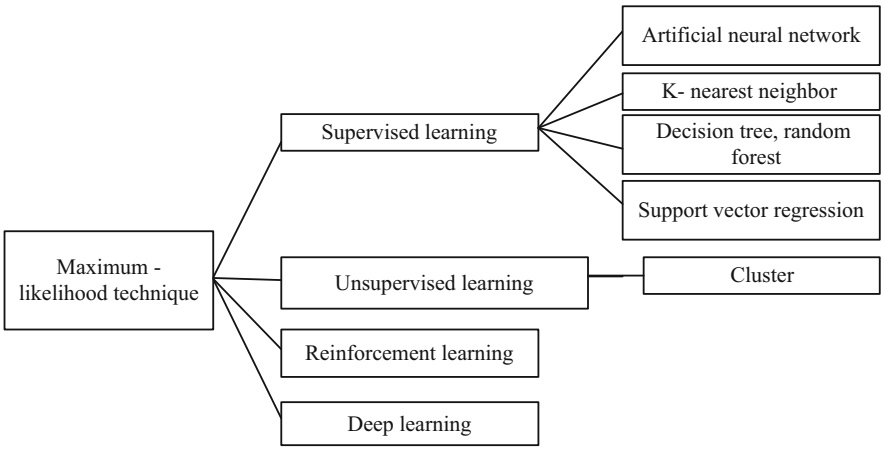

Fig. 37.11 Maximum-likelihood technique classification

may yield more accurate first-step parameter estimation by blending the advantages of each signal feature into a unified estimation framework.

In 2015, Şahin [62] studied the use of AOA–RSS hybrid information for 3D locations, owing to the limitations of the single-location method. When considering the RSS information, the AOA-based location accuracy could be improved by the least-squares method. To address the low precision of NLOS positioning, a correct filtering technology was designed and used to reduce the positioning error. In 2019, Yang [63] proposed a TOA–AOA hybrid location method based on the threshold-comparison weighting method, which used a Kalman filter to eliminate the measurement offsets generated by the signal-propagating TOA; this greatly improved the accuracy of the initial position estimation.

In 2021, Cao [64] proposed a TOA–RSS-fusion location method that used a Kalman filter, particle filter algorithm in the source range-finding phase and inertial sensors in the receiver to analyze the movement with a positioning accuracy of 2.02 cm.

The multifeature fusion location method can compensate for the non-uniqueness of a single feature and improve the location effect of the whole system; however, it increases the complexity of the system. Therefore, it is necessary to make full use of the advantages of multifeature fusion while maintaining a low system complexity.

Summary

Location accuracy, real-time performance, and robustness are three key factors of a VLP system. Current indoor location systems must improve their accuracy and anti-jamming ability based on existing theories. By modeling a complex environment, a positioning system model can be established, according to the actual environment. With the improvement in positioning accuracy, it is necessary to reduce the power

Table 37.5 Performance comparison of machine-learning-based VLP systems

Reference	Algorithm	Dimensionality	Type/size (m)	Data type	Accuracy (cm)
[57]	KNN	3D	Testing $0.35 \times 0.4 \times 0.25$	RSS	<7
[58]	WKNN	2D	Simulation $5 \times 5 \times 3$	RSS	3.4

[61]	KNN clustering and ANN	2D	Testing	RSS	90% accuracy
[29]	DT, SVR, ANN	2D	Simulation $5 \times 5 \times 3$	RSS	99.2%, 97.5%, and 96.7%, respectively
[56]	KNN, SVR, ANN	2D	Simulation $10 \times 10 \times 3$	RSS	Accuracy is greater than 95%
[26]	SVR, RF, KNN, DT	2D	Simulation $5 \times 5 \times 2.5$	RSS	SVR has maximum accuracy of 8.6

consumption and positioning system size and improve the security and privacy of users. The trends in indoor visible light positioning technology are as follows.

1. Researchers have optimized VLP systems based on the light source layout, modulation mode, and machine learning. From previous studies, it was found that a symmetrical light source has a uniform light source distribution, and the location effect is better. Modulating the light source using a multiplexing protocol

can improve the information transmission rate, and it is beneficial to distinguish the characteristic information of different LEDs. The classic geometric location method cannot satisfy the accuracy of the location system; therefore, a combination of machine learning and various intelligent optimization algorithms is the preferred choice for indoor locations.

2. The location performance of the VLP system is affected by the multipath effect. Therefore, it is necessary to reduce the noise using equalization or filtering to reduce the influence of noise on the location accuracy. It may be beneficial to design a new calibration method to improve the location accuracy of the corner and edge areas. Alternatively, a new multisensor fusion method has been studied, which is helpful for extracting multifeature signals and building a higher-precision machine-learning model.
3. Future research should focus on real-time location and tracking, 3D location, complex environment location, and microlocation systems. At present, most research is intended to localize 2D planes. Combining indoor localization systems and ML, along with the flexibility of classic and modern methods, is an important direction for realizing 3D localization. To miniaturize the system, 3D laminated-encapsulation technology must be further explored.

With the increasing demand for indoor location services, indoor location technology will be further developed. The development of new-generation communication technology will significantly promote the progress of indoor positioning technology. The application of millimeter-wave and multiple input multiple output (MIMO) technology can effectively increase the ranging accuracy and improve the anti-multipath capability of the positioning terminal. Low-cost submeter-level or even centimeter-level indoor positioning technology has become a future research trend and hot spot.

Abstract

Uplink refers to the link through which the response signal is transmitted from the receiving end to the sending end. This paper summarizes the research progress of visible light communication uplink at home and abroad, and the existing application scheme of LED visible light uplink, mainly describes the principle and scheme of RF uplink, visible light uplink, infrared uplink, power carrier uplink, and visible light uplink using reverse modulation technology. Finally, the advantages and disadvantages of existing schemes are given, and the development direction of visible light communication uplink is forecasted.

Uplink · Visible light communication · Reverse modulation · Infrared light communication

Introduction

Visible-light communication (VLC) is a type of optical wireless communication. If light-emitting diodes (LEDs) are used as the baseband signal, the light wave emitted by the white LED can be modulated so that it not only transmits light, but also transmits data [1]. As LEDs are gradually becoming the main lighting devices in the world, VLC technology has also attracted the attention of researchers, resulting in its rapid development.

Visible-light communication can solve the shortcomings [2] of traditional RF radio communication. That is, it has the advantages of a simple system structure, large communication capacity, no required spectrum licensing, and no electromagnetic radiation. It is harmless to the human body and is not subject to electromagnetic interference. It has high privacy and confidentiality, low cost, and green environmental protection. These advantages enable visible-light communication technology to be well applied in various scenarios, as shown in Table 38.1.

An uplink refers to the transmission path from a terminal device to the network. Uplinks are mainly proposed to solve the problem of network congestion and are used extensively in today's networks. Downlinks are prone to congestion, resulting in a slow network speed, while uplinks are relatively stable. In addition, a complete communication system must contain a complete two-way communication link, that is, it must include uplinks and downlinks. Downlink application technology has matured, but uplinks have consistently been a problem in two-way communication systems. Existing visible uplink schemes are mainly for radio frequencies, infrared light, and visible light.

This chapter provides a brief overview of the research status of LED visible-light communication uplinks at home and abroad, and introduces five types of uplinks: RF, visible light, infrared, power-carrier using reverse modulation, and indoor

Table 38.1 VLC communication application scenarios

visible-light. Existing schemes, principles, advantages, and disadvantages are also presented.

Visible-Light Communication Systems and Uplinks

Visible-Light Communication-System Composition

The basic structure of a visible-light communication system is shown in Fig. 38.1. It is mainly composed of sending, transmitting, and signal-receiving modules. The system transmission information flow is as follows.

First, to meet the communication requirements, the binary sequence to be sent is encoded and modulated. The modulated electrical signal drives the LED, and the LED modulates the message to be sent into an optical signal. The photoelectric detector receives the optical signal transmitted on the channel, and then transforms the optical signal into an electrical signal. The electrical signal is weak and contains high-frequency noise; therefore, signal processing is necessary to increase the signal and a low-pass filter is used to filter the noise to obtain the appropriate electrical signal. Finally, the signal is demodulated and decoded to restore the binary sequence [3].

Visible-Light Communication Links

Visible-light communication channels differ in different application scenarios. In an outdoor visible-light communication system, the system generally adopts a free-space optical (FSO) channel model [4], as shown in Fig. 38.2; when the outdoor visible light communication is carried out, the noise introduced by the complex outdoor environment and complex background light in the free space will affect the VLC system and cause the light to attenuate.

The line of sight (LOS) indicates the range within which the transmitter and receiver in a visible-light communication system can "see" each other; that is, the transmitter and receiver are within each other's field of view (FOV). For example, in an indoor visible-light communication system, the system usually adopts a direct or diffused line-of-sight communication link [1].

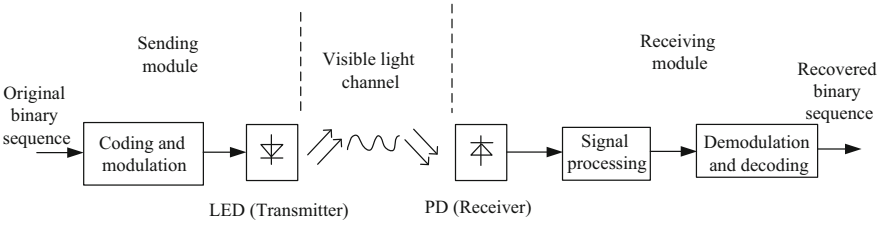

Fig. 38.1 Structure of a visible-light communication system

Fig. 38.2 Schematic diagram of an FSO system

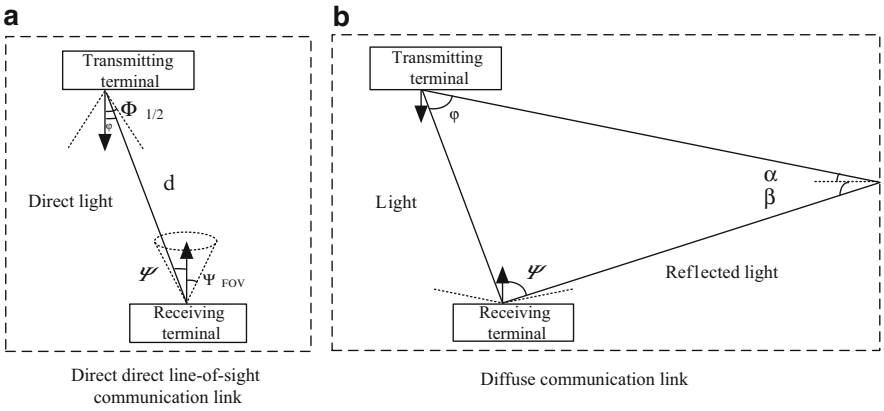

Fig. 38.3 Two types of indoor visible-light communication links

In a direct LOS link, the FOV angle between the transmitting and receiving ends is small. The two ends must be aligned with each other when communicating, and no obstacles can be allowed to block the communication link, as shown in Fig. 38.3a.

In a diffuse communication link, the transmitting and receiving ends of the FOV angle are usually relatively large, with the light evenly distributed in the room. The receiving end can receive direct light from the transmitting end and reflected light from a wall, as shown in Fig. 38.3b. In a diffuse communication link, although the FOV angle is large, the transmission process will produce a multi-path effect [1].

Visible-Light Communication Uplinks

The schematic diagram of a visible-light communication uplink is shown in Fig. 38.4. In a room, the LED hanging from the ceiling serves as the transmitter end of the communication system, and the user's personal computer (PC) serves as the receiver end. The uplink refers to the transmission path from the terminal device (mobile phone, computer, etc.) to the network, while the downlink is the transmission path from the network to the terminal device.

In the downlink, the sequence of information to be sent is first coded and modulated to produce an AC electrical signal. The optical signal emitted by the

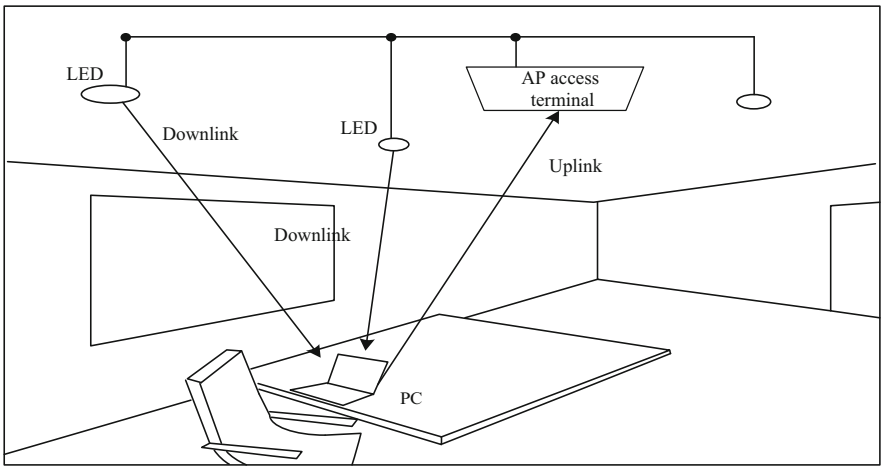

Fig. 38.4 Schematic diagram of an uplink and downlink

LED is detected by the photodetector at the receiving end through the downlink, and the optical signal is converted to an electrical signal. Finally, the original information sequence is recovered from the electrical signal.

In the uplink part, the response signal is sent by the LED driver using visible-light communication, and the signal is received by the photoelectric detector at the LED sending end, forming a closed uplink-communication link.

Uplink Schemes for Visible-Light Communication

Scheme 1: Reference [5] proposes and implements a system that uses an LED as the transceiver component of the optical communication system and can conduct real-time bidirectional visible-light communication. Both the upstream and downstream links of the scheme are visible light, and the system adopts hardware to rapidly switch between the system modes. The system adopts a time-division multiplexing (TDM) method to enable the LED to work in half-duplex mode and designed a communication-control protocol to realize the bidirectional control of the VLC system. An experimental device platform was constructed to realize bidirectional visible-light communication at a distance of more than 2 m and a rate of 8 Mbit/s.

Figure 38.5 shows how to achieve visible-light communication using a TDM channel. When two LED devices send data to each other, they occupy the channel respectively through the upstream and downstream links of different time slots for data transmission. Only one LED can transmit in the same time slot; the other LED is in the sensitive state to receive the sent data. Through channel segmentation, the LEDs can conduct half-duplex bidirectional communication.

Scheme 2: Reference [6] proposed to use an RGB-LED (red, green, and blue light-emitting diode) as the light-emitting element of the system. The blue light was loaded

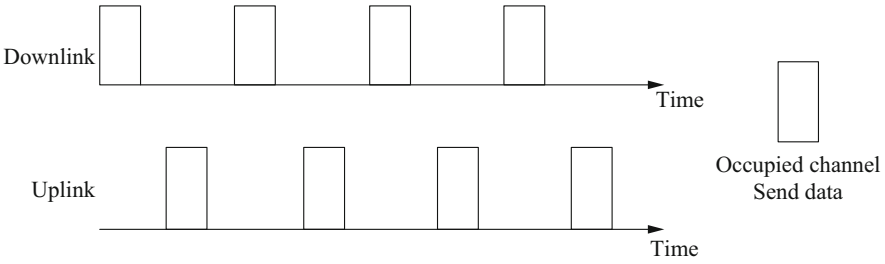

Fig. 38.5 Principle of time-division multiplexing communication in uplinks and downlinks

with a 32/64 orthogonal-amplitude modulation–orthogonal frequency-division multiplexing (32/64QAM-OFDM) uplink signal as the uplink channel of the system.

Loading 32/64QAM-OFDM downlink signals onto the red and green light channels achieved a transmission rate of 300 Mbit/s on the uplink in the 66 cm free space. By installing a filter on the front of the detector, the system can effectively suppress the mutual interference between different wavelength channels and form a wavelength-division duplex system in the visible band. The three-color LED used by the wavelength-division multiplexing technology has only three fixed channels; hence, it cannot flexibly allocate the uplink and downlink rates in the time-division multiplexing method.

Infrared Communication Uplinks

An uplink for infrared light is similar to that for visible light. As shown in Fig. 38.6, general infrared light adopts 780–950 nm wavelengths to transmit information. In early infrared communication technology, the main band of 780–950 nm light had many advantages, such as a small path loss, long-distance transmission, and a narrow infrared-light spectrum with the same emission power.

A narrowband infrared system has a better ability [7] to resist environmental noise interference than a visible light communication system. The 780–950 nm band is exactly consistent with the silicon detector peak frequency band; therefore, the advantages of high infrared detection efficiency in this band make infrared light suitable for use in uplink implementation schemes. Table 38.2 shows a comparative analysis of infrared and white LED communication in a room.

However, infrared communication also has disadvantages. Human eyes are sensitive to 780–950 nm infrared light; hence, the transmitting power must be strictly limited. Because an infrared light beam is more concentrated than visible light, it is necessary to aim more accurately when building the system. Therefore, the link quality of infrared communication will be more limited than that of visible-light communication.

In [6], Cossu et al. used an infrared LED at the sending end and an APD (avalanche photo diode) detector at the receiving end. They placed 473 nm and

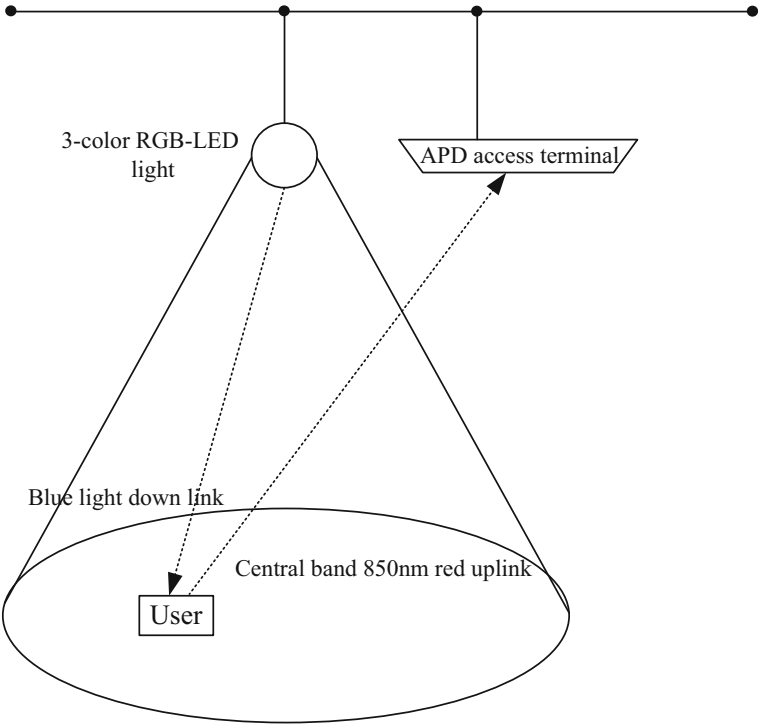

Fig. 38.6 Schematic diagram of an infrared uplink

Table 38.2 Comparison and analysis of infrared and white light in indoor wireless communication

Typical characteristics	Infrared light	White light
Signal light source	Infrared LED	White LED
Working wavelength	800–900 nm	380–780 nm
Modulation bandwidth	Tens of kHz–hundreds of MHz Tens of kHz–hundreds of GHz	Tens of kHz–hundreds of MHz
Interior layout	Additional infrared-communication light source and route must be built	Indoor circuit layout is simplified.
Shadow effect	Susceptibility to shading	Multiple LEDs can be placed to eliminate shadow effects
Transmit power	Transmit power must be limited	No limits in general

805 nm long-wave pass filters before the receiving end and the sending end, respectively, to realize a wavelength-division duplex system. The front filter effectively removed the interference between the upper and lower lines and suppressed the background noise.

The system uplink used an infrared light with an 850 nm central wavelength for communication, the downlink used the blue light channel in an RGB three-color LED, and the upper and lower links used discrete multi-tone (DMT). At the end of the experiment, 400 Mbit/s two-way optical wireless communication at a 2 m distance under 500 lx ambient light was realized.

Domestic and Foreign Research Progress on Uplinks

To address the difficulty of realizing an all-optical communication link in a visible-light communication system, Ke et al. [8] designed a scheme based on defocusing cat's-eye reverse-modulation technology. The upper and lower links of this scheme were independent of each other. They adopted quaternary frequency-shift keying and differential quadratic phase-shift keying modulation to solve the problem that the transceiver ends of a traditional single-light-source full-service communication system needed to cooperate with each other. Finally, in a 3 m data-transmission link, the downlink-transmission rate was 5 Mbit/s, and the uplink transmission rate was 2 Kbit/s. This was the first reported uplink in the field.

Qiu et al. [9] proposed a full-duplex reverse-modulation system using a single light source. The full-duplex system had two modulation processes. To achieve better full-duplex communication, the system proposed that the modulated on–off keying (OOK) signal generated by the signal generator to the light source of the optical transmitter be larger than the amplitude-modulation (AM) signal generated by the signal generator to the Modulated Retro-Reflector (MRR). This view was verified by simulation. Finally, an indoor close-range single-light-source full-duplex reverse-modulation experiment was conducted to achieve a modulation rate of 2.048 Mbit/s at the inquiry end and 2.0 Kbit/s at the reverse end.

Ding et al. [10] designed a portable optical antenna device for full duplex communication. The device uses a single chip microcomputer as the master controller and a 1W white LED and photodiode (PIN) for transmission and reception in the upper and lower communication links, respectively. The system adopted Manchester encoding for encoding and decoding and a serial universal asynchronous receiver/transmitter (UART) interface. They finally realized an up-and-down transmission rate of 115.2 Kbit/s over a 3 m transmission distance for real-time full-duplex communication data reception.

Liu et al. [11] experimentally demonstrated bidirectional transmission links using LED visible-light communication for both downlink and uplink paths. They proposed and demonstrated that time-division duplexing (TDD) could significantly eliminate reflection interference in visible-light communication. A simple OOK control was used to realize 2 m free-space bidirectional transmission.

Using a single light source, Xu et al. [12] successfully built a duplex communication system by combining internal and external modulation. The system uses internal modulation for uplink communication and acousto-optical external modulation for downlink communication, in which the downlink–uplink communication rate is up to 30 Kbit/s, and the downlink communication rate can reach up to 3 Mbit/s.

Little et al. [13], from Boston University, proposed an indoor-fusion lighting system that combined WiFi and VLC. The system used a downlink VLC channel to supplement the uplink RF communication and used a switching mechanism between the uplink WiFi and downlink VLC to dynamically allocate resources and optimize the system throughput. Experiments showed that the communication rate of the VLC downlink reached 10 Mbit/s. The communication rate of the WiFi uplink reached 30 Mbit/s.

Basnayaka [14] of the University of Edinburgh, UK, designed a hybrid system consisting of multiple VLC and RF access points. To improve the interrupt rate and coverage of each user of an independent VLC network, a simple RF-deployment method was proposed. The paper also quantified the minimum spectrum and power requirements of the RF system. As demonstrated through simulation, the method greatly improved the coverage of an indoor visible-light communication system.

Lu et al. [15] designed a full-duplex visible-light communication system that met the technical requirements of Ethernet transmissions. The system was composed of a near end and a far end. The near end used Ethernet optical cat as a terminal for sending and receiving, and the far end was connected to household equipment for transmission. The system downlink was transmitted from the near end to the remote home device and the uplink was sent from the remote home device to the near end of the interface, to complete the full-duplex communication. The upstream and downstream link signals went through the differential to the single-ended circuit, from the single-ended to the differential circuit, then from the single-ended to the differential circuit into the interface into the remote home device. Experiments showed that the system could realize 100 Mbit/s full-duplex Ethernet communication when the communication distance was 10 m.

The Disney Research Institute and Schmid et al. [16] at ETH Zurich proposed a novel approach for using VLC as a short-range, low-bit-rate wireless ad-hoc network for uplinks, downlinks, and visible-light communication (VLC). The system achieved data rates of 800 Mbit/s at a distance of 2 m. New designs for a low-complexity VLC physical layer and VLC media-access-control protocol layer were introduced, and the effectiveness of these two layers was evaluated.

Solemn et al. [17] discussed in detail the application of the visible light communication uplink scheme and proposed that radio frequency, visible light, 780–950 nm red light, and laser could be used in a visible-light uplink scheme. They presented the advantages and disadvantages of each scheme and gave the prospects. They also designed a new VLC uplink scheme using a 1550 nm laser as the carrier. The scheme used a wavelength-division duplex uplink for the 1550 nm laser visible-light downlink. Simulation results showed that, after a preliminary analysis, the uplink rate could reach 1 Gbit/s, which could be matched by the visible-light downlink rate.

Gfeller [18] established an indoor infrared communication-system model, divided indoor channels into line of sight (LOS) and non-line of sight (NLOS), and calculated their impulse response to reflect the characteristics of indoor channels. The indoor infrared communication system was simulated and analyzed.

Zhang et al. [19] proposed a full-duplex radio-over-free-space-optical (RoFSO) transmission-system architecture that physically preserved the uplink light source. The optical center carrier of the downlink double-sideband (DSB) modulated signal was extracted as the uplink light source, which reduced the system complexity.

Komine et al. [20] studied the influence of shadows and wall multipath reflections on the system in a visible-light channel transmission by adopting a time-division multiple access (TDMA) modulation mode. They obtained a data-transmission rate of 800 Mbit/s on the uplink and effectively reduced the influence of shadows on the system.

Yamazato et al. [21] introduced a feasibility study of an uplink VLC beacon system for a universal traffic-management system (UTMS) and proposed an uplink V2I system for UTMS. The system used a photodiode (PD) as a VLC receiver and a commercially available LED headlight as a transmitter. Multiple PDs with lenses were found to be effective, both for forming small communication areas and for applying bit-loading algorithms to further increase the data rate. The results achieved a throughput of 3.1 Mbit/s.

Rana et al. [22] targeted unmanned aerial vehicle–Internet of Things (UAV-IoT)-based communication networks. They proposed an uplink non-orthogonal multiple access (NOMA) resource-allocation algorithm, which provided services for IoT devices of different applications. The optimization problem was formulated under constraints, with the goal of maximizing the data rate and minimizing latency. The scheduler worked in the time domain to optimize the delay and in the frequency domain to optimize the data rate. Power allocation was used to ensure a fair data rate between users who were assigned the same resource block. Simulation results showed that the algorithm significantly improved the fairness, latency, and reliability of the system, while achieving a spectral efficiency and summation rate close to the upper limit of the system.

Alicja et al. [23] proposed a software-defined narrowband Internet of Things (NB-IoT) uplink framework in the design field, as well as its implementation and potential use cases. The framework, which could be used as an academic tool for developing, researching, and optimizing digital-transmitter paths, also highlighted the need for data-processing optimization to minimize the power consumption and resource usage of NB-IoT nodes when transmitting collected telemetry data.

Nakamura et al. [24] proposed cooperative serial-interference cancellation (C-SIC), which solved the problem of adopting uplink NOMA in multi-cell networks. When the uplink could reach multiple base stations, the signal must complete the link SIC at each base station, which reduced the network throughput. The final conclusion was that the SIC processes of different base stations were transmitted through a backhaul link through a combination of signals. Compared with conventional NOMA, it was found that C-SIC could promote the application of uplink NOMA to multi-cell networks.

Kim et al. [25] proposed a spatial-reuse method for uplinks, which used basic-service-set (BSS) color and proximity information to improve the efficiency of carrier perception and thus improved the spatial reuse. Simulation results showed that proximity-based sensitivity control for uplinks (PSC-UL) was comparable to

overlapping BSS/preamble detection on traditional OBSS/PD. The overlapping basic service set/preamble-detection uplink method considerably improved the throughput.

Rosenthal et al. [26] proposed a differential quadrature phase-shift keying (DQPSK) backscatter uplink for a neural brain–computer interface (BCI) as an alternative to active radio. The uplink achieved a throughput of 25 Mbit/s when operating in the 915 MHz industrial, scientific, and medical (ISM) band.

Cahyadi et al. [27] experimentally demonstrated an indoor uplink near-infrared LED camera communication mechanism called an Internet call center (ICC). It used near-infrared (NIR) light as the communication medium and a camera as the receiver, which differed from past studies, which only focused on positioning research. The ICC provided a practical positioning method for uplink indoor wireless communication. It used camera receivers to provide wider coverage and accurate indoor positioning in IR communications.

Kandeepan et al. [28] proposed an exponential waveform modulated optical wireless communication (OWC) uplink where each waveform was treated as a virtual transmitter. Additional data were transmitted via the index of the selectively activated virtual transmitter, and increased the OWC uplink speed while achieving similar bit-error rate (BER) performance. The exponential waveform modulated uplinks were experimentally demonstrated in NIR OWC systems. The results showed that the proposed waveform-index modulated uplink could achieve a data rate of up to 15 Gbit/s, which significantly improved the data rate under similar power and BER conditions.

Yun et al. [29] analyzed a VLC link, the characteristics of the VLC channel, and visible-light demodulation technology in detail. They simulated an OOK modulation and demodulation scheme and an orthogonal frequency-division multiplexing (OFDM) modulation and demodulation scheme. The simulation results showed that both technologies could be used as indoor visible-light modulation technologies. To reduce the influence of intersymbol interference (ISI) caused by high-speed data transmissions, the OFDM modulation and demodulation scheme was selected, which could be used for indoor lighting and high-speed data transmissions. Finally, an implementation scheme for VLC modulation and demodulation was given, which laid a theoretical foundation for further experimental research.

Ke et al. [30] from Xi'an University of Technology proposed a multi-dimensional coding method of a visible light communication system with a multi-primary LED modulated by PPM, which could effectively improve the spectrum utilization rate and small time-slot error rate of visible light communication. Finally, the hardware platform of an indoor visible light communication system with an RGB3-color LED was constructed, and a multi-primary LED was used for multi-dimensional coding. The experiment realized 1.5 Mbit/s video communication at a 3 m distance.

Song et al. [31] proposed a new cost-effective single-frequency network (SFN) video-broadcast system-design scheme based on the deep integration of a programmable logic controller (PLC) and VLC. This scheme greatly reduced the complexity of the VLC network protocol and provided better information coverage. In the

following year, they studied the PLC-VLC system channel problem, and analyzed the PLC-VLC system channel as a whole for the first time.

Chen et al. [32] detailed the current research status, key technologies, application scenarios and development trend of visible light communication with white LEDs, in which the literature gives that the future visible light communication must contain a complete two-way communication link, and gives two scenarios in which the RF uplink and VLC form a converged system with power carrier and RF.

Ke et al. [33] comprehensively introduced visible-light LED communication technology, the basic principle of LED-device luminescence, the optimal-position deployment of LEDs in an indoor VLC system, the array design at the receiving end, and three link-configuration methods at the receiving and sending ends of the VLC system. Moreover, they presented the bottleneck faced by VLC-technology research institutes.

Zhang et al. [34] proposed a full-duplex communication system using a dual-wavelength emission mode. The system adopted a 1530-nm laser-communication light source in the forward link and 1550 nm laser-communication light source in the reverse link. The optical signals between the forward and reverse links did not interfere with each other, which effectively improved the communication rate of the reverse link. Moreover, the system simplified the complexity of the full-duplex MMR communication system. The simulation results showed that the communication rate reached 1 GHz and the communication distance was 300 km. The link communication margin was greater than 5 dB, and the bit-error rate was better than 10^{-15}.

Duan et al. [35] proposed an uplink signal transmission in the general model of a multiple-input multiple-output (MIMO) system to remove cellular mass. Based on an analysis of the TDD and frequency-division duplex (FDD) modes, the source of pilot pollution in the system running in TDD mode and the classification of the effect function in power optimization were observed. Using partial minimum mean-square error (MMSE) signal-detection technology and access-point selection technology, the spectrum-efficiency expression of the system uplink was derived. To improve the system's spectral efficiency, the pilot-allocation algorithm was designed first, and then the pilot-power and data-power maximum–minimum optimization problem was modeled.

Liu et al. [36] studied a type of Ethernet mutual-integration technology for LED VLC. The technology integrated LEDs and Ethernet through an optical-communication medium-conversion module. The system used wired media as the downlink and wireless media as the uplink. Finally, an experiment on mutual-convergence network communication was conducted. The experimental results showed that the data transmission between each client in the fusion local area network (LAN) could be very good, and the communication rate could reach 1 Mbit/s.

Sun et al. [37] proposed and designed an Ethernet communication system to solve the problem of transmitting uplink and downlink Ethernet signals without

modulation. They built a test environment to conduct a 10 m distance network-communication test with both uplink and downlink transmission rates of 100 Mbit/s.

Based on the original indoor VLC network, Feng et al. [38] used a combination of VLC and laser communication to realize an indoor wireless-communication LAN. They considered whether the uplink should be a laser instead of visible light, or whether visible light should be used for the downlink. The system optical code-division multiple access (OCDMA) technology used optical orthogonal code (OCC) as address codes to encode and transmit signals. The performance of the system before and after the improvement was compared and analyzed. The simulation results showed that the system performance was obviously improved, compared with the traditional system where both the upper and lower links are visible.

Zeng et al. [39] discussed the application of VLC and related business scenarios of telecom operators. They proposed a fusion system using visible-light and base-station back-transmission; that is, radio-frequency propagation was used in the downlink, and visible light was used in the uplink. The transmission performance of the fusion system was analyzed. In the R8 version of a long-term evolution (LTE) network, the system bandwidth was 20 MHz. The downlink rate was 100 Mbit/s and the uplink rate was 135 Mbit/s.

Zhu et al. [40] proposed the use of relay technology in VLC, which could solve the problem of link occlusion in VLC technology. The role of a relay in the system differed in the upper and lower links. The relay node in the downlink was mainly to assist the source node to forward information. The role of the relay node in the uplink was to reduce the transmission power of the light source and reduce the damage to the human eye.

Wang et al. [41] proposed a new uplink-scheduling algorithm that solved the problems of poor fairness and high packet-discarding. The algorithm established a target integer linear-programming model according to the delay constraints of real-time services, and then scheduled according to the target integer linear-programming model. Simulation experiments were conducted in which the method was compared with the dynamic Hungarian algorithm with modification (DHAM). The performance fairness of DHAM was improved without sacrificing the MAC-layer throughput.

To improve the uplink, Wu et al. [42] studied the user-association and inter-cell interference problems. For the user-association problem, the advantages and disadvantages of each method were presented, and a new uplink-interference mitigation technology was proposed, which mitigated the co-channel interference through a dynamic distributed power-control scheme. To solve the inter-cell interference problem, an improved inverse frequency-multiplexing scheme was proposed. The purpose of this scheme was to solve the spectrum-allocation problem, so that the uplinks of users in densely distributed areas could be distributed to different frequency bands for uplink communication. This simultaneously increased the distance of users in the same frequency, reduced the interference of users in the same frequency, and increased the utilization rate of the spectrum. Finally, the effectiveness of the dynamic distributed power-control scheme and the improved inverse frequency-multiplexing scheme was verified by simulation.

Komine et al. [43, 44] proposed a fusion system, then presented the overall structure of the fusion system, and conducted a qualitative analysis of power-line communication (PLC) and VLC channels.

Amirshahi et al. [45, 46] evaluated the performance of integrated power-line and visible-light communication systems using turbo-coded OFDM. They analyzed PLC channels, VLC channels, and channel noise.

In 2015, Song et al. [47, 48] analyzed the integrated channel of a fusion system, and adopted a series PLC channel, VLC channel, LED equivalent channel, and other forms to create a fusion-system channel-analysis model [49].

RF Uplinks

Wireless-network data consumption is growing dramatically, owing to the growing demand for mobile services and applications. RF communications using deployed networks are characterized by shared media, limited available spectrum, and limited ability to scale. Directional communications, including visible-light communications, can limit contention in controlled environments. If properly distributed, they can provide massive aggregated data capacity [50–52] in indoor scenarios. As Internet-Protocol (IP) data traffic tends to increase wireless usage and video streaming, the limitations of deployed RF technology will become apparent.

Traditional wireless-communication systems use radio frequencies as the carrier for information transmission; however, visible-light communication can still use radio frequency as the uplink [53–55]. To solve the VLC uplink problem in the physical layer (PHY), researchers have studied other heterogeneous schemes, such as power-line communication (PLC) and visible-light communication (VLC) fusion systems, WiFi and visible-light communication fusion systems [56], etc.

Visible-light communication has advantages that radio-frequency communication does not; however, it is not without disadvantages. In outdoor environments, owing to environmental and sun lighting, visible-light communication systems will be subjected to background noise. Moreover, with indoor VLC, because light cannot penetrate walls, each room in a building will need to set up access points to ensure that it can use visible-light communication. Table 38.3 [57] shows a comparison of the main features of radio-frequency and visible-light wireless communication systems.

In summary, both VLC and RF communication have advantages and can be used as alternative uplinks. An optical wireless communication system is more suitable for indoor applications with short distances, high throughput, and low mobility, while RF-wireless communication systems are suitable for long-distance environments with high mobility.

Composition of an RF–VLC Two-Way Communication System

The sending and receiving ends of a hybrid RF–VLC visible-light bidirectional communication system are shown in Fig. 38.7. The complete system includes a downlink visible-light communication link and uplink RF communication link.

Table 38.3 Comparison of the main characteristics of optical and radio-frequency wireless communication systems

Media characteristics	Radio frequency	Optical communication
Bandwidth is limited	Yes	No
Can traverse through walls	Yes	No
Multipath fading	Yes	No
Multipath distortion	Yes	Yes
Path loss	High	High
In-band noise source	Other-user interference	Background noise

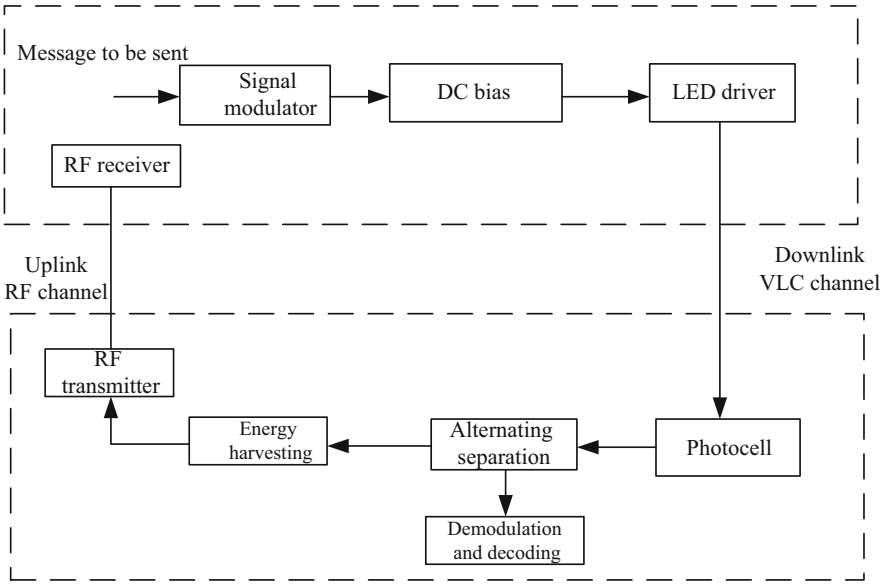

Fig. 38.7 Block diagram of an RF–VLC system

On the downlink, the transmission information sequence is coded and modulated to generate AC electrical signals, and then a DC bias is added to ensure that the output signal of the drive LED is non-negative. The LED emits a light signal through a direct line-of-sight channel using the receiving end of the photocell detection; then, the light signal is converted into an electrical signal that is separated into DC and AC components by AC and DC separation. The original information sequence is restored by the AC component and the DC component is used for energy collection.

The uplink part uses the electrical energy collected during visible-light communication to drive the RF transmitter to transmit the response signal and is received by the RF receiver at the LED sending end to form a closed uplink communication link.

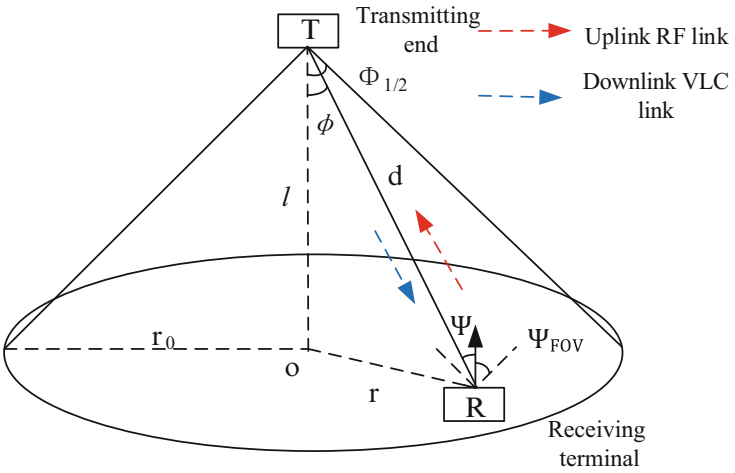

Fig. 38.8 Downlink VLC and uplink RF communication links

Uplink RF Communication-Link Channel

Figure 38.8 shows how the system achieves bidirectional communication in an indoor environment. We assume that there is only one pair of sending and receiving ends in the entire system. The sending end T is in the ceiling, the power half-angle of the LED light source is one-half, and the LED can cover the communication range delimited by the cone in the figure, with height l and bottom radius r_0.

The receiving end R can occur randomly at any place on the bottom of the cone, and it is distance r from the center O of the bottom surface. In the communication process, the sending end first sends the message to the receiving end through the downlink. When the receiving end successfully receives the signal, the collected electrical energy is used to drive the RF device to send the response signal, which forms an overall two-way communication system.

WiFi–VLC Communication System

At present, WiFi uplinks have become the mainstream of RF uplinks. The omnipresent and omnidirectional characteristics of WiFi can be easily used as uplinks; hence, WiFi and VLC fusion communication systems have become mainstream, especially if VLC can be used to reduce the congestion on an RF uplink as a heterogeneous network. Indoor wireless local-area networks (WLANs) are currently the most widely used and deployed, and the most mature technology is the WiFi protocol, that is, the IEEE 802.11-series protocol.

Existing mobile terminals have more installed WiFi modules, and WiFi hotspots have been generally deployed; however, with the increasing number of users, the collision probability and the waiting time of retreating into the

channel are also increasing. Consequently, the visible-light communication system can be used to carry downlink data, and WiFi is used for uplink data. Visible-light communication is a line-of-sight (LOS) link. If the receiver and LED emission source are blocked by obstacles, WiFi can also provide a downlink transmission for a short time to ensure the quality of service (QOS). Thus, the deep integration of visible-light communication and WiFi has been realized and a heterogeneous network is formed.

However, an RF uplink also has some drawbacks. For example, an RF uplink will interfere with the existing system, and occupy the already-crowded spectrum resources. In addition, electromagnetic radiation results when a radio frequency propagates upward. This electromagnetic radiation cannot be allowed in electromagnetic-sensitive environments, such as gas stations, hospitals, and ammunition warehouses. It also greatly reduces the confidentiality of visible-light communication.

At present, the design scheme of an indoor VLC-WiFi network usually depends on the VLC deployment. When planning and deploying indoor lights, the actual needs of the indoor-light users must be fully considered when the complete house design begins. Moreover, the indoor light intensity must meet the international lighting standard of 300–1500 lx [58]. Otherwise, the indoor light is too strong or too weak and may have an impact on human-eye health.

The simple model of the VLC system with the mixed WiFi and VLC uplink is shown in [59] Fig. 38.9. The user's uplink is taken care of by the WiFi-access or APD-access end, and the user's downlink is taken care of by VLC. The ellipses show the communication range of each LED, and the communication range of the WiFi and VLC covers two LED lights. The WiFi access end, APD access end, and VLC end are connected to the external network through wired mode. The WiFi access end

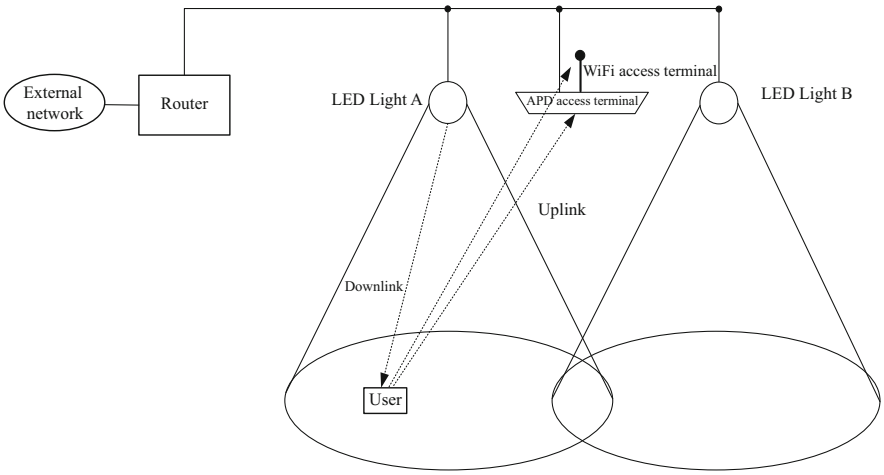

Fig. 38.9 WiFi–VLC system model diagram

and the infrared access end broadcast their respective loads and other relevant information to the VLC end in wired mode.

Power-Carrier Uplinks

Power-line communication (PLC) technology refers to using medium- and low-voltage power lines to transmit data, voice, and other signals. Its advantage is that the coverage is large, the first line is dual-use, and all types of electrical appliances can directly act as network terminals. PLC for internal home networking has mature standards and products and provides a strong competitive solution to solve the "last 300-m/100-m" problem [60].

Power-line communication uses a power line as a channel. Using the principles of spectrum shift and frequency-band division, after one or several modulations, the original signal is moved to a specific frequency band, which is conducive to its transmission in the channel. That is, the signal needing to be sent by the sending end is modulated by power-line modulation technology and then passes through the coupler so that the high-frequency information carried in the signal can be sent in the power line.

After the signal is transmitted to the receiving end, the modulated signal is removed by the coupler and demodulated to obtained the required communication signal. Power-line connections can directly use existing 220 V or 380 V low-voltage power lines as a communication medium to meet the needs of residential communication, but they also can be used in [60] family, office, and other local area networks.

The natural integration of PLC and VLC makes it more convenient for indoor visible-light communication to access the Internet. A PLC–VLC fusion system has good performance and does not require additional wiring; hence, it is widely used in power systems (including smart grids), Internet of Things, and digital homes [61]. However, when the indoor visible light communication system uses an LED as a wireless transmitter, it is necessary to eliminate the problem of information island [62].

PLC–VLC-Fusion Communication-System Structure

At present, a PLC–VLC fusion has two main fusion modes. First, the signal loaded on the power line is demodulated and amplified and then loaded on the LED; this is the decode-forward amplify-forward (DF/AF) mode [63], as shown in Fig. 38.10. In the figure, DF demodulates the signal transmitted on the power line, while AF amplifies the signal transmitted on the power line.

The second mode is the deep fusion of PLC and VLC; that is, the PLC signal is directly loaded onto the LED, without modulation, decoding, or amplification, as shown in Fig. 38.11. An APD is used in the receiving end of both fusion systems to convert optical signals into electrical signals [64].

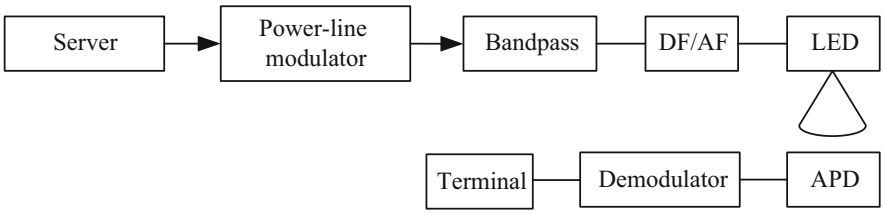

Fig. 38.10 DF/AF fusion method

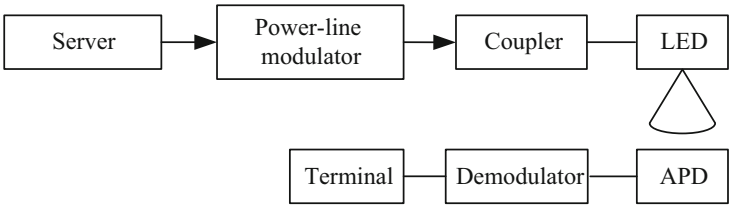

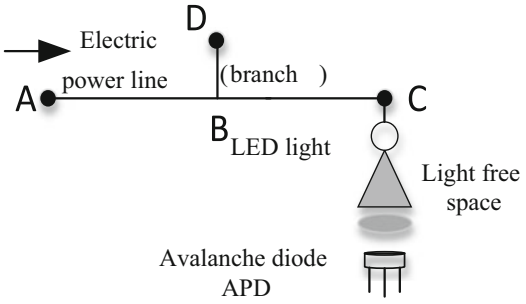

Fig. 38.11 Deep-fusion method

Fig. 38.12 Channel structure model of a PLC–VLC fusion system

Channel Model of a PLC–VLC-Fusion Communication System

Figure 38.12 shows the channel model [65] of the fusion system. The system mainly includes PLC, LED-sending, free-space, and APD-receiving parts. The transmission process is as follows. The signal is first loaded onto the power line, and transmitted to the LED through the power line. Then, the LED converts the electrical signal on the power line to an optical signal and then transmits it. Finally, the APD restores the optical signal to an electrical signal during reception, and the communication is complete.

PLC–VLC-Fusion Communication-System Scheme

At present, there are three PLC–VLC fusion system schemes [66], as follows.

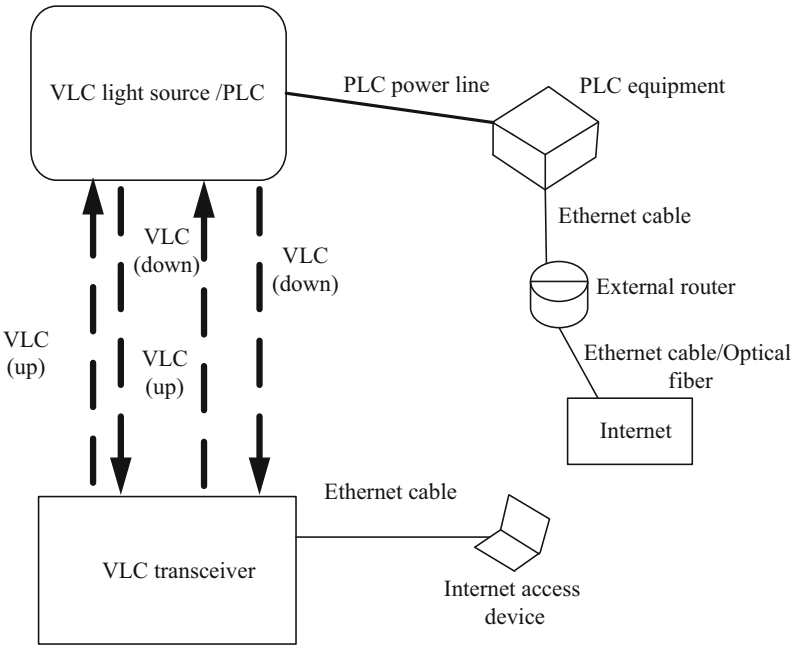

Fig. 38.13 Scheme 1: VLC fixed-position transmission schematic diagram

Scheme 1: The VLC is in a fixed position. Specifically, a special VLC transceiver is arranged below the VLC light source to enable the VLC transmission to be completed from a fixed position. As shown in Fig. 38.13, any Internet access device is connected to the VLC transceiver through an Ethernet cable, and VLC upstream and downstream communication is completed between the VLC light source and VLC transceiver. The VLC light source and external network port device are connected through the PLC device.

The advantage of this plan is that the Internet equipment does not need to be modified; it only needs to access a network line to be connected to the Internet. The earliest VLC and PLC combination scheme is the simplest, and requires the fewest equipment changes [67].

Scheme 2: VLC fixed-point transmission. In this case, multiple VLC devices are equipped with VLC transceivers and can communicate simultaneously with the VLC light. Figure 38.14 shows that several VLC devices can share a VLC light source in the same room. The scheme can also be generalized to have multiple VLC light sources in a room. The VLC light sources can be networked and communicate through a PLC power line, and users can use the nearest VLC light source for Internet communication.

Scheme 3: VLC down, PLC up. As shown in Fig. 38.15, indoor VLC equipment can be uplinked back through the PLC, which effectively reduces the optical-signal interference caused by the light emitted between VLC devices.

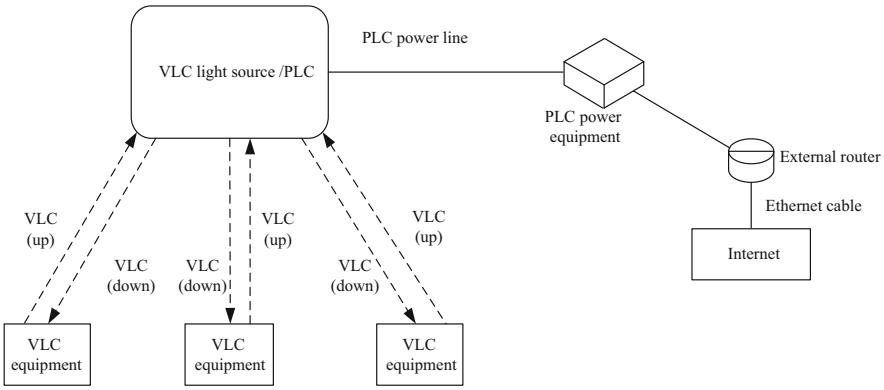

Fig. 38.14 Scheme 2: VLC fixed-point transmission

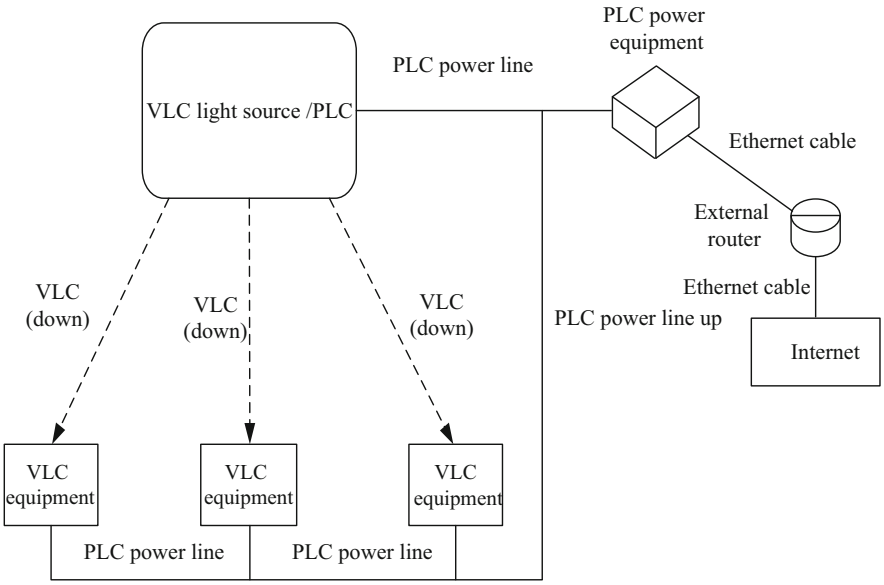

Fig. 38.15 Scheme 3: VLC downlink, PLC uplink

Uplinks with Reverse-Modulation Technology

Downlink application technology tends to be mature; however, the uplink problem has always plagued bidirectional communication systems. The existing visible-uplink solutions are mainly RF, infrared light, and visible light. Other solutions contain drawbacks. For example, the RF-uplink confidentiality is poor and it cannot

be applied in electromagnetic-sensitive environments, such as gas stations, ammunition depots, and nacelle.

Most visible-light and infrared-light uplink structures are more complex. Moreover, the mobile light source carried by the mobile terminal brings more interference, causes discomfort to human eyes, and other problems. Applying reverse-modulation technology to a visible uplink removes the need for an additional light source, as well as the need for a spectrum license. It also ensures human-eye safety, has other inherent advantages, and greatly reduces the complexity of the system structure [68].

Commonly used reverse modulators (modulating retro-reflectors (MRRs) [8]) are angle reflector and cat's eye MRRs. The angle-reflector MRR includes an angle reflector and light modulator. The transmission-type light modulator arranges the angle reflector into the pupil position to change the reflected-light signal strength to achieve reverse modulation. A cat's-eye MRR is composed of a focusing lens and modulating reflector. The modulating reflector is placed in the focal plane of the cat's-eye reverse reflector, and uses reflector-reflectivity or reflector-defocusing changes to control the intensity of the reflected light, to achieve reverse modulation [69].

Structure of a Reverse-Modulation System

The indoor visible-light single-source full-duplex communication system in Fig. 38.16 consists of two parts: the active end and the reverse end. The active end of the system is generally fixed to the ceiling and is responsible for sending information while lighting the room. The reverse end is generally arranged on various types of terminals, and is responsible for providing return data after receiving the downlink information transmitted by the sending end.

The active terminal consists of an Ethernet card, field-programmable gate array (FPGA), analog-to-digital convertor (ADC), digital-to-analog convertor (DAC), LED driver circuit, photoelectric receiving circuit, and signal-processing circuit.

The reverse end includes a defocusing cat's-eye reverse modulator and drive circuit, photoelectric receiving circuit, ADC/DAC circuit, FPGA master module, Ethernet card, etc.

The current shortcoming of reverse-modulation technology applied in the uplink is that the transmission rate is low; however, this technology has the advantages of a simple system, no harm to the human body, no need for a spectrum license, etc. Consequently, reverse modulation has great development potential in the future.

Reverse-Modulation Uplinks

An uplink is a reverse communication link from the reverse end to the active end. Figure 38.17 shows the structure diagram of a reverse communication system. The reverse communication link takes the cat's-eye reverse-modulation system as the

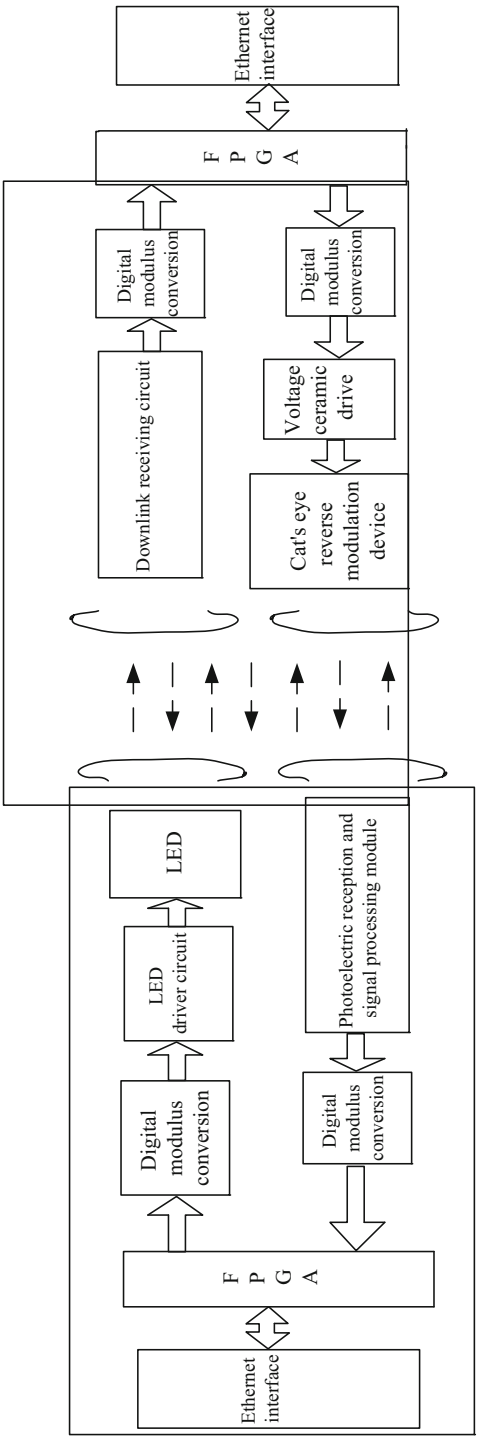

Fig. 38.16 Overall structure of the single-source full-duplex communication system

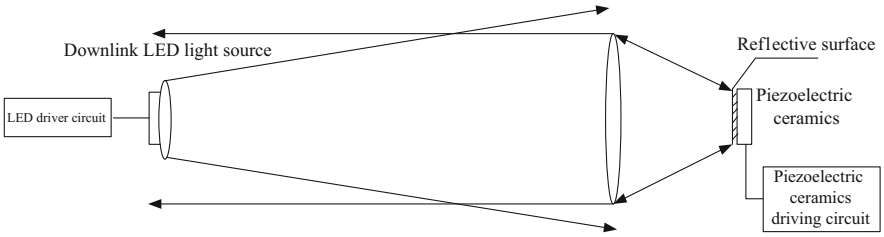

Fig. 38.17 Structure diagram of a reverse-communication system

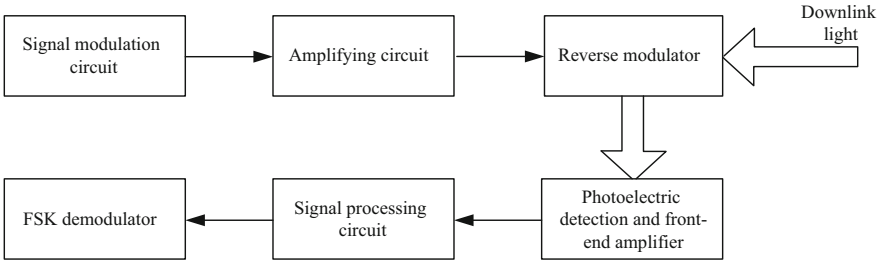

Fig. 38.18 Schematic diagram of the uplink

core. The defocusing cat's-eye reverse modulator includes an optical lens, piezoelectric-ceramic plate, modulation drive circuit, echo receiving circuit, etc.

During the working process, the active end must transmit the modulated light signal to the reverse-modulation end. Owing to the large divergence angle of a white LED beam, the focusing lens of the reverse end and the cat's-eye reverse modulator must be arranged side by side. They are both located in the effective illumination range of the LED light source.

In the reverse transmission, the downlink light signal first goes through the secondary modulation of the reverse modulator, modulates to the downlink light path, and reaches the active end through reflection. At the active end, the optical receiver receives the back optical signal, and after demodulation and processing, the original data information is obtained to complete the duplex communication.

The uplink hardware [68] is composed of a cat's-eye reverse modulator, drive circuit, and signal-receiving circuit. Figure 38.18 shows the block diagram of the uplink.

Summary

This chapter introduced the advantages and disadvantages of existing uplink schemes, as shown in Table 38.4.

Table 38.4 Advantages and disadvantages of common visible-optical communication uplink schemes

Type	RF	Visible light	Reverse modulation	Infrared light	Power carrier
Advantages	Mature system, communication links can be masked, and large channel capacity	Simple system structure, large communication capacity, and no need to design an uplink system	System structure, no need for a spectrum license, ensures the safety of human eyes	Mature system, simple structure, single, low system cost	Long transmission distance, strong anti-interference ability, high infrastructure utilization rate
Disadvantages	Incompatible with existing systems, RF interference exists, and occupies spectrum resources	Uplink light is visible to the human eye, has a visual impact, and limits the applications	Low transmission rate	Short communication distance, low communication bandwidth, the human eye is sensitive to infrared light, and poor security	Low transmission rate, low security

The prospects of visible uplinks are very broad, and further research in the future includes the following:

1. Researchers should investigate the matching degree of uplink and downlink transmission rates and improve uplink transmission rates and distances to meet the needs of different scenarios.
2. Researchers should investigate combinations of uplinks and other technologies, such as a heterogeneous network system combining visible light as the downlink and WiFi as the uplink, and full-duplex communication systems in which both uplinks and downlinks use VLC to improve the uplink-transmission performance and reliability.
3. Researchers should consider the application of reverse-modulation technology in the uplink scheme, because it ensures the security of the human eye and simplifies the system structure.
4. Researchers should apply uplink technology to life, such as Internet of Things, Internet of vehicles, drones, industrial automation, smart homes, mobile communication, and other fields.

Abstract

In the indoor visible light communication system, in order to ensure that many users in different directions can get better communication quality and achieve uniform optical power coverage on the receiving surface, it is necessary to reasonably optimize the layout of the light source. Reasonable light source layout design can achieve stable signal transmission, improve the signal-to-noise ratio of the transmitted signal and reduce inter-symbol interference, and help to improve the communication rate. This chapter briefly describes the proposal, development, and

Introduction

At present, the scarcity of wireless-spectrum resources requires a more efficient and secure communication method. Optical-communication technology is gradually replacing traditional wireless-communication methods, owing to its high signal-to-noise ratio, fast modulation rate, good confidentiality, and other advantages. Visible-light communication (VLC) has become a hot spot. Visible-light communication technology can transmit information while lighting a room and solves the problems of broadband access and high-speed data transmissions [1–6].

Most existing VLC technologies use white light-emitting diodes (LEDs) as the signal source. In an indoor environment, each LED can be used as an optical access point, and multiple LEDs in a room can constitute an optical cellular wireless network [7]. Because the coverage of a single LED is limited and cannot meet the lighting and communication requirements of all users in a room, the LED layout becomes very important in VLC systems. A reasonable layout can distribute the light sources evenly, improve the signal-to-noise ratio of the transmitted signal, reduce inter-code interference, and greatly help to improve the data-communication rate [8].

Visible-Light Communication Systems

Principle of Visible-Light Communication Systems

In indoor VLC systems, visible light is used to transmit information. LEDs, which are commonly used in daily life, are often used as light sources [9]. Visible-light communication systems use light that is visible to the human eye, with wavelengths between 380 nm and 780 nm, for data transmission [10, 11], as shown in Fig. 39.1.

A visible-light communication (VLC) system consists of a modulation module, driver circuit, LEDs, channel, optoelectronic conversion module, circuit amplifier, equalizer, judgment circuit, and other modules.

The signal is modulated and converted into a form suitable for transmission to the driver circuit. The role of the driver circuit is to perform an electrical/optical

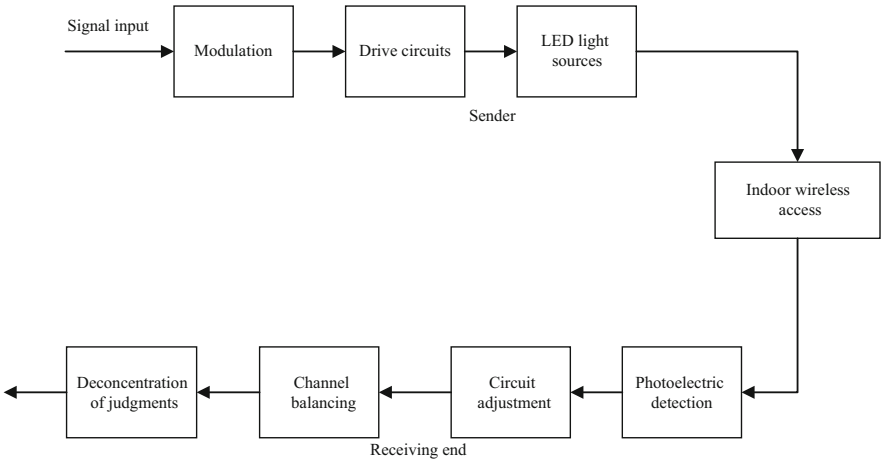

Fig. 39.1 Block diagram of an indoor visible-light communication system [12]

conversion on the modulated signal, provide the appropriate drive-current size, and load it onto the LED light source. The light signal is then transmitted through an indoor wireless channel. The photodetector receives the visible-light signal from the light source and converts the light signal into an electrical signal under illuminated conditions, enabling the information to be recognized and processed.

The VLC-system LED light source radiates illumination following the Lambert model, with radiant energy at a directional angle of

$$I(\phi) = I(0)COS^{m}(\phi) \tag{39.1}$$

where m is the Lambert factor. $I(0)$ is the light intensity when the relative angle between the light source and receiver is 0°, at which point, the total energy of the light source, P_t, can be expressed as

$$P_t = 2\pi I(0)\frac{1}{m+1}. \tag{39.2}$$

The expression for the Lambert factor m in the above equation is

$$m = -\frac{1}{log_{\,2}\,cos\left(\phi_{1/2}\right)} = \frac{-In2}{In\ cos\left(\phi_{1/2}\right)}. \tag{39.3}$$

The optical gain of an ideal nonimage concentrator with an internal refractive index n can be expressed as

$$g(\theta) = \begin{cases} \dfrac{n^2}{\sin^{\,2}(FOV)} & 0 \le \theta \le \text{FOV} \\ 0 & \theta > \text{FOV} \end{cases} \tag{39.4}$$

FOV is the field of view of the receiving device and θ is the light angle of incidence. The strength of the received energy determines the quality of communication in a VLC system. The channel characteristics affect the received field of view and the angle of incidence of the incident light, as well as parameters such as the transmission power and receiving area of the photodiode. To ensure stable visible-light communication, the VLC channel model must be analyzed.

Channel Model and Light-Source Layout for Visible-Light Communications

Indoor visible-light communication systems have LEDs and receivers installed at different positions and angles. Figure 39.2 shows a model of the most significant indoor line-of-sight and non-line-of-sight links.

In an indoor VLC system, signals are transmitted and received through three processes. However, owing to obstructions, such as walls and partitions in the room, the transmitter transmits the signal to the receiver through two different channels.

In the first channel, called a direct-vision link, the optical signal is sent directly from the transmitter to the receiver, without being obstructed by obstacles. The advantages of a direct-vision link are that it has strong anti-interference performance, its bandwidth is relatively high, and it can support high-speed data transmissions. However, a direct-vision link limits the locations of the transmitter and receiver.

Some signals cannot reach the receiver directly from the transmitter, but are obstructed by obstacles during transmission. This type of channel is called a

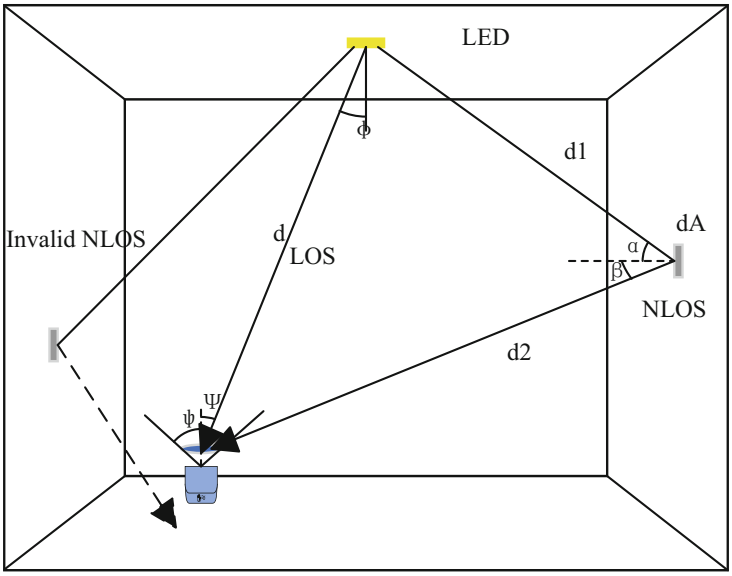

Fig. 39.2 Indoor VLC channel model [13]

non-direct vision link. Owing to the poor transmission path of a non-direct vision link, the receiver must receive direct light from one of the LED light sources to reduce the communication and illumination blind spots [14].

Therefore, the light-source layout of indoor VLC systems should be optimized, to achieve the necessary illuminance distribution and ensure the required receiving-power distribution. The layouts of VLC-system light sources can be divided into indoor-communication layouts, vehicle-communication layouts, and customized layouts for special occasions with special needs, according to the actual requirements. They can also be divided into LED lamp-bead layouts and relative light-source position layouts, according to the research objective.

This chapter summarizes the layout and design methods for VLC-system light sources and compares different research results to illustrate future research directions and development trends.

Domestic and Foreign Research Progress on VLC Light-Source Layouts

Researchers have optimized and improved the layouts of light sources in VLC systems such that the optimized layout meets both the light-illumination and communication-quality criteria. The broad improvement options include geometric layouts, and using intelligent optimization algorithms for light-source location and parameter optimization.

Geometric-Layout Methods

In 2004, Fan et al. [15] designed a square light-source layout in a 5 m × 5 m × 3 m room. They analyzed the differences in the light paths of multiple LEDs using different layout methods and investigated the differences between direct and non-direct links in the room. The effects of the LED layout on the signal-to-noise ratio (SNR) and transmission rate of the VLC system were investigated. Although this layout improved the illumination of the indoor light source, it lost a large amount of energy from the light source. Simple position optimization is not sufficient for stable communication; therefore, researchers have introduced multi-lamp-source models.

In 2006, Sivabalan et al. [16] analyzed the effects of multiple LED light sources on the power distribution and channel bandwidth. The results showed that a uniform light-intensity distribution was obtained when multiple light sources were used in a room. The key to this was the locations of the light sources. The optimal light-source locations were symmetrically distributed throughout the room, with respect to the floor and ceiling.

In 2007, Ding and Ke from Xi'an University of Technology [17] proposed a model for the layout and transmission of light sources for indoor optical communication. They analyzed the relationship between the layout and received power

distribution of the system, calculated the DC gain, and arrived at the optimal layout for using four LED light sources in a room. However, as this was the initial stage of indoor optical-communication research, only the direct-light case was considered, for the convenience of the simulation experiments, which had significant limitations.

In 2010, Nguyen et al. [18] devised a column-array layout to replace the common light-source layout method with LED light sources as the center point. The array had a high offset rate at all locations of the walls in the room to create a blind-spot-free indoor data-transmission range. Although innovative, the communication performance and appropriate number of central LEDs were not investigated in depth.

In 2012, Siwamogsatham et al. proposed a system that transmitted multiple beams simultaneously in a uniform circular-array layout with a transmitter source that finally converged for the output. They created a multiple-input single-output beamforming system with a tunable optical transmitter in a uniform circular-array layout [19] to achieve higher channel capacity and better transmission performance.

In 2013, Chen [20] designed a novel layout model that ensured illumination while reducing the number of LEDs. By focusing on the non-direct-vision link characteristics and the factors that created multipath effects in the system, this study ensured the system reliability while improving the uniformity of the illumination and reception rates.

In 2016, Wang et al. [21] proposed an elliptical distribution layout based on the room aspect ratio in a 5 m $\times$ 4 m $\times$ 3 m indoor space. The LEDs were reasonably arranged according to the room size to prevent performance degradation, owing to coverage blindness in indoor VLC systems. The simulation results showed that the elliptical LED layout better improved the communication quality.

Chen [22] proposed a double-button-line light-source layout for same-size rectangular rooms to solve the problem of uneven illumination and poor communication quality in the system, using the same number of LEDs. However, this optimization was not supported by mathematical theory, and the lower received power in the corners of the room, compared to the center, led to a reduction in communication quality.

In 2017, Zhao and Peng [23] proposed a 4 + 1 layout, based on the traditional layout, and optimized the original layout. The 4 + 1 layout method needed to consider other aspects, in addition to light uniformity and communication effects.

In 2017, Chen and Garg et al. [24, 25] presented quadrilateral and hexagonal LED-layout methods to improve indoor visible-light coverage. However, they only considered the number of LED positions in a specific environment and did not provide the specific positions and layout numbers of the LEDs; thus, this method was not universal. In 2017, Zhao et al. [26] developed a new layout array and constructed a model consisting of a five-LED array. This scheme reduced the energy consumption of the system.

In In 2017, Wang and Che et al. [27] designed a new circular-layout scheme for a square room. This method enabled the communication system to consume less energy and achieve the best communication effect, with a minimum number of LEDs. The scheme proposed in this study overcame the limitations of the original idea and made the design more flexible.

In the same year, Zhao and Song et al. [28] proposed a scheme completely different from the conventional layout. They used a central-compensation scheme consisting of five arrays, where the considered usage scenario was no longer a square room but a narrower indoor space. After the simulation, it was concluded that the center-compensated structure was the best solution to satisfy both the lighting and communication requirements.

In 2018, Zhao et al. [29] used a 4 m × 4 m × 3 m room as a model and established a ring light-source layout with a single LED array and a light strip under the original array-layout model using the light-intensity compensation principle. This paper proposed a scheme for the layout of ring light sources that considered the communication quality while ensuring the uniformity of the light intensity. It provided an effective optimization method for light-source layouts for indoor visible-light communication.

In 2019, Sharma et al. [30] proposed four types of LED patterns in a defined-size indoor room: diagonal, horizontal centerline, horizontal and vertical lines, and finally, two diagonal lines. They concluded that the two-diagonal design provided the maximum emitted power.

In 2019, Chen et al. [31] proposed a square-array plus circle layout, which consisted of four $N \times N$ squares and m LEDs arranged in a circle. Compared to the traditional square-array layout, the optimized layout had 48 fewer lamp sources. Moreover, the uniformity was improved after using the principle of minimum-illumination mean-square difference for power distribution.

In 2020, Jiang et al. [32] proposed a ring-angle-compensated array light-source layout to study the layouts of array light sources with different arrangements. This method effectively improved the illumination, received power, and signal-to-noise ratio at the receiving end. It also enhanced the signal quality, which was beneficial for the implementation of high-speed VLC systems.

In 2021, Wang et al. [33] proposed the minimum mean-squared error principle to design a circular-layout scheme. Based on this, two types of layouts, circular and rectangular, were used to simulate the received-power distribution and signal-to-noise ratio distribution. The received-power distribution of the non-direct-view link outperformed that of the direct-view link when the number of LEDs was the same; however, the reflection from the wall surface reduced the signal-to-noise ratio. This study provided a new concept for light-source layouts for indoor VLC systems and establishing indoor VLC links (Table 39.1).

Light-Source-Location Optimization Methods Based on Intelligent-Optimization Algorithms

In 2009, Cao et al. [34] proposed an improved particle-swarm optimization (PSO) algorithm. The algorithm effectively avoided the problem of easily falling into local extremes and reduced the accuracy of the optimization calculation when the number of particles remained constant. The algorithm could effectively optimize the layout when there were multiple light sources.

Table 39.1 Research progress in geometric-layout methods

Year	Researchers	Study content	Progress
2004	Fan et al.	Square diode layout, and differences in channel characteristics between different layouts	Derived the effect of different light-source layouts on data-transfer rates
2007	Ding	Developed a transmission model for indoor optical communication based on four LEDs. Analyzed the system layout in relation to the received power distribution	Optimal layout of four LED light sources based on a DC-gain design
2010	Nguyen	Used f an array layout with a high offset ratio	Layout enabled data to be transmitted without blind spots
2012	Siwamogsatham	Uniform circular-array layout with multiple beams emitted simultaneously from the source	Achieved a higher channel capacity and more stable transmission performance
2016	Wang	Proposed an elliptical distribution model based on room aspect ratios	Used an oval LED layout for better communication quality
2016	Chen	Proposed a lemniscate layout suitable for rectangular rooms	Lemniscate layout had a higher uniformity of illumination than other layouts, ensuring uniformity of communication and illumination
2017	Chen	Proposed quadrilateral and hexagonal LED layout methods to improve indoor visible-light coverage	Solved the light-coverage problem in specific environments, but was not universal
2017	Wang	Designed a new circular layout in a square room	Enabled communication systems to consume less energy and achieve the best possible communication with the minimum number of LEDs
2018	Zhao	Modeled the layout of a ring light source with single LED arrays and light strips	Provided communication quality with guaranteed light-intensity uniformity
2019	Chen et al.	Proposed a layout model of a square-array plus circle	Illumination requirements of the room were met with an improved mean-square and uniformity
2020	Jiang et al.	Proposed a ring-angle compensated array light-source layout	Improved illumination, received power, and signal-to-noise ratio at the receiving end; also enhanced signal quality

In 2013, Guan et al. proposed a single-LED layout scheme and an array LED-based layout scheme [35] to obtain an optimal light-source layout scheme, and improved the layout scheme using PSO algorithms. The results showed that the proposed LED-layout method based on the PSO algorithm outperformed the random method.

In 2015, Fu [36] used a genetic algorithm to optimize the position of light sources and reasonably designed an adaptation function. The results showed that the illumination uniformity on the receiving surface reached 97.4% after optimization. The uniformity was improved; however, the distribution of light-source positions was too dispersed for practical use.

In 2016, Nicolas K et al. [37] established an analytical model for the optimal layout of light sources using a novel downhole positioning algorithm that improved the accuracy of the position by controlling the number of light sources and providing a reasonable position layout.

In 2016, Gao [38] proposed a light-source layout for a VLC system in a spacious lighting environment. They analyzed the VLC system-design scheme, adjusted the layout while reducing the number of LEDs in the array, and used a combination of simulated annealing and genetic algorithms to optimize the light-source positions to achieve uniform lighting and communication stability. However, this algorithm was based on the overall optimization of the position, making the searched position highly random. The light-source distribution was not aesthetically pleasing and had low practicality.

In 2016, Ajmani et al. [39] proposed a novel algorithm that estimated the position of a receiver relative to a reference light source when the receiver received signals from multiple LEDs. The optimal beam radius between two LEDs in this array was derived by analyzing parameters, such as the room size, number of light sources, and spacing.

In 2017, Liu and Wang [40] proposed the use of a genetic algorithm for gene density to arrange the layout of a specific room and obtain an ideal power distribution by optimizing the layout of the light-source locations. This algorithm calculated the light-source distribution scheme by itself; therefore, it could be very effective in avoiding manual errors or ideological limitations.

In 2018, Liu [41] proposed a novel light-source layout scheme to improve the signal uniformity of indoor visible-light communication. The method was optimized using a hybrid particle-swarm algorithm to improve the communication performance of the system.

In 2019, Zhai et al. [42] proposed an LED lighting-layout optimization scheme using an artificial fish-swarm algorithm to investigate two different light-source layout methods: rectangular and elliptical. By minimizing the power variation of the receiving surface as the objective function and optimizing the position of the LEDs, an optimal LED-layout pattern was obtained. Further improvements were made to the power coefficient of the LEDs.

In 2020, Liu et al. [43] proposed a light-source layout model based on a multiple-swarm genetic algorithm, which was developed based on a traditional genetic algorithm to find the optimal LED light-source location information. The results showed that the optimized light uniformity reached 91.73% and the illuminance range was 889–1009 lx. Both of these were significantly better than those based on the traditional layout model under a genetic algorithm. Thus, this provided a new reference method for LED light-source layouts.

Ma et al. [44] used particle-swarm algorithms to satisfy the overall light-intensity lighting conditions in the light-source layout in a cabin-lighting communication

system. They ensured that the light power met the requirements, and optimized the position and angle of each light source to minimize light-intensity fluctuations.

In 2021, Li [45] improved the LED layout to address the problems of user distribution and inter-user interference in indoor VLC systems. They used white LEDs as lighting and information transmitters to meet the user-experience quality and demand. To address the distribution of users in different cases, they proposed an algorithm, based on the quality of user experience, to improve the LED layout.

In the same year, Li et al. [46] proposed an improved artificial bee-colony algorithm to optimize the position and layout of light sources to find their specific positions for an optimal lighting effect. They compared the lighting effect of rooms with different specifications. The results showed that the standard lighting-layout requirements could be met without the general light-source layout for irregular rooms to achieve lighting effects and save energy.

In 2022, Qu [47] proposed an evolutionary-algorithm scheme for maximizing the LED layout, based on signal-to-noise coverage. They simulated the illuminance and signal-to-noise ratio of polygonal and circular layouts in a 5 m $\times$ 4 m $\times$ 3 m room, and continuously improved the light-source coordinates to find an optimized layout. The effect of the orientation of the LED arrangement on the performance of the room system was investigated, and this study provided a new method of considering the layout of indoor light sources (Table 39.2).

The above light-source-layout optimization methods all optimize for the location of the light source. Although the light uniformity of the receiving surface is improved and lighting standards are met, to a certain extent, optimizing the light-source location as a whole through intelligent-optimization algorithms is not sufficiently comprehensive. This leads to very random locations, a less aesthetically pleasing distribution of light sources, and lower practicality.

The light-source parameters can be further optimized or the position and parameters can be co-optimized to achieve uniform lighting and improve the communication quality. The following describes light-source parameter-optimization methods based on intelligent optimization algorithms.

Methods for Optimizing the Light-Source Parameters Based on Intelligent Optimization Algorithms

In 2012, Ding et al. [48] proposed a new method for fully diffusing indoor VLC using a custom-evolved algorithm to dynamically optimize the signal-to-noise ratio over the communication layer in multiple scenes. They controlled the optical power of individual LED-lighting devices to achieve fully diffuse indoor VLC with improved light uniformity.

In 2014, Wang and Su [49] used a simulated-annealing algorithm to optimize circular as well as rectangular arrays to obtain uniform illumination on the receiving surface. They also constructed an evaluation function to analyze the parameters affecting uniformity. Finally, it was concluded that the optimal radius of the array was independent of the number of light sources and produced a uniform distribution of light sources on the target surface.

Table 39.2 Research progress on the optimization of light-source positions

Year	Researchers	Study content	Progress
2009	Ca o	Proposed a quasi-sinusoidal particle-swarm algorithm to optimize the placement of light sources	Avoided the problem of local extremes, but reduced the computational accuracy of the algorithm, while keeping the number of particles constant
2015	Fu	Optimized the light-source position using a genetic algorithm	The lighting requirements were met but the placement of the light sources was too scattered for practical use
2016	Gao	Optimized the light-source position using a hybrid simulated annealing–genetic algorithm	Achieved uniform light and communication stability, but the distribution was not aesthetically pleasing and the practicality was low
2017	Liu and W	Optimized the light-source location layout using genetic algorithms for gene density	To obtain the ideal power distribution, the researcher could calculate the light-distribution scheme
2019	Zhai	Used an artificial fish-swarm algorithm to minimize the power variation at the receiving surface as an objective function and to optimize the position of the LEDs	Optimal LED-layout patterns were obtained and further improvements were made to the LED power factor
2020	Liu	Optimized LED light-source location information using multiple-swarm genetic algorithms for light-source layout models	Significantly better than layout models based on traditional genetic algorithms
2021	Li et al.	Proposed an improved artificial bee-colony algorithm to optimize the position and layout of light sources	For irregular rooms without a general light-source layout, the requirements of a standard lighting layout could also be met
2022	Qu	Proposed an evolutionary algorithm scheme for optimizing light-source positions based on maximizing the LED layout in terms of signal-to-noise coverage	Provided a new manner of thinking about the layout of interior light sources

In 2015, Chen et al. [50] used an ant-colony algorithm to find a set of power-adjustment factors to achieve illumination requirements and power uniformity on the receiving surface, thus ensuring fairness in communication between multiple users.

In 2018, Kumawat et al. [51] attempted to minimize the received power-fluctuation values in a room using a whale-optimization algorithm to obtain an optimal LED light-source layout. In the same year, Yang [52] used a bat algorithm to optimize the power of each light source, while applying it to a special indoor environment, and achieved the expected results.

In 2019, Yang et al. [53] proposed a power-optimization method with an improved ant-colony algorithm to ensure uniform lighting, found a set of power

factors to optimize them, and combined this algorithm to establish a scheme for visible-light communication. The results showed that this method improved the computing efficiency and ensured the stability of the communication environment with better convergence.

In the same year, You et al. [54] studied the layout of optical-communication light sources based on the co-optimization of position and power. They used a firework algorithm to achieve an optimal distribution of LED light-source positions and power, so that different users could receive the same, improved, quality of signal.

In 2020, Wang et al. [55] proposed an improved artificial fish-swarm algorithm to find the optimal light-source layout to search for an optimized layout that provided better communication performance. The results showed that the uniformity of the received optical power was improved and the received optical-power fluctuations were reduced, providing good communication performance by optimizing the layout of the LED light sources while meeting indoor-lighting standards.

In 2020, Zhai et al. [56] proposed a multiple-swarm genetic-algorithm-based LED light-source layout with 20 LEDs as columns to solve the problem of uneven light and power distribution by optimizing parameters, such as the position, power, and angle of the light source. This method provided a reference for LED-layout design and contributed to indoor visible-light communication systems.

In 2020, Han [57] proposed a layout design scheme for LEDs using the fast convergence and high solution efficiency of the whale-optimization algorithm to improve the LED layout, uniformity of the room lighting, and data-transmission capability. They analyzed and compared the distribution of the light sources, received power, and bit-error rate (BER) under the whale-optimization algorithm.

In 2021, Zhou et al. [58] proposed a method for jointly optimizing lamp-source locations and parameters to address the problem of uneven light-source distributions in indoor VLC systems. This method rearranged LED arrays while maintaining a constant total power and optimized the parameters in each LED array using an improved PSO algorithm. The results showed that this method could reduce the total power of the light-source layout under indoor-lighting conditions and effectively improved the light uniformity on the receiving surface, compared with conventional light-source distributions.

In 2022, Che et al. [59] proposed a square-plus-elliptical light-source layout to construct a 6 m $\times$ 5 m $\times$ 3 m room model for the problem of uneven indoor visible illumination. They used a simulated-annealing particle-swarm algorithm to optimize the spacing of the LED light sources, system-illumination uniformity, and signal-to-noise ratio to find the optimal light-source layout. The lighting and communication performance were significantly improved, compared to the traditional layout.

In 2022, Xu et al. [60] used a genetic algorithm to optimize LED emitter-unit layout parameters using a square layout to minimize 3D normalized positioning-error metrics and provided a non-uniform rectangular structure to reduce the optimized size. The results showed that this method reduced the positioning error compared to a uniform layout and provided a dense LED layout for indoor systems.

In 2022, He et al. [61] proposed a new polygonal layout, based on a rectangular planar stereoscopic space, where the illumination and signal-to-noise ratio of polygonal and circular layouts were simulated in a 5 m $\times$ 4 m $\times$ 3 m room. The location

and power of the polygonal layout were further optimized by a particle-swarm algorithm. The illumination uniformity and signal-to-noise quality factor of the optimized polygonal layout were improved.

In 2022, Zhang et al. [62] proposed an optimal layout scheme based on a parallel fully connected convolutional neural network model. They used a particle-swarm optimization algorithm to optimize the light-source position, power, angle, and other parameters. They used fully connected and parallel neural networks to model indoor VLC channels; hence, the proposed method was highly applicable to any number of light sources and any specific indoor-space size. The proposed light-source layout scheme under this model was more suitable for actual indoor scenarios, and the received signal strength was more uniform (Table 39.3).

Table 39.3 Research progress on light-source parameter optimization

Year	Researchers	Study content	Progress
2012	Ding	Custom evolved algorithms controlled the light power of individual LED lighting devices.	Enabled fully diffuse indoor visible-light communication with improved light uniformity
2014	Wang and Su	The parameters affecting homogeneity were analyzed using a simulated-annealing algorithm.	The optimum radius of the array was independent of the number of light sources and produced a uniform distribution of light sources on the target surface.
2015	Chen	An ant-colony algorithm was used to find a set of power-conditioning factors.	Provided optical power and light intensity for indoor VLC systems, ensuring fair communication between multiple users
2018	Kumawat	Received power fluctuations in the room were minimized by means of the whale-optimization algorithm.	Obtained the optimal LED light-source layout
2019	Yang	Proposed a power-optimization method with an improved ant-colony algorithm to find an optimal set of power factors.	Improved computing efficiency while ensuring a stable communication environment with good convergence
2020	Zhai et al.	Optimized light-source position, power, and angle parameters based on multiple-swarm genetic algorithms	Solved the problem of non-uniform light and power distributions
2021	Zhou	Optimized parameters in each LED array using an improved particle-swarm optimization algorithm	Reduced the total power of the light-source layout under indoor-lighting conditions and improved the light uniformity on the receiving surface
2022	Xu et al.	Optimized LED emitter-unit layout parameters using genetic algorithms	Reduced positioning errors compared to uniform layouts and provided a reference indicator for dense indoor LED layouts
2022	Zhang	Optimized the light-source position, power, angle, and other parameters using particle-swarm optimization algorithms	Could be used with any number of light sources and any specific room size for more-uniform signal strength

Summary of Research Progress

Through the previous review and analysis of research progress, this chapter presents a general outline of light-source layouts for VLC systems. According to traditional search algorithms, the light-source layout in a room can only be adjusted to meet general lighting and communication needs. However, the lighting area is not uniformly bright, while the light signal has blind spots in some areas.

Researchers have proposed a variety of light-source distribution schemes to solve such problems. While focusing on the impact of the arrangement of the light beads within the light source on the overall system, rectangular layouts of light beads have evolved to circular and hexagonal layout combinations. The research problem has been more refined through algorithms to adjust the power of each light source, emission angle, and other parameters to further improve the uniformity and stability of the power coverage.

Considering the interaction between the sources and changes in channel characteristics caused by the movement of people in the room, neural-network intelligence algorithms were integrated into the light-source layout system, which constantly adjusted the system-layout and light-source parameters according to the perceived situation to achieve real-time adaptive changes.

Visible-Light Communication Light-Source-Layout Analysis

Light-Source-Layout Principles

Indoor visible-light communication uses light-emitting diodes, such as LED lamps, as a signal source for communication; therefore, in indoor VLC, LEDs must be reasonably laid out to meet communication requirements. In general, the layout of indoor visible-light communication should consider the following aspects:

1. Light-source location: In VLC systems, the luminaires themselves act as light sources and communication devices; therefore, they must be placed in the best locations to achieve the best lighting effect and communication quality. It is recommended that luminaires for VLC systems be installed on the ceiling or walls of a room, with higher luminaires covering a wider area, and lower luminaires providing stronger communication signals.
2. Layout uniformity: Similar to the layout of visible light in a room, the layout of the light sources in a VLC system must be uniform. It is recommended to set multiple luminaires at uniform distances within the entire room and adjust the brightness control of each luminaire to improve illumination uniformity and communication signal coverage.
3. Communication obstructions: In VLC systems, obstacles significantly affect the signal, particularly when the line of sight is blocked. Therefore, when laying out light sources, the location and number of obstacles in the room must be considered to determine the best light-source-layout solution.

4. Type of light source: VLC systems can use different types of lamps, such as LED lamps and fluorescent lamps. It should be noted that different types of luminaires have different wavelengths and power characteristics, and the advantages and disadvantages of different types of luminaires and their scopes of application must be considered when designing.
5. Lighting needs: When laying out light sources, the requirements for lighting in the room must also be considered. The lighting effects should not be sacrificed because of VLC communication. It is recommended that the advantages of VLC technology be fully exploited by combining it with VLC communication technology to ensure the lighting quality.

Light-Source Spatial Layout

The spatial layout of an LED light source directly affects its irradiation characteristics, the size of the received field of view, and the received power distribution at the receiving end of the communication system. It can be determined by studying the interaction between the light source, irradiation characteristics, and indoor boundary conditions. Following years of research and development, various layout models have been developed. The following four LED-layout methods are introduced separately and the most widely used layout models are described.

Thiessen Polygon Layout

The Thiessen polygon layout is an earlier proposed model for light-source layouts for VLC systems. It is shown in Fig. 39.3, where the red triangle represents the

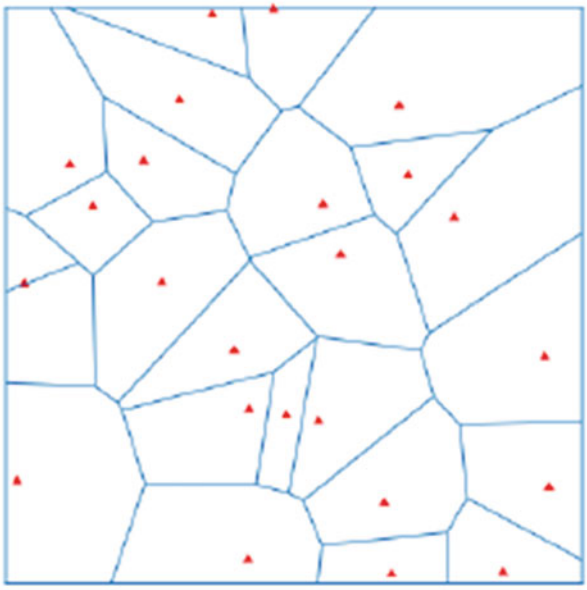

Fig. 39.3 Thiessen polygon layout [65]

location of the LED, the blue circle represents the location of the user, and the blue line represents the managed cell boundary [45].

Considering the LED positions in the room as point sets, let the number of LEDs in the room be N_l; the point set is the set of all LED positions, and the corresponding set expression is

$$I = \left\{ \left(x_1^l, y_1^l\right), \ldots, \left(x_2^l, y_2^l\right), \ldots, \left(x_N^l, y_N^l\right) \right\}. \tag{39.5}$$

Each LED serves a communication user in the corresponding area, with a total number of users N_u, and k users in each cell. The location of the user in the i^{th} cell is denoted as [63]

$$V_i = \left\{ \left\| u_i - \left(x_i^l, y_i^l\right) \right\| < \left\| u_i - \left(x_j^l - y_j^l\right) \right\|, \forall j \neq i \right\}, \tag{39.6}$$

where $\left(x_i^l, y_i^l\right)$ represents the location of the user in the i^{th} cell, $\left(x_j^l, y_j^l\right)$ represents the user location in the j^{th} cell, and V_i denotes the cell. If all cells in the room satisfy Eq. (39.6), the layout is called a Thiessen polygon layout; the distance between all users in each served area is always less than the distance between users in other cells [64]. The generation of a Thiessen polygon layout is not related to the user location [65].

Center-of-Mass Thiessen Polygon Layout

The Thiessen polygon layout was further developed, deducing the center-of-mass Thiessen polygon layout, as shown in Fig. 39.4. The geometric definition of the Thiessen polygon layout is obtained from Eq. (39.6). The user distribution is introduced to produce a center-of-mass Thiessen polygon layout, based on the user-distribution locations [66], where ρ is the location of all users, u. The center-of-mass location in the i^{th} cell is defined as

$$(x_i, y_i) = \frac{\int_{vi} u\rho(u)d\sigma}{\int_{vi} \rho(u)d\sigma}, \tag{39.7}$$

where $\left(x_i^l, y_i^l\right)$ moves the position of the LED in the i^{th} cell in the Thiessen polygon layout to the position after the center of mass. After moving all the LEDs in the cell to the position of the center of mass, it is called a center-of-mass Thiessen polygon layout. The user distribution determines the positions of the LEDs, and the positions of the LEDs in the simulation are constantly iterated according to the user distribution. The positions of the LEDs are reduced with the distance between users and finally converge.

The cost function for acquiring VLC services for a user is denoted as $F(I)$ [67]:

$$F(I) = \sum_{i=1}^{Ni} F_i = \sum_{i=1}^{Ni} \int_{vi} \left\| u_i - \left(x_i^l, y_i^l\right) \right\|^2 \rho(u)d\sigma \tag{39.8}$$

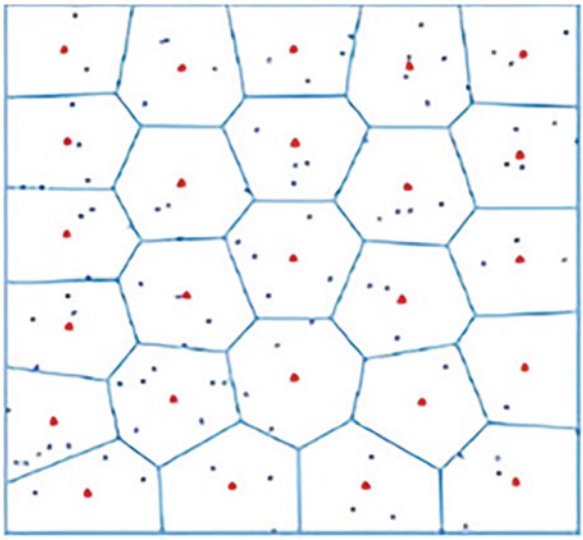

Fig. 39.4 Center-of-mass Thiessen polygon layout [45]

$F(I)$ is a function of the distance between the indoor LED and the user, and F_i represents the cost function of the horizontal distance between the LED and the user in the i^{th} cell:

$$F_i = \int_{vi} \left\| u_i - \left(x_i^l, y_i^l\right) \right\|^2 \rho(u) d\sigma \tag{39.9}$$

where $d\sigma$ denotes the integral over the area of the lighted area. In a right-angle coordinate system, $d\sigma = dxdy$, where $d\sigma$means the integration of the i^{th} cell V_i from the x and y directions. $\int_{vi} d\sigma$ and $\int_{vi} \rho(u) d\sigma$ denote the area of V_i and the number of users, respectively. A partial differentiation of the user positions in Eq. (39.9) yields

$$\frac{\partial F_i}{\partial\left(x_i^l, y_i^l\right)} = 2\int_{vi} \rho(u)\left[x_i^l, y_i^l - u_i\right] d\sigma \tag{39.10}$$

$$\frac{\partial F_i}{\partial\left(x_i^l, y_i^l\right)} = 0. \tag{39.11}$$

The user position can be expressed using Eq. (39.11), where $\left(x_i^l, y_i^l\right)$is the center-of-mass position of the Thiessen polygon layout [68]. The center-of-mass Eq. (39.11) is substituted into Eq. (39.10) and minimized; the expression is as follows:

$$F(I) = \sum_{i=1}^{Nl} F_i = \sum_{i=1}^{Nl} \int_{vi} \left\| u_i - \frac{\int_{vi} u\rho(u)d\sigma}{\int_{vi} \rho(u)d\sigma} \right\|^2 \rho(u)d\sigma \tag{39.12}$$

The above expression is the expression for the center-of-mass Thiessen polygon layout. The equal distance of the Thiessen polygon layout to discrete points in the area makes the received power distribution more uniform throughout the indoor optical communication; the irradiance can also meet the lighting requirements, and the practical application illustrates its reasonableness.

Wireless-Communication Network Layout

The wireless-communication network layout is divided into quadrangular and hexagonal layouts, as shown in Fig. 39.5; it divides the room into a square network based on the layout of the light-source locations. The quadrangular layout is widely used in indoor scenarios because of its advantages, such as uniform lighting and simple design. However, traditional layouts cannot accommodate different user distributions. In this typical LED layout, the number of light sources should be consistent.

For example, in a quadrangular layout, the number of LEDs can be 9, 16, 25, 36, 49, etc. When the user distribution changes, LEDs in other areas do not work properly because of the uneven distribution of users. This affects the communication and lighting of the entire indoor light communication system, as shown in Fig. 39.5. The hexagonal grid layout has the same advantages and disadvantages as the quadrangular grid. In the hexagonal grid layout, the number of LEDs can be 14, 23, 30, 33, 42, etc [45].

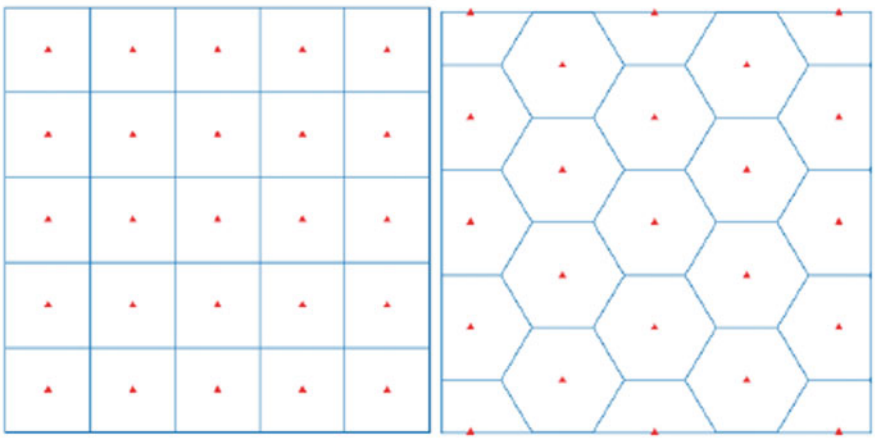

Fig. 39.5 Quadrangular and hexagonal layouts [45]

LED-Array Light-Source Layouts

Common LED-array light-source layout models include square, circular, and hexagonal [69]. Jiang et al. [32] studied the luminosity distribution of different light-source arrays composed of multiple LED beads and improved them to obtain a uniform LED-light arrangement and optimal spacing. Based on the luminosity distribution of the LEDs, a model of the luminosity distribution between individual LEDs and beads was constructed and derived for a multiarray LED [32].

Figure 39.6a–c show the square, hexagonal, and circular-array light-source layouts, respectively.

To obtain higher-quality signals, Jiang et al. [32] considered the three array-layout methods mentioned above. After continuous experimental derivation, they concluded that the relative position between the receiving surface and the LED in the visible-light communication system was fixed. Therefore, a compensation array could be added to the four directions of the annular array; after adjustment, it formed a new layout: the annular-angular-compensation array light-source layout.

Key Algorithms for Light-Source Layout Parameters

When the light-source layout is implemented under short-distance lighting conditions, it is more flexible and convenient to use algorithms to design the layout. When optimizing light-source layouts, the following algorithms have been used by scholars at home and abroad to optimize light-source layouts, which are described below.

Particle-Swarm Algorithm

The particle-swarm algorithm is a commonly used evolutionary optimization algorithm, as shown in Fig. 39.7. The particle-swarm algorithm views the candidate solutions as particles and iteratively searches for the optimal solution. Each particle adjusts its speed and position, according to its own optimal solution and that of the entire particle swarm.

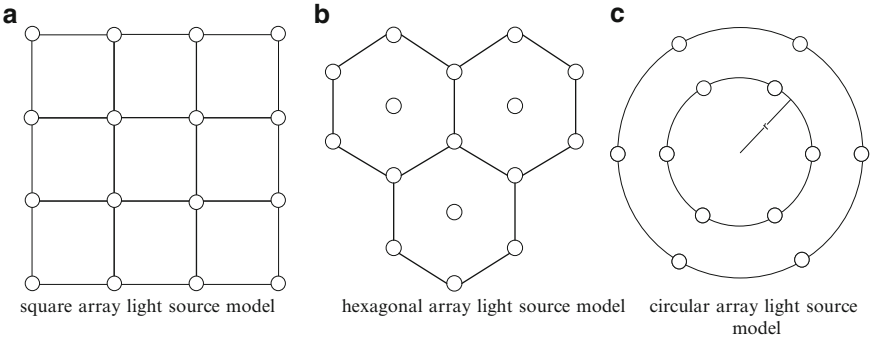

Fig. 39.6 LED-array light-source layout models [32]

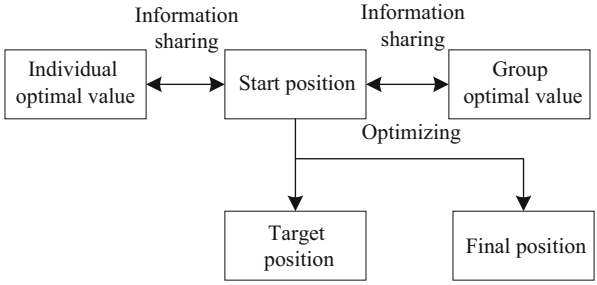

Fig. 39.7 Schematic diagram of particle-swarm optimization [22]

The particle-swarm algorithm has a good global-search capability and convergence and has been widely used in multi-objective optimization. Through continuous iteration and optimization, the particle-swarm algorithm can determine the optimal solution to a problem until the maximum number of iterations is reached. In [22], this algorithm was used to determine the optimum LED position in a rectangular plane to obtain an improved light-source layout.

An optimized layout solution based on the particle-swarm algorithm can achieve better lighting uniformity and improve the communication quality of the system, while meeting the lighting and communication requirements.

Genetic Algorithm

A flowchart of the genetic algorithm is shown in Fig. 39.8. A genetic algorithm is an optimization algorithm based on the idea of natural evolution. It searches the problem space and continuously and iteratively searches the solution space to find the optimal solution step-by-step. Genetic algorithms are widely used for optimization problems. In [38], Gao used this algorithm to optimize the light-source layout of a system using a genetic-algorithm design to obtain the LED-chip coordinates when the light distribution was optimal by optimizing the objective function.

Ant-Colony Algorithm

The ant-colony algorithm is an intelligent-optimization algorithm developed based on the foraging behavior of ants. It is highly efficient and accurate in solving various optimization problems, has good global-optimization capabilities, and can effectively handle large-scale, complex optimization problems.

Chen et al. [50] used the global-search capability of an ant-colony algorithm to find an optimal set of power-conditioning factors. The key steps of this were the selection of the objective function and state-transfer probability. To further improve the convergence of this algorithm, the intensity values were dynamically adjusted. On this basis, the light-source layout of the system was optimized, and the light uniformity in the receiving plane and the communication stability were ensured.

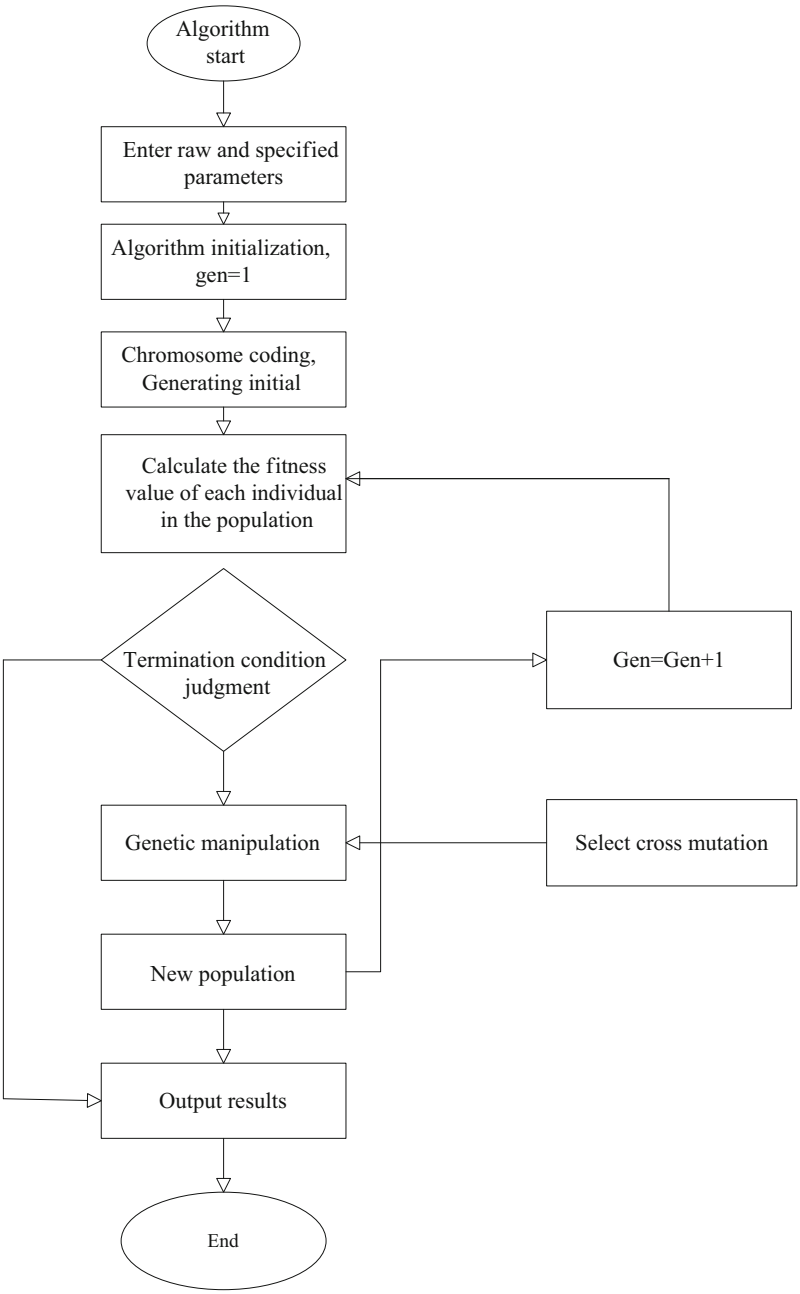

Fig. 39.8 Flowchart of a genetic algorithm [35]

Application of Intelligent Neural-Network Algorithms

In the process of optimizing the light-source layout for VLC systems, the layout must be adjusted according to the irradiation characteristics of the light-source room, received power distribution, and other parameters, and many intelligent algorithms have been introduced.

For example, the LED power factor can be adjusted in real time, based on a genetic simulated-annealing algorithm. It seeks to globally optimize the power distribution according to the cost function, ensuring the search capability and evolutionary ability of the algorithm in the process.

With the development of network technology, artificial neural-network algorithms have been applied to optimize indoor light-source layout models. Deep learning can solve the problems of long comparison and iteration processes, and the slow calculation speed of traditional algorithms.

Tan proposed the use of a feed-forward artificial neural network to optimize light-source layouts [70]. The accuracy of its prediction could be determined by comparing the optimal light-source layout scheme obtained by the genetic algorithm with that obtained by neural-network calculation. The accuracy was calculated by dividing the number of points of the same light-source arrangement by the total number of light sources.

A hybrid immunoclonal bat algorithm was proposed to optimize the layout of LED light sources in a room [71]. The optimized received optical power, signal-to-noise ratio, and illuminance distribution were compared with unoptimized and optimized data from other algorithms. Specifically, the variance in the optical power in the receiving plane was as low as 0.026 dB, after optimization using the immunoclonal bat algorithm.

Research on VLC Light-Source Layouts at Xi'an University of Technology

Received-Power Analysis

The received power is a parameter that must be considered during the VLC light-source layout; it directly determines the communication quality of the VLC system. In the design process, the received power at different locations in the room should be average and stable. Firstly, a receiving channel model was constructed to analyze the received power; the received power at a certain point in the room is shown in the figure below.

According to the reception process shown in Fig. 39.9, the received power of a point (x, y, z) is

$$P_r(x, y, z) = \sum_{j=1}^{j} H_j(0) P_t j, \tag{39.14}$$

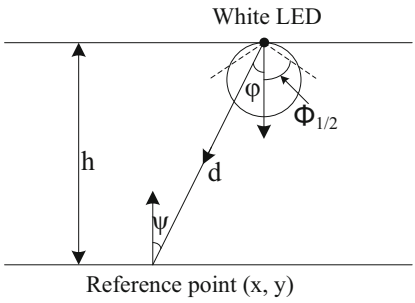

Fig. 39.9 Schematic diagram of the received power at some point in the room [72]

where P_{tj} is the total emitted power of the j^{th} array light source. $H_j(0)$ represents the channel DC gain of the j^{th} array light source at point (x, y, z), which can be expressed as [73]

$$H_j(0) = \frac{I_j(x,y,z)AT_s(\psi)\cos(\psi)}{r_j^2} rect\left(\frac{\psi}{\psi_c}\right) \tag{39.15}$$

$$rect(x) = \begin{cases} 1 & |x| \ll 1 \\ 0 & |x| > 1 \end{cases} \tag{39.16}$$

In the above equation, $I_j(x, y, z)$ is the luminous intensity distribution of the light-source array, A is the photodiode-detector receiving area, ψ is the angle of incidence, $T_s(\psi)$ is the optical-filter gain, Ψ_c is the receiver field-of-view angle, r_j is the distance between the receiver and the j^{th} array light source, and n indicates the reflection index. The optical concentrator $g(\psi)$ can be expressed as

$$g(\psi) = \frac{n^2}{\sin^2\psi_c} rect\left(\frac{\psi}{\psi_c}\right). \tag{39.17}$$

Optimal Design of a Light-Source Layout

In an indoor VLC system, each room has different dimensions and equipment, and the LED layout is arranged according to the different rooms to achieve the best communication effect. The results show that planar-array light sources have better light uniformity than linear-array light sources, suggesting a planar-array indoor VLC system.

Figure 39.10 shows a room with dimensions L × W × Z_H. For example, let there be a total of J LED-array light sources, designed as a spherical-array light source. Subsequently, the distribution of the reception rate on the plane $z = h$ is

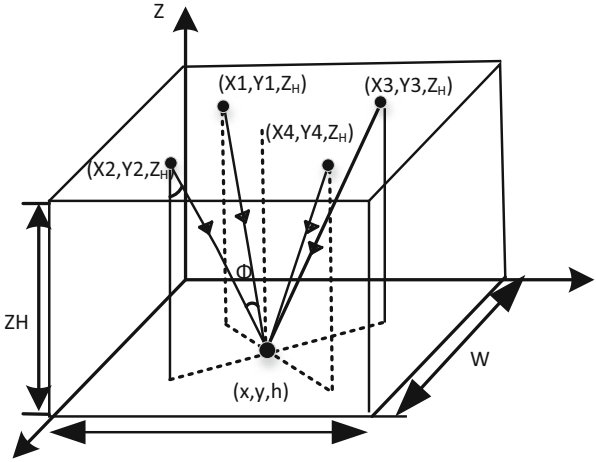

Fig. 39.10 Schematic diagram of a light-source layout [72]

analyzed. When the received-power distribution is the smallest, the LED light-source layout is the best.

Let the coordinates of the LED-array light source be (X_1, Y_1), (X_2, Y_2), ⋯, (X_J, Y_J). They can be derived from the indoor plane $z = h$ on the average value of the received power; that is, the average received power is

$$E(p_r) = \bar{p_r} = \frac{1}{s}\iint_{\Omega} p_r(x, y)dxdy, \tag{39.18}$$

where $p_r(x, y)$ is the received power value, which is distributed with equal probability in the $z = h$ plane. s is the area of plane $z = h$ in the room, and Ω represents this area.

Layout-Model Simulation Analysis

The lighting consists of an array of white LEDs [72]. To facilitate the selection of the optimal LED arrangement, the effects of the LED arrangement and received power were numerically simulated. The simulation parameters are listed in Table 39.4.

Optimal Layout Design under Different Numbers of White LED-Array Light Sources

The indoor environment is 5.0 m × 5.0 m × 5.0 m, h is 0.85 m, $X_1^* = Y_1^* = 1$, a spherical-surface array light source is used, and the design parameters are two layers, seven LEDs, $d = 0.1$ cm, and $\theta = 10^0$. The simulation results are shown in Fig. 39.11a–d.

From Fig. 39.11a–d, it can be seen that the range of received power increases from small to large as X_1 and Y_1 change from 0 m to 2 m. When $X_1 = Y_1 = 1$ m, the distribution of light power at the receiving surface is the most uniform, at which time

Table 39.4 Simulation parameters [72]

Parameter	Numerical value
Emission light power	20 [mW]
Reflective index	1.5
Transmission-power half-angle	60 [deg]
Receiver FOV	60 [deg]
PD area	1.0 [cm^2]
Optical-filter gain	1.0
Photoelectric-conversion efficiency	0.53 [A/W]
Power-transmission half-angle	60 [deg]
$W \times L \times Z_h$	$5.0 \times 5.0 \times 5.0$ [m]
h	0.85 [m]

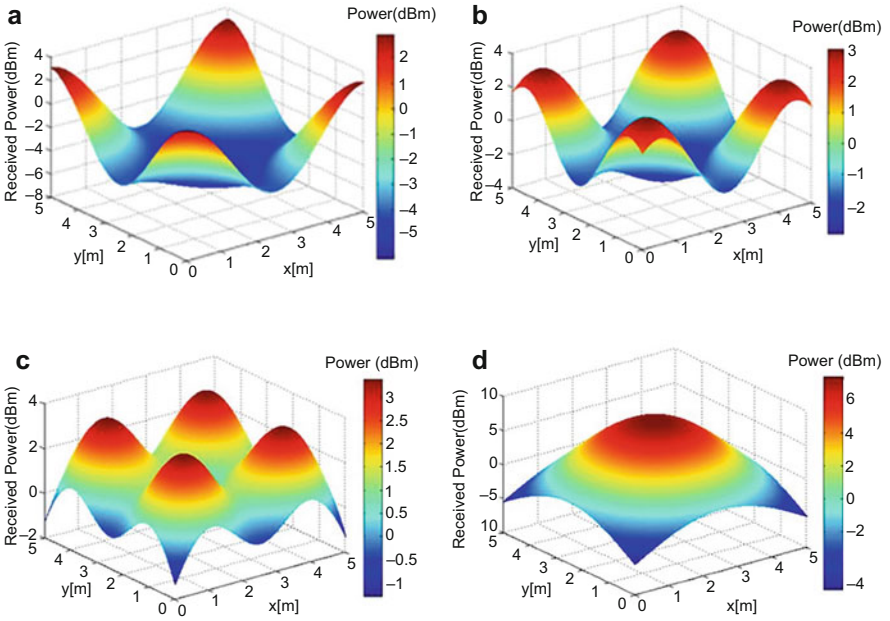

Fig. 39.11 Received optical-power distribution. (**a**) Received power distribution at $X_1 = Y_1 = 0$ m [17]. (**b**) Received power distribution at $X_1 = Y_1 = 0.5$ m [17] (min = −6.0 dBm, Max = 2.98 dBm) min = −2.9 dBm, Max = 3.0 dBm). (**c**) Received power distribution at $X_1 = Y_1 = 1$ m [17]. (**d**) Received power distribution at $X_1 = Y_1 = 2$ m [17] (min = −1.3 dBm, max = 3.4 dBm) (min = −5.6 dBm, max = 3.4 dBm) [17]

the maximum value is 3.4 dBm and the minimum value is −1.3 dBm, thus verifying the accuracy of the theoretical model.

Influence of White LED-Array Light-Source Design Parameters on the Light-Intensity Distribution

When the light-source layout is optimal, the design parameters of the LED-array light source will affect the light-power distribution in the room. The selection of key parameters, such as array-element distribution, array-element optical-axis pole

angle, and number of elements in a multi-array light source, can effectively regulate the distribution of light power and improve the light-intensity fluctuation. The following is an analysis of the impact of the design parameters of a multiarray light source on the light-intensity distribution in a room.

Figure 39.12 shows the indoor received-power distribution of the spherical-array light source. To simplify the analysis, one array light source was used. The optimal position of the array light source was in the center of the ceiling, and the number of LEDs in each layer was one, four, eight, and 16. The 3D spherical-array light sources had a height of 0.13 m; when the height of the light source is 0, the 3-D array light source becomes a 2-D array light source.

From Fig. 39.13, it can be concluded that the LED optical-axis pole angle has a great influence on the optical-power distribution: the smaller the pole angle, the greater the fluctuation and value of the optical power. Therefore, as large an optical-axis pole angle as possible should be selected while ensuring the minimum light power. Compared to 2-D array light sources, the smaller the number of layers in 3-D-array light sources, the smaller the fluctuation of the optical power distribution. The higher the number of layers of the 3-D array light sources, the larger the fluctuation of the optical-power distribution [72].

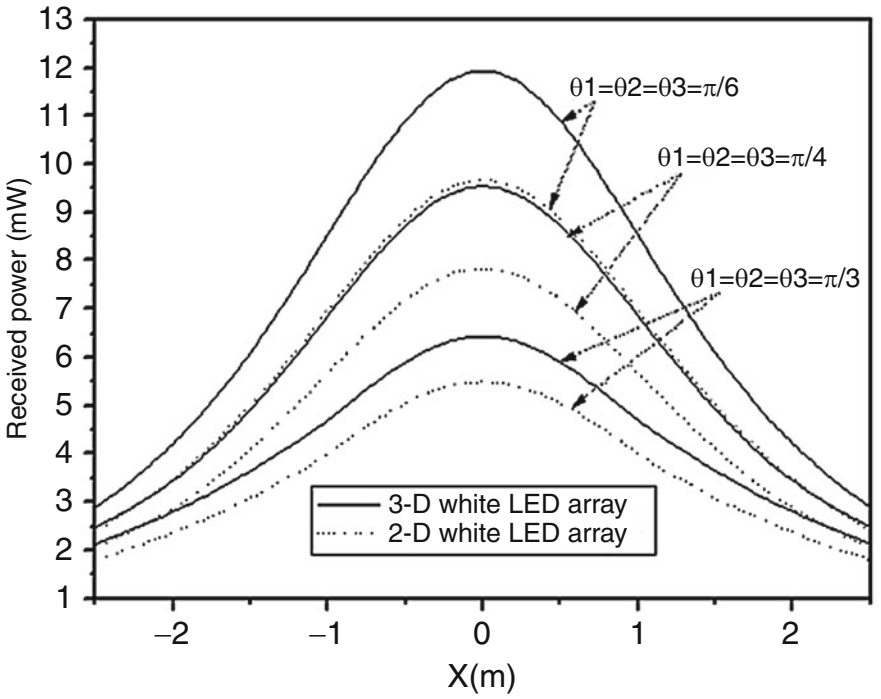

Fig. 39.12 Optical power distribution of an indoor zonal 2-m plane receiving from a spherical-array light source [72]

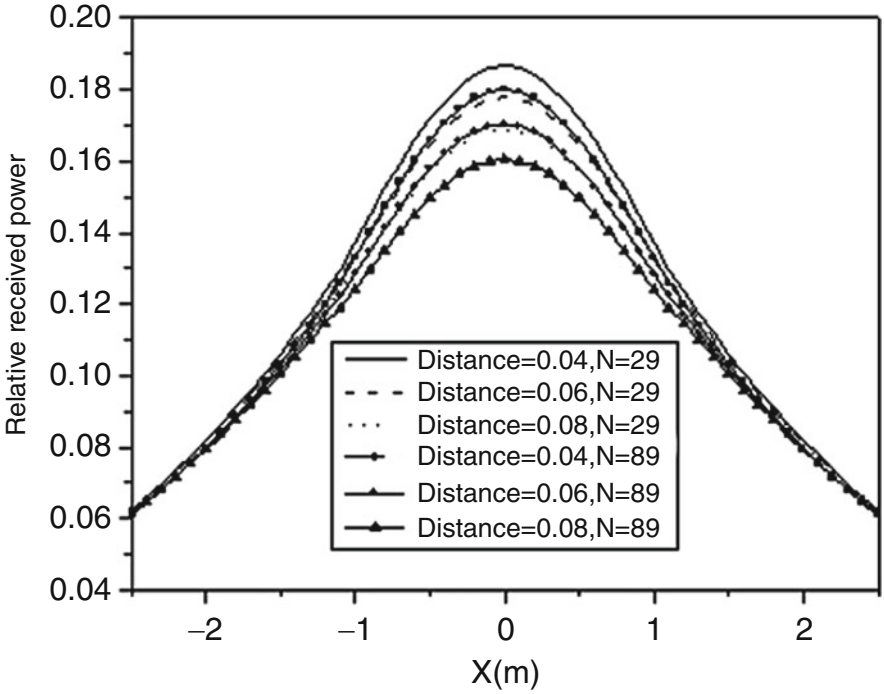

Fig. 39.13 Effect of layer spacing and number of LED elements on indoor light-intensity distribution [72]

Figure 39.13 shows the light-intensity distribution relative to the room for different LED-array unit-layer spacings and array-element numbers. Assuming that multiple white LED arrays emit an equal total power for unit 1, the luminous intensity of each array element in the 3-D spherical-surface array light-source design was spaced equally. The larger the layer spacing, the smaller the fluctuations in the light-intensity distribution. However, the layer spacing is not infinite and must be selected reasonably [72].

Summary

Visible-light communication (VLC) is an emerging communication technology whose basic principle is to use LED lights to emit data streams and transmit information through strobes that are imperceptible to the human eye. This chapter briefly introduced indoor visible-light communication systems and provided an overview of the current research status of the light-source layouts in China and abroad. It summarized and compared the existing layout models with missing light-source space and LED light beads, summarized and explained the algorithms in the

layout design process, and finally, provides an outlook on the future development of VLC and light-source layouts.

At present, the application of indoor visible-light communication still has many problems. The main light source for visible-light communication is an LED lamp. Parameters such as its brightness and the irradiation angle of divergence affect the indoor lighting situation, while the strobe characteristics also affect the quality of optical communication, human-eye health, and mental state.

Optical receiver designs, anti-interference algorithms, stable reception technology, multiple-input multiple-output technology, and more sensitive receivers will improve the quality of communication in VLC systems and are issues that need to be addressed in the process of integrating smart-living and intelligent-transport optical networks.

Currently, VLC applications are mainly focused on indoor, in-vehicle, and mining scenarios, in which the impact of the light-source distribution on the channel characteristics cannot be ignored. VLC-system light-source-layout research has produced many results, and the light-source layouts may take the following research directions in the future.

1. Multipoint access technology: Future indoor VLC systems will use multipoint access technology to support multiple users communicating simultaneously. It will use multiple light sources to provide wider coverage, higher reliability, and more fault-tolerant services. The rate and coverage area of communication systems can be further increased. This requires setting up additional light sources in the room and assigning appropriate light sources to corresponding users for communication.
2. Intelligent light-source layouts: With the development of artificial intelligence, systems can automatically optimize the position and number of light sources for intelligent management and control using machine learning and other technologies. This enables more efficient and larger data transmissions and communication.
3. Adjustable light-source layouts: In indoor visible-light communications, the brightness and color of the light source can be adaptively adjusted according to environmental changes, thereby achieving more stable and efficient communication. The layouts of future light sources will also consider these factors and more flexible, intelligent, and adjustable light-source layouts will be designed.
4. Multi-functional integrated technology: In the future, indoor VLC systems based on LED light sources will be further developed with more innovative designs and intelligent features. For example, functions such as audio, video, and data processing can be integrated into a light source for multimedia and data communication within the same light band, using spectral-analysis and demodulation algorithms. This will provide users with more convenient and richer communication services.

Overall, the layout of light sources in future indoor visible-light communications will become more intelligent, personalized, and flexible to better meet people's needs for high-speed, reliable, and secure communications.

Abstract

To address the problem of resource-allocation strategies that limit the system transmission rate in visible light communication and radio frequency (VLC/RF) systems, a new resource-allocation method is proposed and orthogonal frequency-division multiple-access (OFDMA) technology is introduced. Thus, the capacity of the communication system is effectively increased. In the VLC/RF system model based on OFDMA, the Lyapunov optimization method is used to transform the time-averaging problem into a series of single-slot online problems. To reduce its computational complexity, the optimization problem is decomposed into three independent subproblems. The Lagrange relaxation method and convex-optimization theory are used to solve the subproblems to maximize the average system transmission rate. The Lyapunov drift is used to ensure the stability of the system. The simulation verified that the Lyapunov optimization algorithm does not require iterations, which greatly improves the optimization speed. In addition, the simulation results show that using OFDMA technology in

the indoor VLC/RF system effectively improves the system capacity, while solving the optimization problem. The proposed resource-allocation strategy effectively balances the system queue length and transmission rate, and maximizes the average system transmission rate while ensuring system stability. The Lyapunov optimization algorithm is comparable to other algorithms in terms of system stability and transmission rate, thereby proving its effectiveness.

Indoor visible light communication · Orthogonal frequency-division multiple access · Resource-allocation strategy · Lyapunov optimization algorithm · Average transfer rate

Introduction

Future 6G networks will support data rates of up to 1 Tbit/s, while also facing the challenge of coping with a large number of mobile devices [1]. However, it is difficult for limited radio spectrum resources to meet the needs of massive amounts of data transmissions transmissions. Visible light communication (VLC) combines the advantages of lighting and communication with hundreds of high-frequency bandwidth spectra that do not require certification [2], alleviating the pressure on the insufficient radio frequency (RF) spectrum.

VLC has several advantages, such as a high data rate, low power consumption, high security, and low latency [3]. Therefore, VLC is considered a promising complementary technology for emerging wireless communication. Data transmissions in VLC systems are achieved through intensity modulation on the transmitter side and direct detection on the receiver side (IM/DD).

As with other high-frequency communication technologies, signal propagation at this frequency is highly susceptible to obstacles. Therefore, data transmissions between the transmitter and receiver in VLC require a line of sight (LOS) path. When there is a non-line of sight (NLOS) transmission between the VLC access point (AP) and the user AP, the VLC performance degrades sharply. The coverage area of the VLC AP is limited, therefore transmission reliability has become the main concern for VLC systems.

Conversely, in the case of NLOS transmissions, RF systems can provide a wider coverage area [4]. Therefore, VLC/RF heterogeneous networks have received considerable attention in recent years and have significantly improved in terms of the sum rate [5], spectral efficiency [6], power consumption [7], and energy efficiency [8]. However, the introduction of VLC into RF systems faces problems of access-point and resource allocation.

For VLC/RF heterogeneous systems, access-point and resource allocation are two important issues to be resolved before the user transmits data and are also important factors affecting the system transmission rate. At present, most research on VLC/RF

hybrid systems is focused on power allocation, and few related studies have been conducted on how to reasonably allocate APs to users.

Ma et al. [9] developed a two-stage access-point selection (APS) method based on a fuzzy logic algorithm to maximize the energy efficiency under minimum transmission-rate requirements and power constraints. Obeed et al. [10] proposed an iterative algorithm to assign APs to users, and derived a new efficient algorithm to find the optimal dual variable through dual-variable correlation. It allocates the power of each AP to connected users, to maximize the total system capacity and improve the system fairness. Pratama et al. [11] proposed a bandwidth aggregation protocol to optimize the system throughput. However, while ensuring system stability, challenges still exist in effectively and dynamically allocating AP, bandwidth, and transmission power, and jointly optimizing the system performance. First, different types of APs can make system design difficult. In general, binary allocation variables and power allocation cause the resource-allocation problem to become a mixed-integer nonlinear-programming (MINP) problem, which is a nonconvex problem with high computational complexity. Second, resource allocation should be carried out under random channel conditions. As a joint optimization problem, it is usually necessary to optimize multiple parameters simultaneously. Thus, the resource-allocation optimization problem is affected by many factors and is difficult to solve.

Domestic and Foreign Research Progress

Visible light communication is a key research direction in optical wireless communication (OWC). An OWC system relies on light radiation to transmit information in free space with wavelengths ranging from infrared (IR) to ultraviolet (UV), including the visible spectrum. Infrared with wavelengths ranging from 780–950 nm is the best choice for IR indoor optical wireless systems. Within this range, it is easy to obtain a low-cost light source, and the frequency band is consistent with the peak sensitivity of inexpensive photodiodes.

In 1996, the IR system proposed by March and Khan [12, 13] achieved a data rate of 50 Mbit/s. In 2000, Carruther and Kahn [13] developed an angular-diversity infrared communication system that could achieve a data rate of 70 Mbit/s and proved that the system could theoretically achieve a communication rate of 100 Mbit/s.

Subsequently, visible light communication technology using white light-emitting diodes (LEDs) was proposed and has received increasing attention from academia and industry. As early as 1999, Pang et al. [14] proposed to modulate information onto an LED. Owing to the high switching-cycle frequency of the LED, the human eye cannot distinguish it, making the LED appear to be constantly illuminated without affecting its lighting function. Subsequently, an experimental system was developed by Kwan to use LEDs for synchronous signals and communication. Line of sight (LOS) and IM/DD were used in LED traffic lights. The transmission

distance of the experimental system reached 20 m [15], which was the beginning of VLC research.

Subsequently, many researchers conducted extensive research on VLC and explored the influence of different factors on VLC systems. In 2000, Tanaka et al. [16] introduced a wireless home link (WHL) into visible light communication and proposed a wireless VLC system based on white LEDs. The communication system was simulated using subcarrier modulation and binary phase-shift keying (BPSK). The influences of the optical-link parameters and field of view (FOV) on the communication system were discussed. Conclusions were drawn through the simulation experiments.

When only an LOS link is used, the noise bandwidth determines the communication performance of the system, and intersymbol interference (ISI) has a greater impact when considering multipath dispersion. The larger the FOV, the more paths detected by the receiver, which leads to a decrease in performance; therefore, it is necessary to select the appropriate FOV.

The following year, Tanaka et al. studied a three-color LED and conducted simulation experiments, which increased the VLC data-transmission rate to 400 Mbit/s [17]. In 2002, Fan and Komine et al. [18] studied the effects of reflective optical communication in VLC communication systems. The study found that, owing to the multipath effect, the communication interference near the wall increased and the communication performance characteristics worsened. Therefore, the system transmission rate could be improved by reducing the interference of multipath optical signals, as well as using parallel transmissions.

Many organizations and institutions have provided VLC standards and practical models, which have made significant contributions to its rapid development. In 2003, several scientific research institutions and enterprises in Japan established the Visible Light Communication Association [19]. It attracted the interest of a large number of research institutions and enterprises, and greatly promoted the commercial development of visible light communication. In addition, it has studied other uses of VLC, such as applications in indoor positioning, and promoted VLC development. In 2004, the Visible Light Communication Association announced the practical use of white LEDs in communication, and released an indoor VLC communication system and its basic principles and channel models to the public [20].

In 2006, Hidemitsu et al. [21] proposed a new modulation method that used reverse pulse-position modulation (RPPM) and subcarrier RPPM for VLC, which improved the brightness of LEDs and weakened the influence of background light on communication. In the same year, Afgani et al. [22] verified the feasibility of orthogonal frequency-division multiplexing (OFDM) technology in visible light communication. When the transmitter and receiver were 1 m apart and the bit-error rate (BER) was 10^{-3}, the communication performance of a single LED was improved. Moreover, it was verified that reducing the bit-error rate enabled a longer communication distance.

In 2008, Hashemi et al. [23] used OFDM technology in a VLC system to reduce the intersymbol interference (ISI). Because ISI is caused by the multipath effect, the system improved the LOS and diffused multipath links. Binary phase-shift keying

(BPSK), quadrature phase-shift keying (QPSK), and quadrature-amplitude-modulation (QAM) schemes were applied to OFDM, and their communication performance was analyzed. The simulations achieved a transmission rate of 100 Mbit/s.

In 2009, Langer et al. [24] presented a practical system based on indoor VLC using on–off keying (OOK) to achieve a transmission rate of 125 Mbit/s over a distance of 5 m. They presented a visible light link using discrete multitone (DMT) to realize digital signal processing, achieving a transmission rate of more than 200 Mbit/s.

In 2009, Vucic et al. [25] demonstrated a VLC system using DMT signal modulation. The transmission rate exceeded 200 Mbit/s at the position where the receiver could obtain approximately 1100-lx illumination. The transmission rate reached 180 Mbit/s at the position where the receiver could obtain approximately 550-lx illumination, and the transmission rate reached 100 Mbit/s at the position where the receiver obtained approximately 180-lx illumination.

In 2010, Vucic et al. proposed a wireless point-to-point communication link based on white LEDs and avalanche photodiodes. By effectively utilizing the modulation bandwidth and high signal-to-noise ratio (SNR) of the LED, and using QAM and DMT technologies, the data rate was increased to 513 Mbit/s [26]. In 2012, Vucic et al. proposed a VLC system based on wavelength-division multiplexing (WDM) and DMT modulation. In this system, an RBG-type LED was used to achieve a communication rate of 830 Mbit/s [27].

In addition to studying modulation methods, many researchers have focused on device performance and combined multiple modulation techniques to improve the performance of VLC systems. In 2010, Ahmad et al. [28] presented a high-speed VLC system that used an imaging receiver. The system used multiple-input multiple-output (MIMO) OFDM technology, a 2×1 LED emission matrix, and a 3×3 photodetector array to achieve a transmission rate of 220 Mbit/s within 1 m. However, the coverage of the system was small and could only cover an area of 8 cm $\times$ 9.7 cm.

In 2013, Zhang et al. [29] used complementary metal oxide semiconductor (CMOS)-integrated GaN-based blue micron-sized LEDs for communication. They achieved a maximum data-transmission rate of 1.5 Gbit/s in free space using 16 independent parallel data streams. In 2014, Tsonev et al. [30] presented a VLC system based on QAM-OFDM. The system used a high-modulation-bandwidth GaN LED, combined with equalization and adaptive data-loading technology, to achieve a transmission rate of 3.5 Gbit/s.

In 2016, Lu et al. [31] proposed and demonstrated a high-speed wireless VLC system with a modulation bandwidth of 1 GHz. Through various techniques, such as forward error correction, OFDM, and bit power-loading algorithms, a rate of 11.1 Gbit/s was achieved in a 1.2-m free space.

In recent years, many researchers have applied new technologies, such as multi-color modulation and nonorthogonal multiple access (NOMA), to VLC and have achieved good results. In 2019, Ye et al. [32] proposed a 4×4 color-polarization multiplexing method. The available bandwidth of blue and green LEDs for signal modulation was greater than 465 MHz. Under the extremely low illumination of

6.9–136.1 lx indoors, the VLC system provided a 1.7–2.3 Gbit/s OOK service rate in a free-space transmission length of 1–4 m. In addition, the measured BER of each LED was less than 3.8×10^{-3} and the system performance was good.

In 2020, Gunawan et al. [33] proposed a color-shift keying embedded DC optical OFDMA scheme for a VLC system and presented a demonstration. The VLC system not only provided nonblinking color-shift keying signals but also provided additional modulation sizes by including high-data-rate OFDM signals. In 2021, Lin et al. [34] studied signal-demodulation and signal-recovery methods for the NOMA-VLC system. They proposed a NOMA-VLC demodulator based on a convolutional neural network, so that the signal could be simultaneously compensated and recovered. This method effectively improved the system transmission performance, user's channel gain, and user's transmission rate, while satisfying the bit-error rate limit.

Resource allocation is also an important method for improving the transmission rate of VLC systems. Different resource-allocation algorithms have been proposed for different network environments and system-performance requirements.

Abdelhady et al. [35] proposed a low-complexity, nonconvex, joint time and power-allocation method to maximize the spectral efficiency (SE) and minimize the rate constraint of the algorithm. In a VLC system with time-division multiple access (TDMA), the successive convex approximation (SCA) and Karush–Kuhn–Tucker (KKT) methods were used to simplify the optimization problem. Subsequently, an SCA problem-solving method based on the interior-point method was proposed to reduce the complexity of the optimization process.

Considering the problems of inter-cell interference (ICI) and LOS link congestion in VLC systems, Aboagye et al. [36] proposed an optimization method based on energy efficiency (EE). Considering the minimum rate limit of users, the joint subchannel and power-allocation problem for maximizing the EE appeared. To address this problem, a low-complexity iterative solution based on the fractional-programming theory and a quadratic-transformation method was proposed.

Fu et al. [37] studied the power-allocation problem of OFDM-based non-orthogonal multiple-access (NOMA) VLC systems. Considering any number of multiplexed users, an enhanced power-allocation scheme was proposed to optimize the subcarrier power, which greatly improved the subcarrier loss rate and total data-transmission rate of the system.

In VLC/RF heterogeneous networks, resource allocation is also an important way to improve the system performance. To maximize the average system throughput, Li et al. [38] studied the load-balancing problem in VLC/RF heterogeneous networks and proposed centralized and distributed schemes. Based on user fairness, these two schemes provided the AP service-time ratio and access scheme for each user. These two schemes solved the time-proportion problem using nonlinear programming and average allocation, respectively. In the distributed scheme, the load-scheduling problem was solved using the Lagrange duality method.

Mohanad et al. [39] proposed a joint power-allocation and load-balancing algorithm to maximize the system throughput. The method allocated power and bandwidth equally among users accessing different access points. According to the established throughput utility-function expression, the Lagrange multiplier method

was used to optimize the load and power. This scheme allowed access to a large number of users and improved the system throughput and fairness.

Kafafy et al. [40] proposed a joint power and bandwidth allocation scheme for improving the power efficiency in VLC/RF heterogeneous networks. This method iteratively optimized the allocation of access points, as well as the power and bandwidth allocated to users by the APs to improve the power efficiency of the system.

In this study, we investigated the performance of VLC/RF systems based on orthogonal frequency-division multiple-access (OFDMA) technology. The system consists of multiple VLC APs and one RF AP that work together to serve multiple users. Using the OFDMA scheme, resources can be simultaneously divided into the time and frequency domains, and the divided time-frequency block is called a resource block (RB). For each resource block, the smallest indivisible block is called a resource unit (RU).

OFDMA technology allows multiple users to share all the subcarriers of a system; however, each subcarrier is limited to one user in a given time slot. If other users need to use this subcarrier, they must queue up for the next time slot, which reduces the system efficiency. Allocating system resources to different users, rather than simply allocating subcarriers or time slots, can improve the efficiency and flexibility of the entire communication system.

In addition, OFDMA can flexibly select channels with different frequencies for users and adaptively allocate resources, thereby significantly improving the spectral efficiency and transmission rate of the system. At present, in the field of VLC, OFDMA research mainly focuses on spectral efficiency; however, its combination with the system transmission rate and stability has not been thoroughly investigated.

In this study, in an indoor VLC/RF system based on OFDMA technology, Lyapunov optimization was used to transform the time-averaging problem into a single time-slot problem, which was divided into three independent subproblems to optimize a single time slot.

System Model

The VLC system model uses VLC technology to transmit signals. In this model, the downlink uses VLC and RF technologies. VLC is complementary to RF in transmitting information in the form of visible light to the receiver through LED lights. The uplink uses RF technology to transmit the user's feedback signal back to the transmitter using radio waves.

This model takes advantage of the high frequency and large bandwidth of visible light, making data transmissions more efficient and reliable. In addition, by using RF technology as an uplink, users can easily interact and provide feedback to the system.

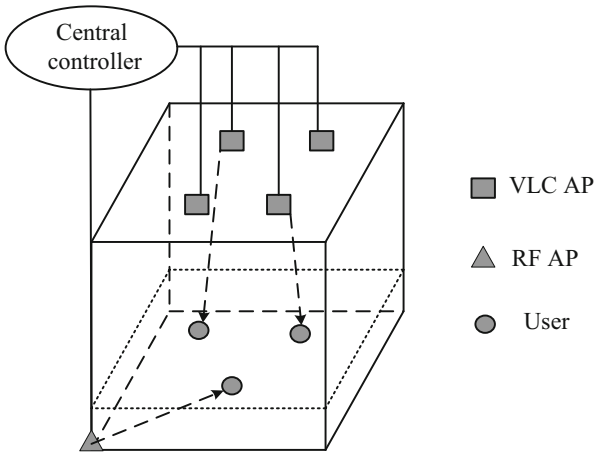

Fig. 40.1 Indoor VLC/RF heterogeneous system model

Downlink Communication

A model of the indoor VLC/RF heterogeneous system is shown in Fig. 40.1. It contains one RF AP, L VLC APs, and U users. The VLC AP was mounted on the ceiling, assuming that the RF AP could cover the entire room area. All APs were connected to a central controller responsible for collecting user feedback, scheduling, associations, and resource allocation. The users were evenly distributed on the receiving plane and equipped with VLC and RF receivers.

The set of APs is $L = L_{\mathrm{VLC}} + L_{\mathrm{RF}} = \{0, 1, 2,\ldots, L\}$, where $L_{\mathrm{VLC}} = \{1, 2,\ldots, L\}$ and $L_{\mathrm{RF}} = \{0\}$, representing the sets of VLC APs and RF APs, respectively. The user set is $U = \{1, 2,\ldots, U\}$. In this study, the communication system was divided into T time slots, and the duration of each time slot was t s. It was assumed that all user locations remained unchanged for a short period of time.

For network selection, the variable $a^{(u,\ l)}(t)$ is introduced, where $a^{(u,\ l)}(t) = 1$ indicates that user u uses AP_l for access in time slot t. Otherwise, $a^{(u,\ l)}(t) = 0$. As a single user can only be served by one AP in a time slot, the following constraints are obtained:

$$\sum_{l \in L} a^{(u,l)}(t) = 1, a^{(u,l)}(t) \in \{0, 1\}, \forall l. \tag{40.1}$$

VLC Channel Model

For indoor VLC systems, directional direct-view communication links are generally used [12]; that is, the transmitter and receiver of the VLC system are within their respective field-of-view (FOV) ranges, as shown in Fig. 40.2. For the VLC system investigated in this study, the LOS channel gain between the AP_l and user u is

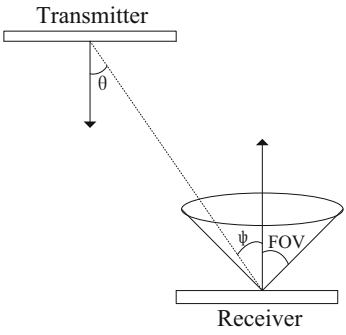

Fig. 40.2 Indoor VLC downlink LOS link model

$$h^{(u,l)} = \begin{cases} \dfrac{(m+1)A_p}{2\pi d^2} \cos^m(\theta) \cos(\varphi) T_l G_l, (\varphi \leq \text{FOV}) \\ 0, (\varphi > \text{FOV}) \end{cases}, \tag{40.2}$$

where $m = -\ln 2/\ln(\cos(\text{FOV}))$ is the Lambertian order, FOV is the half angle of the light-source transmitting power, A_p is the effective area of the receiver photodiode, d represents the distance between AP_l and user u, and θ and φ represent the irradiation and incidence angles, respectively. T_l represents the gain of the optical filter and G_l represents the gain of the concentrator.

In VLC systems, signal-transmission methods for intensity modulation and direct detection (IM/DD) have been adopted. Because the LED operates in a linear region, the output optical power of the modulated signal is proportional to the input voltage, ensuring that the signal transmitted to the receiving end is positive and steady. In addition, the average emitted electrical power P_e is satisfied by the average emitted optical power P_o:

$$P_e = \beta (P_o)^2, \tag{40.3}$$

where β is the DC bias factor of the VLC AP.

Assuming that there are K subcarriers in the VLC system, $b_k^{(u,l)}(t)$ represents the distribution coefficient of user u with the K subcarriers of VLC AP_l in time slot t, and $b_k^{(u,l)}(t) = 1$ indicates that AP_l assigns subcarrier k to the user for communication in time slot t. Otherwise, $b_k^{(u,l)}(t) = 0$.

The signal-to-noise ratio on the kth subcarrier between user u and VLC AP_l is

$$\xi_k^{(u,l)} = \frac{\left| \varepsilon \beta p_{k,o}^{(u,l)}(t) h_k^{(u,l)}(t) \right|^2}{\sigma_{\text{VLC}}^2} = \frac{p_k^{(u,l)}(t) \left| \varepsilon h_k^{(u,l)}(t) \right|^2}{\sigma_{\text{VLC}}^2}, \tag{40.4}$$

where ε represents the photoelectric-conversion coefficient received by the user, σ^2_{VLC} represents the noise power in the VLC channel, and $p^{(u,l)}_{k,o}$ represents the transmit power of VLC AP_l to user u on subcarrier k.

From Shannon's formula, the effective information-transfer rate between VLC AP_l and user u on subcarrier k of time slot t is

$$\nu^{(u,l)}_k(t) = B_{\mathrm{VLC}} \log_2\left(1 + \xi^{(u,l)}_k(t)\right) \tag{40.5}$$

where B_{VLC} is the subcarrier bandwidth. Because each subcarrier can only be assigned to one user in a single time slot, the following constraints exist for each subcarrier k:

$$\sum_{u \in U} a^{(u,l)}(t) b^{(u,l)}_k(t) \le 1, a^{(u,l)}(t) \in \{0,1\}, b^{(u,l)}_k(t) \in \{0,1\}, \forall l \in L_{\mathrm{VLC}}. \tag{40.6}$$

The transmission rate of VLC AP_l and user u in time slot t is

$$R_{\mathrm{VLC}}(t) = a^{(u,l)}(t)\nu^{(u,l)}(t) = a^{(u,l)}(t) \sum_{k \in K} b^{(u,l)}_k(t)\nu^{(u,l)}_k(t) \tag{40.7}$$

In time slot t, the transmit power of VLC AP_l is

$$P^l_{\mathrm{VLC}}(t) = \sum_{u \in U} a^{(u,l)}(t) P^{(u,l)}(t) = \sum_{u \in U} a^{(u,l)}(t) \sum_{k \in K} b^{(u,l)}_k(t) p^{(u,l)}_k(t) \tag{40.8}$$

To save power, the upper limit of the time-averaged power consumption of VLC AP_l can be set to

$$0 \le \lim_{T \to \infty} \frac{1}{T} \sum_{t=0}^{T-1} E\left[P^l_{\mathrm{VLC}}(t)\right] < P_{\mathrm{ave,VLC}} \tag{40.9}$$

where $P_{\mathrm{ave,\ VLC}}$ represents the maximum average power consumption on VLC AP_l.

RF channel model

The RF communication path loss is represented by PL [41] and typically takes the following form:

$$\mathrm{PL}[dB] = A \log_{10}\left(d^{(u,l)}\right) + B + C \log_{10}\left(\frac{f_c}{5}\right) + X \tag{40.10}$$

where $d^{(u,\ l)}$ is the distance between the RF AP and the user; f_c is the carrier frequency in GHz; A, B, and C are constants that depend on the propagation model; and X represents the loss caused by shadow effects in different environments.

RF communicates using OFDM, in which the RF AP uses I resource blocks (RBs). In time slot t, $x_i^{(u,0)}(t)$ represents the allocation relationship between user u and the ith RB, if $x_i^{(u,0)}(t) = 1$ and AP_l assigns RB_i to user u; otherwise, $x_i^{(u,0)}(t) = 0$. Because there is only one RF AP in a VLC/RF heterogeneous network, channel interference in the RF system can be ignored.

Assuming that the RF AP transmits power to user u on RB_i of $p_i^{(u,0)}(t)$, the signal-to-noise ratio between user u and the RF AP is

$$\xi_i^{(u,0)}(t) = \frac{p_i^{(u,0)}(t) g_i^{(u,0)}(t)}{\sigma_{\mathrm{RF}}^2}, \tag{40.11}$$

where $g_i^{(u,0)}(t) = 10^{-\mathrm{PL[dB]}/10}$ represents the RF channel power gain and σ_{RF}^2 represents the noise power of the RF channel.

According to Shannon's formula, the information-transmission rate between RF AP subchannel i and user u in time slot t is

$$\nu_i^{(u,0)}(t) = B_{\mathrm{RF}} \log_2\left(1 + \xi_i^{(u,0)}(t)\right), \tag{40.12}$$

where B_{RF} denotes the bandwidth of RB_i. Because each RB can serve only one user in a time slot, the following must be satisfied for each RB_i:

$$\sum_{u \in U} a^{(u,0)}(t) x_i^{(u,0)}(t) \leq 1. \tag{40.13}$$

Therefore, in time slot t, the information-transfer rate between the RF AP and user u is

$$R_{\mathrm{RF}}(t) = a^{(u,0)}(t) \nu^{(u,0)}(t) = a^{(u,0)}(t) \sum_{i \in I} x_i^{(u,0)}(t) \nu_i^{(u,0)}(t). \tag{40.14}$$

The transmit power of the RF AP is derived from the following equation:

$$P_{\mathrm{RF}}^0(t) = \sum_{u \in U} a^{(u,0)}(t) P^{(u,0)}(t) = \sum_{u \in U} a^{(u,0)}(t) \sum_{i \in I} x^{(u,0)}(t) p_i^{(u,0)}(t). \tag{40.15}$$

Considering the power condition, the transmitting power should satisfy

$$P^0 = \lim_{T \to \infty} \frac{1}{T} \sum_{t=0}^{T-1} E\left[P_{\mathrm{RF}}^0(t)\right] < P_{\mathrm{ave,RF}}, \tag{40.16}$$

where $P_{\mathrm{ave,RF}}$ is the maximum average power consumption of the RF AP.

Uplink Communication

When the downlink successfully receives a signal, it replies to the sender through an RF transmitter, indicating that the response was successfully received. As RF communication is performed indoors, the Rayleigh fading channel [42] was selected as the upstream RF communication-link channel model. The channel coefficient h of the Rayleigh fading channel follows a complex Gaussian distribution with a mean of 0 and a variance of σ^2, i.e., $h \sim CN(0, \sigma^2)$, where $\sigma^2 = d^{-\alpha}$, d represents the RF communication distance, and α represents the path-fading factor in RF communication. In an indoor environment, the value is usually set as 2–4.

The signal transmitted by the RF transmitter is $\sqrt{P_{\mathrm{RF}}}\chi_{\mathrm{RF}}(t)$, where P_{RF} is the power of the response signal, $\chi_{\mathrm{RF}}(t)$ is the normalized signal, $\chi_{\mathrm{RF}}(t) \in [-1, 1]$, and $E[|\chi_{\mathrm{RF}}(t)|^2] = 1$. The signal at the RF receiver can be expressed as

$$y_{\mathrm{RF}}(t) = \sqrt{P_{\mathrm{RF}}} h \chi_{\mathrm{RF}}(t) + n_{\mathrm{RF}}(t), \tag{40.17}$$

where $n_{\mathrm{RF}}(t)$ is additive white Gaussian noise and follows a complex Gaussian distribution with a mean of zero and variance of σ^2_{RF}.

OFDMA System Model

In this study, a VLC system model based on OFDMA technology was adopted, which aimed to combine optimization objectives with system stability. According to the different M-QAM modulation methods, M-ary QAM can be adaptively applied to different OFDM subcarriers [43]. Different spectral efficiencies (SE) can be achieved for each subcarrier; S_k is used to represent the SE of each subcarrier. The value of S_k depends on the order of the M-QAM. The modulation order of M-QAM is adaptively selected, based on the signal-to-interference-plus-noise ratio (SINR) between the user and the VLC AP. The relationship between S_k and the SINR was determined using the modulation and coding scheme (MCS). These values are listed in Table 40.1.

SINR can be expressed as

$$\mathrm{SINR}(f) = \frac{(\varepsilon P_o H)^2}{N_0 B + \sum\limits_{l \in L} \left(\varepsilon P_o H^{(u,l)}\right)^2}, \tag{40.18}$$

where N_0 represents the noise power spectral density in the VLC channel, B represents the bandwidth of the VLC-baseband modulated signal, H represents the channel gain between the VLC AP providing the service and user u, and $H^{(u,\ l)}$ represents the channel gain between the nonservice VLC AP and user u, which is regarded as interference noise.

The model uses $t = 0, 1, 2, \ldots, T$ as variables by allocating subchannels by time slot, studying the changes in the system as time passes, and reassigning subchannels.

Table 40.1 Relationship between the SINR, modulation, coding rate, and SE [44]

$SINR_{min}$ [dB]	Modulation mode	Encoding rate	SE [bit/Hz]
–	–	–	0
1	QPSK	0.44	0.8770
3	QPSK	0.59	1.1758
5	16QAM	0.37	1.4766
8	16QAM	0.48	1.9141
9	16QAM	0.60	2.4063
11	64QAM	0.45	2.7305
12	64QAM	0.55	3.3223
14	64QAM	0.65	3.9023
16	64QAM	0.75	4.5234
18	64QAM	0.85	5.1152
20	64QAM	0.93	5.5547

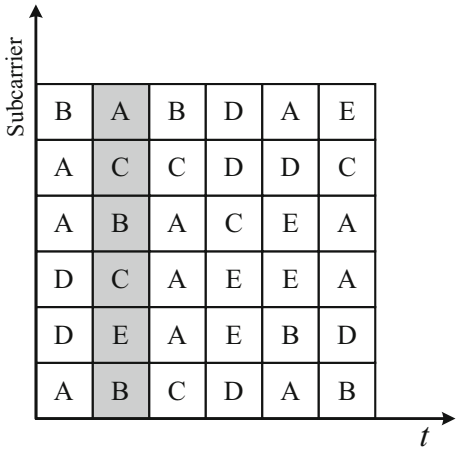

Fig. 40.3 OFDMA system resource-allocation model

This method fundamentally improves the frequency of system resource allocation, such that the system can quickly make optimal allocations as time passes. In addition, we used the Lyapunov optimization method for this optimization process to ensure that the system remained stable during changes within $t = 0, 1, 2, \ldots, T$.

Figure 40.3 shows the OFDMA system resource-allocation model. The dark part represents the resource-allocation scale; for each RB, the smallest block of indivisible resources is called the resource unit (RU). The RU allocates resources in each time slot, and each RU allocation process is independent. This allocation process differs from one-dimensional resource allocation in that in each time slot, the resource-allocation problem in OFDMA is degraded from two dimensional to one dimensional by setting the integer restriction to $b_k^u(t) \in \{0, 1\}$, and the integer allocation is reduced to a 0–1 integer-allocation problem.

In VLC systems, it is generally believed that the channel is time-flat and that there is no fading during communication. Therefore, the channel-state information is constant for each time slot. Suppose that the VLC AP providing the service and subscriber-device subcarrier k can achieve the rate represented by the following equation:

$$\nu_{k,u}(t) = 2BS_k/K. \tag{40.19}$$

The transmission rate between the user on subchannel k and the VLC AP providing the service is

$$R_{k,u}(t) = b_k^u(t)\nu_{k,u}(t). \tag{40.20}$$

The transfer rate provided by the VLC AP to user u is

$$R_u(t) = \sum_{k \in K} R_{k,u}(t). \tag{40.21}$$

Because a subcarrier can serve only one user per time slot, its distribution coefficient must satisfy the following constraints:

$$\sum_{u \in U} b_k^u(t) = 1, b_k^u(t) \in \{0, 1\}, \forall k \in K. \tag{40.22}$$

Queue Model

When the system begins transmitting data, let $Q_u(t)$ represent the length of the queue that the system maintains for user u at the beginning of time slot t. $D_u(t)$ represents the amount of data that user u sends at time slot t, which is independently and identically distributed across different time slots [45]. Assuming that the average data-arrival rate of user u in time slot t is $\gamma_u(t)$, the following conditions are met for $D_u(t)$:

$$E[D_u(t)] = \gamma_u(t), \forall u \in U, \tag{40.23}$$

where γ_u is a bounded variable that guarantees the stability of the system. According to the above analysis, $Q_u(t)$ can be expressed as

$$Q_u(t+1) = [Q_u(t) - R_u(t), 0]^+ + D_u(t), \tag{40.24}$$

where $R_u(t)$ represents the amount of data left and $[x, 0]^+ = \max[x, 0]$.

For each user u, the randomness of $D_u(t)$ and the time-varying nature of $R_u(t)$ are provided to make the queuing process random. If we only consider maximizing the system-transfer rate and ignore the impact of the queue, data will accumulate in the

queue during transmission, resulting in the system operating abnormally. Therefore, a queue-stability model must be established; it is generally defined as

$$\lim_{T\to\infty}\frac{1}{T}\sum_{t=0}^{T-1}E[Q_u(t)]<\infty. \tag{40.25}$$

If all queues in the system are stable, the VLC communication system will also be stable. This means that the average departure rate in the queue is greater than or equal to the average input rate. Once this condition is met, all data in the queue are sent to the corresponding user.

Optimization Theory

The goal of this study was to achieve the maximum transfer rate, while keeping the system stable. Within time slot t, the transmission rate of the entire system can be expressed as

$$R(t)=\sum_{u\in U}R_u(t)=\sum_{u\in U}\sum_{l\in L}R^{(u,l)}(t). \tag{40.26}$$

To achieve the optimization goal of maximizing the average system transmission rate, the above function was designed as a time-averaged expression. Therefore, the stochastic optimization problem was formulated as follows:

$$\begin{cases}
\max\ \lim\limits_{T\to\infty}\dfrac{1}{T}\sum\limits_{t=0}^{T-1}E\left[R(t)\right] & \\
\text{s.t}\ \lim\limits_{T\to\infty}\dfrac{1}{T}\sum\limits_{t=0}^{T-1}E\left[Q_u(t)\right]<\infty,\ \forall u\in U & \text{(a)}\\
\sum\limits_{l\in L}a^{(u,l)}(t)=1,\ a^{(u,l)}(t)\in\{0,1\},\ \forall u\in U,\ \forall l\in L & \text{(b)}\\
\sum\limits_{u\in U}a^{(u,0)}(t)x_i^{(u,0)}(t)\le 1,\ a^{(u,l)}(t)\in\{0,1\},\ x_i^{(u,0)}(t)\in\{0,1\},\ \forall u\in U & \text{(c)}\\
0\le\lim\limits_{T\to\infty}\dfrac{1}{T}\sum\limits_{t=0}^{T-1}E\left[P_l(t)\right]<P_{l,ave},\ P_{l,ave}=\begin{cases}P_{ave,RF},\ \text{if } l=0\\ P_{ave,VLC},\ \text{if } l=1,\cdots L\end{cases} & \text{(d)}\\
\sum\limits_{u\in U}a^{(u,l)}(t)b_k^{(u,l)}(t)\le 1,\ a^{(u,l)}(t)\in\{0,1\},\ b_k^{(u,l)}(t)\in\{0,1\},\ \forall l\in L_{VLC} & \text{(e)}\\
\sum\limits_{u\in U}b_k^{u}(t)=1,\ \forall k\in K & \text{(f)}\\
P_i^{(u,0)}(t)\ge 0,\ P_k^{(u,l)}(t)\ge 0,\ \forall l\in L_{VLC},\forall u\in U & \text{(g)}
\end{cases} \tag{40.27}$$

where (a) is the system stability requirement; (b) ensures that in each time slot, the user can only be served by one AP; (c) ensures that for the RF AP, only one user can be served on each resource block; (d) represents the average power-budget constraint of each AP; (e) ensures that each subchannel of the VLC AP can only serve one user; (f) ensures that for one VLC AP, each subcarrier can only be assigned to one user at a time; and (g) means that the transmit power of all APs is nonnegative and meets the actual conditions.

The above problem has long-term constraints. To effectively handle long-term time-average power constraints, virtual queues in Lyapunov optimization can be used to convert (d) into queue-stability constraints [46]. Virtual queues are defined as $Z(t) \cong \{Z_1(t),\ldots, Z_l(t),\ldots, Z_L(t)\}$. $Z_l(t)$ evolves as follows:

$$Z_l(t+1) = \max\{Z_l(t) - P_{l,\text{ave}}, 0\} + P_l(t). \tag{40.28}$$

It should be noted that there is no actual queue data in queue $Z_l(t)$; it is only proposed to satisfy constraint (d). If virtual queue $Z_l(t)$ is average-rate-stable, constraint (d) automatically holds [47].

Suppose the order vector of the queue length in the system is $\Theta(t) = [Q(t), Z(t)]$. The Lyapunov function is defined as a measure of the total queue length for each time slot t and is denoted by the following equation:

$$\mathrm{L}(\Theta(t)) = \frac{1}{2}\sum_{\substack{u \in U \\ l \in L}} Q_u^2(t) + \frac{1}{2}\sum_{l \in L} Z_l^2(t). \tag{40.29}$$

In each time slot, the conditional Lyapunov drift is defined as

$$\Delta(\Theta(t)) \triangleq E[\mathrm{L}(\Theta(t+1)) - \mathrm{L}(\Theta(t))|\Theta(t)]. \tag{40.30}$$

In each time slot, the Lyapunov function controls the final value of the Lyapunov drift by adjusting the final queue length. The purpose of this study is to maximize the average system-transfer rate. The drift-penalty function term is defined as

$$\Delta(\Theta(t)) - VE[R(t)|\Theta(t)], \tag{40.31}$$

where V is a nonnegative constant parameter used to balance the drift with a reward. When V increases, the system assigns a higher priority to maximize the transmission rate; that is, it sacrifices the queue length. When the V value decreases, the system prioritizes the queue length to maintain the system stability.

For each time period, for a given $V \geq 0$, the upper bound of the drift-penalty function for any possible $\Theta(t)$ is

$$\begin{aligned}\Delta(\Theta(t)) - VE[R(t)|\Theta(t)] &= E[\mathrm{L}(\Theta(t+1)) - \mathrm{L}(\Theta(t))|\Theta(t)] - V\sum_{\substack{u\in U\\ l\in L}} E\left[R^{(u,l)}(t)|\Theta(t)\right] \\ &\le C + \sum_{\substack{u\in U\\ l\in L}} E\left[Q_u(t)\left(D_u(t) - a^{(u,l)}(t)\nu^{(u,l)}(t)\right)|\Theta(t)\right] \\ &\quad + \sum_{l\in L} E[Z_l(t)(P_l(t) - P_{l,\mathrm{ave}})|\Theta(t)],\end{aligned} \tag{40.32}$$

where C is a constant satisfying the following conditions:

$$C \ge \frac{1}{2}\sum_{u\in U} E\left[D_u^2(t) + R_u^2(t)|\Theta(t)\right] + \frac{1}{2}\sum_{l\in L} E\left[P_l^2(t) + (P_{l,\mathrm{ave}})^2|\Theta(t)\right]. \tag{40.33}$$

According to the Lyapunov optimization method [48], the network utility is optimized by minimizing the drift-penalty function term to minimize the queue length. Therefore, Eq. (40.28) can be transformed into minimizing the upper bound of the Lyapunov drift-penalty function in each time slot, which is expressed as

$$\begin{cases} \min \sum\limits_{\substack{u\in U\\ l\in L}} Q_u(t)\left(D_u(t) - a^{(u,l)}(t)\nu^{(u,l)}(t)\right) + \sum\limits_{l\in L} Z_l(t)(P_l(t) - P_{l,\mathrm{ave}}) - V\sum\limits_{\substack{u\in U\\ l\in L}} a^{(u,l)}(t)\nu^{(u,l)}(t) \\ \text{s.t (27c) (27d) (27f) (27h).} \end{cases} \tag{40.34}$$

The reformulated optimization problem, Eq. (40.34), is a constrained mixed-integer programming problem, where $a^{(u,\,l)}(t)$, $x_i^{(u,0)}(t)$, and $b_k^{(u,l)}(t)$ take integer values, and $p_i^{(u,0)}(t)$ and $p_k^{(u,l)}(t)$ take continuous values. Therefore, optimization problem (40.34) is decomposed into three relatively independent subproblems, and a corresponding optimization algorithm is proposed.

AP Allocation

The AP allocation variables $a^{(u,\,l)}(t)$ in the system can be obtained by solving the following subproblems:

$$\begin{cases} \min \sum\limits_{\substack{u\in U\\ l\in L}} Q_u(t)\left(D_u(t) - a^{(u,l)}(t)\nu^{(u,l)}(t)\right) - V\sum\limits_{\substack{u\in U\\ l\in L}} a^{(u,l)}(t)\nu^{(u,l)}(t) \\ \text{s.t} \sum\limits_{l\in L} a^{(u,l)}(t) = 1, a^{(u,l)}(t) \in \{0,1\}, \forall u \in U, \forall l \in L. \end{cases} \tag{40.35}$$

From (40.35), it can be observed that the network selection between different users is independent. Therefore, problem (40.35) can be decomposed into U subproblems, where each subproblem is

$$\begin{cases} \max \sum\limits_{l \in L} a^{(u,l)}(t) e^{(u,l)}(t) \\ \text{s.t} \sum\limits_{l \in L} a^{(u,l)}(t) = 1, a^{(u,l)}(t) \in \{0,1\}, \forall u \in U, \forall l \in L, \end{cases} \tag{40.36}$$

where $e^{(u,\ l)}(t) = (Q_u(t) + V)\, v^{(u,\ l)}$. As (40.36) is a linear-optimization problem, its solution is as follows:

$$a^{(u,l)}(t) = \begin{cases} 1, l = \arg\max\limits_{l'} \left\{ e^{(u,l')}(t), 0 < l' < L \right\}, \\ 0, \text{otherwise}. \end{cases} \tag{40.37}$$

Under the above network-selection strategy, $e^{(u,l)}(t)$ can be regarded as the congestion cost of the AP serving the user within time slot t. Then, Eq. (40.37) ensures that the user can connect to the AP with the lowest congestion cost.

VLC AP Joint Subcarrier and Power Allocation

According to the access-point allocation variable $a(t)$, obtained from Eq. (40.35), the joint subcarrier and power-allocation subproblems in the VLC system can be continuously solved.

$$\begin{cases} \max \sum\limits_{\substack{u \in U \\ l \in L_{\text{VLC}}}} a^{(u,l)}(t) \nu^{(u,l)}(t) (Q_u(t) + V) - Z_l(t)(P_l(t) - P_{\text{ave,VLC}}(t)) \\ \text{s.t} \sum\limits_{u \in U} a^{(u,l)}(t) b_k^{(u,l)}(t) \le 1, a^{(u,l)}(t) \in \{0,1\}, b_k^{(u,l)}(t) \in \{0,1\}, \forall u \in U, \\ p_k^{(u,l)}(t) \ge 0, \forall u \in U. \end{cases} \tag{40.38}$$

Because the selection of subcarriers is independent among different VLC APs, problem (40.38) can be decomposed into $|L_{\text{VLC}}|$ subproblems, and each subproblem is expressed as

$$\begin{cases} \max \sum\limits_{u \in U} B_{\text{VLC}} \log_2 \left(1 + \dfrac{p_k^{(u,l)}(t) \left| \varepsilon h_k^{(u,l)}(t) \right|^2}{\sigma_{\text{VLC}}^2} \right) (Q_u(t) + V) - Z_l(t)(P_l(t) - P_{\text{ave,VLC}}(t)) \\ \text{s.t} \sum\limits_{u \in U} a^{(u,l)}(t) b_k^{(u,l)}(t) \le 1, a^{(u,l)}(t) \in \{0,1\}, b_k^{(u,l)}(t) \in \{0,1\}, \forall u \in U_l, \\ p_k^{(u,l)}(t) \ge 0, \forall u \in U_l, \end{cases} \tag{40.39}$$

where U_l denotes the set of users connected to the VLC AP. The VLC joint subcarrier and power-allocation problem is a hybrid combinatorial optimization problem. To solve this problem, the Lagrange relaxation method can be used to transform the original mixed-integer-programming problem into a convex-optimization problem. Relaxing $b_k^{(u,l)}(t) \in \{0,1\}$ to $\tilde{b}_k^{(u,l)}(t) \in [0,1]$, the optimization problem is reformulated as

$$\begin{cases} \max \sum\limits_{k \in K} \sum\limits_{u \in U_l} \tilde{b}_k^{(u,l)}(t)(Q_u(t)+V)B_{\mathrm{VLC}}\log_2\left(1+\dfrac{p_k^{(u,l)}(t)\left|\varepsilon h_k^{(u,l)}(t)\right|^2}{\tilde{b}_k^{(u,l)}(t)\sigma_{\mathrm{VLC}}^2}\right) \\ \quad - Z_l(t)\left(\sum\limits_{k \in K}\sum\limits_{u \in U} p_k^{(u,l)}(t) - P_{\mathrm{ave,VLC}}(t)\right) \\ \text{s.t} \sum\limits_{u \in U_l} \tilde{b}_k^{(u,l)}(t) \le 1, \forall u \in U_l, \\ \quad 0 \le \tilde{b}_k^{(u,l)}(t) \le 1, \forall u \in U_l, \\ \quad p_k^{(u,l)}(t) \ge 0, \forall u \in U_l. \end{cases} \tag{40.40}$$

As $\sum\limits_{k \in K}\sum\limits_{u \in U_l} \tilde{b}_k^{(u,l)}(t)(Q_u(t)-V)B_{\mathrm{VLC}}\log_2\left(1+\dfrac{p_k^{(u,l)}(t)\left|\varepsilon h_k^{(u,l)}(t)\right|^2}{\tilde{b}_k^{(u,l)}(t)\sigma_{\mathrm{VLC}}^2}\right)$ is a convex function of $\tilde{b}_k^{(u,l)}(t)$ and $p_k^{(u,l)}(t)$, it is considered a linear function of $\log_2\left(1+\frac{p_k^{(u,l)}(t)\left|\varepsilon h_k^{(u,l)}(t)\right|^2}{\sigma_{\mathrm{VLC}}^2}\right)$. Therefore, the given optimization problem is a $K \times |U_l|$ linear combination of convex functions.

Let $\mathrm{L}(P) = \sum\limits_{k \in K}\sum\limits_{u \in U_l} \tilde{b}_k^{(u,l)}(t)(Q_u(t)+V)B_{\mathrm{VLC}}\log_2\left(1+\frac{p_k^{(u,l)}(t)\left|\varepsilon h_k^{(u,l)}(t)\right|^2}{\tilde{b}_k^{(u,l)}(t)\sigma_{\mathrm{VLC}}^2}\right) - Z_l(t)\sum\limits_{k \in K}\sum\limits_{u \in U} p_k^{(u,l)}(t)$ be the objective function and determine the partial derivative of $p_k^{(u,l)}(t)$ for $\mathrm{L}(P)$.

$$\frac{\partial \mathrm{L}(P)}{\partial p_k^{(u,l)}(t)} = \frac{\tilde{b}_k^{(u,l)}(t)(Q_u(t)+V)B_{\mathrm{VLC}}\left|\varepsilon h_k^{(u,l)}(t)\right|^2}{\left(\tilde{b}_k^{(u,l)}(t)\sigma_{\mathrm{VLC}}^2 + p_k^{(u,l)}(t)\left|\varepsilon h_k^{(u,l)}(t)\right|^2\right)\ln 2} - Z_l(t) \tag{40.41}$$

According to the Karush–Kuhn–Tucker (KKT) condition, the system can achieve optimal power allocation when the following conditions are satisfied:

$$\begin{aligned} &\frac{\partial\left[\mathrm{L}(P) - \left(\sum\limits_{k \in K}\sum\limits_{u \in U_l} \mu_k^u p_k^{(u,l)}(t)\right)\right]}{\partial p_k^{(u,l)}(t)} \\ &= \frac{\tilde{b}_k^{(u,l)}(t)(Q_u(t)+V)B_{\mathrm{VLC}}\left|\varepsilon h_k^{(u,l)}(t)\right|^2}{\left(\tilde{b}_k^{(u,l)}(t)\sigma_{\mathrm{VLC}}^2 + p_k^{(u,l)}(t)\left|\varepsilon h_k^{(u,l)}(t)\right|^2\right)\ln 2} \end{aligned} \tag{40.42}$$

$$-Z_l(t) - \mu_k^u = 0 \tag{40.43}$$

$$\mu_k^u p_k^{(u,l)}(t) = 0, \forall k, u \tag{40.44}$$

$$\mu_k^u \geq 0, \forall k, u, \tag{40.45}$$

where μ_k^u is a multiplier used to construct the Lagrange function.

To ensure that (40.44) holds true, we use $\mu_k^u = 0$ or $p_k^{(u,l)}(t) = 0$. The partial derivative of (40.42) is 0, and the relationship between $p_k^{(u,l)^*}(t)$ and $\tilde{b}_k^{(u,l)}(t)$ is obtained.

$$p_k^{(u,l)^*}(t) = \left[\frac{(Q_u(t) + V)B_{\mathrm{VLC}}}{Z_l(t)\ln 2} - \frac{\sigma_{\mathrm{VLC}}^2}{\left|\varepsilon h_k^{(u,l)}(t)\right|^2} \right]^+ \tilde{b}_k^{(u,l)}(t). \tag{40.46}$$

The power-allocation result is used to obtain subcarrier allocation. By substituting Eq. (40.46) into Equation $\mathrm{L}(P)$, we obtain

$$\mathrm{L}(P) = \sum_{k \in K} \sum_{u \in U} L_k^u(P) \tilde{b}_k^{(u,l)}(t), \tag{40.47}$$

where

$$L_k^u(P) = (Q_u(t) + V)B_{\mathrm{VLC}} \log_2 \left(1 + \left[\frac{(Q_u(t) + V)B_{\mathrm{VLC}}}{Z_l(t)\ln 2} - \frac{\sigma_{\mathrm{VLC}}^2}{\left|\varepsilon h_k^{(u,l)}(t)\right|^2} \right]^+ \frac{\left|\varepsilon h_k^{(u,l)}(t)\right|^2}{\sigma_{\mathrm{VLC}}^2} \right)$$
$$-Z_l(t) \left[\frac{(Q_u(t) + V)B_{\mathrm{VLC}}}{Z_l(t)\ln 2} - \frac{\sigma_{\mathrm{VLC}}^2}{\left|\varepsilon h_k^{(u,l)}(t)\right|^2} \right]^+. \tag{40.48}$$

Equation (40.47) is a linear-assignment problem that can be decomposed into k subproblems. Each subproblem is represented by the following equation:

$$\mathrm{L}_k(P) = \sum_{u \in U} L_k^u(P) \tilde{b}_k^{(u,l)}(t). \tag{40.49}$$

For subcarrier k, the optimal allocation obtains the user with the maximum $L_k^u(P)$, and the solution can be obtained:

$$\tilde{b}_k^{(u,l)^*}(t) = \begin{cases} 1, u = \underset{u'}{\mathrm{argmax}} \left(L_k^{u'}(P), u' \in U_l \right), L_k^{u'}(P) > 0, \\ 0, \text{otherwise.} \end{cases} \tag{40.50}$$

RF AP Joint Resource Block and Power Allocation

In RF communication systems, the RF AP joint resource block and power-allocation subproblem can be expressed as

$$\begin{cases} \max \sum\limits_{u \in U_0} a^{(u,0)}(t)(Q_u(t)+V) - Z_0(t)(P_0(t) - P_{\text{ave,RF}}(t)) \\ \text{s.t} \sum\limits_{u \in U_0} x_i^{(u,0)}(t) \le 1, a^{(u,0)}(t) \in \{0,1\}, x_i^{(u,0)}(t) \in \{0,1\}, \forall u \in U_0 . \\ p_i^{(u,0)}(t) \ge 0, \forall u \in U_0 \end{cases} \quad (40.51)$$

It can be seen from the above equations that the joint RB and power-allocation problems are independent of each other on different time slots t. Therefore, the objective function of problem (40.51) is a function of discrete variable $x_i^{(u,0)}(t)$ and continuous variable $p_i^{(u,0)}(t)$; thus, the problem is also a mixed-integer nonlinear convex-optimization problem, which can be solved by the Lagrange relaxation method.

Firstly, $x_i^{(u,0)}(t)$ is relaxed to the continuous interval [0, 1], and a new variable $\tilde{x}_i^{(u,0)}(t)$ is defined. Problem (40.51) can be rewritten as:

$$\begin{cases} \max \sum\limits_{i \in I} \sum\limits_{u \in U_0} \tilde{x}_i^{(u,0)}(t)(Q_u(t)+V) B_{\text{RF}} \log_2 \left(1 + \dfrac{p_i^{(u,0)}(t) g_i^{(u,0)}(t)}{\tilde{x}_i^{(u,0)}(t)\sigma_{\text{RF}}^2}\right) - Z_0(t) \sum\limits_{i \in I} \sum\limits_{u \in U_0} p_i^{(u,0)}(t) \\ \text{s.t} \sum\limits_{u \in U_0} \tilde{x}_i^{(u,0)}(t) \le 1, \tilde{x}_i^{(u,0)}(t) \in [0,1], \forall u \in U_0 \\ p_i^{(u,0)}(t) \ge 0, \forall u \in U_0 \end{cases} . \quad (40.52)$$

Let the objective function be

$$\mathrm{L}(P) = \sum_{i \in I} \sum_{u \in U_0} \tilde{x}_i^{(u,0)}(t)(Q_u(t)+V) B_{\text{RF}} \log_2 \left(1 + \frac{p_i^{(u,0)}(t) g_i^{(u,0)}(t)}{\tilde{x}_i^{(u,0)}(t)\sigma_{\text{RF}}^2}\right) - Z_0(t) \sum_{i \in I} \sum_{u \in U_0} p_i^{(u,0)}(t),$$

and calculate the partial derivative of $p_i^{(u,0)}(t)$:

$$\frac{\partial \mathrm{L}(P)}{\partial p_i^{(u,0)}(t)} = \frac{\tilde{x}_i^{(u,0)}(t)(Q_u(t)+V) B_{\text{RF}} g_i^{(u,0)}(t)}{\left(\tilde{x}_i^{(u,0)}(t)\sigma_{\text{RF}}^2 + p_i^{(u,0)}(t) g_i^{(u,0)}(t)\right) \ln 2} - Z_0(t). \quad (40.53)$$

According to the KKT condition, the system achieves the optimal power allocation when the following conditions are satisfied:

$$\frac{\partial \left[\mathrm{L}(P) - \left(\sum\limits_{i \in I} \sum\limits_{u \in U_0} \mu_i^u p_i^{(u,0)}(t) \right) \right]}{\partial p_i^{(u,0)}(t)} = \frac{\tilde{x}_i^{(u,0)}(t)(Q_u(t)+V) B_{\text{RF}} g_i^{(u,0)}(t)}{\left(\tilde{x}_i^{(u,0)}(t)\sigma_{\text{RF}}^2 + p_i^{(u,0)}(t) g_i^{(u,0)}(t)\right) \ln 2} \quad (40.54)$$

$$-Z_0(t) - \mu_i^u = 0 \tag{40.55}$$

$$\mu_i^u p_i^{(u,0)}(t) = 0, \forall i, u \tag{40.56}$$

$$\mu_i^u \geq 0, \forall i, u, \tag{40.57}$$

where μ_i^u is a multiplier used to construct the Lagrange function. To ensure that Eq. (40.56) holds, then $\mu_i^u = 0$ or $p_i^{(u,l)}(t) = 0$. When the partial derivative of Eq. (40.54) is zero, the relationship between $p_i^{(u,l)^*}(t)$ and $\tilde{x}_i^{(u,l)}(t)$ can be obtained:

$$p_i^{(u,0)^*}(t) = \left[\frac{(Q_u(t)+V)B_{\mathrm{RF}}}{Z_0(t)\ln 2} - \frac{\sigma_{RF}^2}{g_i^{(u,0)}(t)}\right]^+ \tilde{x}_i^{(u,0)}(t). \tag{40.58}$$

The results of the power allocation are used to allocate the RF resource blocks. Substituting Eq. (40.56) into $\mathrm{L}(P)$, we obtain

$$\mathrm{L}(P) = \sum_{i \in I} \sum_{u \in U_0} L_i^u(P)\tilde{x}_i^{(u,0)}(t), \tag{40.59}$$

where

$$\begin{aligned} L_i^u(P) = {} & a_i^{(u,0)}(t)(Q_u(t)+V)B_{\mathrm{RF}}\log_2\left(1 + \left[\frac{a_i^{(u,0)}(t)\tilde{x}_i^{(u,0)}(t)(Q_u(t)+V)B_{\mathrm{RF}}}{Z_0(t)\ln 2} - \frac{B_{\mathrm{RF}}\sigma_{\mathrm{RF}}^2}{g_i^{(u,0)}(t)}\right]^+ \frac{g_i^{(u,0)}(t)}{B_{\mathrm{RF}}\sigma_{\mathrm{RF}}^2}\right) \\ & - Z_0(t)\left[\frac{a_i^{(u,0)}(t)\tilde{x}_i^{(u,0)}(t)(Q_u(t)+V)B_{\mathrm{RF}}}{Z_0(t)\ln 2} - \frac{B_{\mathrm{RF}}\sigma_{\mathrm{RF}}^2}{g_i^{(u,0)}(t)}\right]^+. \end{aligned} \tag{40.60}$$

Problem (40.59) is also a linear-assignment problem. Therefore, it can be decomposed into i subproblems, each of which is expressed as

$$\mathrm{L}_i(P) = \sum_{u \in U} L_i^u(P)\tilde{x}_i^{(u,0)}(t). \tag{40.61}$$

The objective of this problem is to maximize the $\mathrm{L}_i(P)$ of all subcarriers. Therefore, for all subcarriers i, the optimal allocation involves selecting the user with the largest $\mathrm{L}_i(P)$.

$$\tilde{x}_i^{(u,l)^*}(t) = \begin{cases} 1, u = \underset{u'}{\mathrm{argmax}}\left(L_i^{u'}(P), u' \in U\right) \\ 0, \text{otherwise.} \end{cases} \tag{40.62}$$

Algorithm Simulation Results Analysis

In this section, we analyze the simulation results of the Lyapunov optimization algorithm and verify the performance of the proposed indoor VLC/RF system resource-allocation scheme using OFDMA technology. Assuming that the room size is 8 m × 8 m × 3 m, as shown in Fig. 40.1, four VLC APs are installed on the ceiling, which are located at (3, 2, 3), (5, 2, 3), (3, 5, 3) and (5, 5, 3), respectively, and each AP has 25 subcarriers. The RF AP is located at (0, 0, 0), and it has four RBs. The other key simulation parameters of the system are listed in Table 40.2.

To simplify the simulation, we consider the following:

1. The VLC AP and RF AP have a normalized spectrum bandwidth.
2. The traffic arrival for each user device follows the Poisson distribution.
3. The average traffic arrival rate is expressed in γ.
4. The traffic arrival rate and RF channel conditions remain constant within a time slot and change on the time-slot boundary.
5. Specific γ values are given in the simulation.

The spectral bandwidth is normalized and the unit of transmitted data volume is set to one package. Therefore, assuming that the average communication rate of the VLC AP subcarrier in the system is five packages, and the average communication rate of a single RF AP RB is three packages, the average traffic arrival rate is limited to less than five packages.

Figure 40.4a shows the relationship between the penalty parameter V and the average queue length Q under different average traffic arrival rates γ. It can be observed that the Q value in the system increases with the increase of V, and as the average traffic arrival rate γ increases, the average queue length Q also increases.

Figure 40.4b shows the change of penalty parameter V and average transmission rate R under different average traffic arrival rates γ. It can be observed that the average transfer rate R increases with an increase in V because when V increases, the algorithm's optimization of the average transmission rate increases.

Table 40.2 Simulation parameters

Parameter	Meaning	Value
L × W × H	Room size	8 m × 8 m × 3 m
$\Phi_{1/2}$	Power half angle	70°
FOV	Field of view	60°
n	Number of LEDs	5
P_{ave}	LED transmit power	4 W
A_p	Effective PD receiving area	1 cm^2
T_l	Optical-filter gain	1
G_l	Concentrator gain	1
ε	Photoelectric conversion factor	0.52 A/W
n_{re}	PD refractive index	1.5

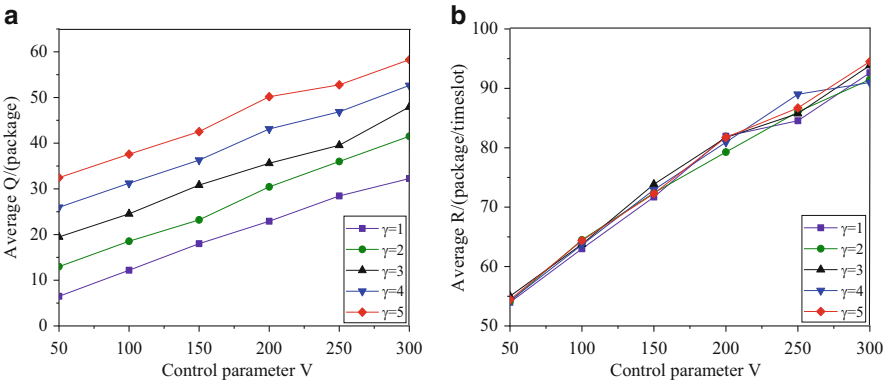

Fig. 40.4 (**a**) Relationship between average queue length Q and control parameter V. (**b**) Relationship between average transmission rate R and control parameter V

In addition, as the average traffic arrival rate γ increases, the growth rate of the average transmission rate decreases, because when γ is small, the amount of data transmitted by the system can meet the amount of arriving data. When γ is large, the system rejects additional packets to ensure data-queue stability.

According to Little's theorem [49], because the average transmission delay is proportional to the average queue length, the average queue length can be used to describe the average delay. In the Lyapunov optimization process, selecting the appropriate control parameter V can balance the relationship between the average transmission rate and average transmission delay.

In addition, the instantaneous change in the system was simulated. Assuming that the user's position changes in each time slot, the instantaneous change of the user in 30 time slots is given.

Figures 40.5a–c depict the instantaneous transfer rate and queue-length change for the four users in the system, when the penalty parameter V was 50, 150, and 300. It can be observed that for each user, as their queue length increases, so does their data-transfer rate. This is because the Lyapunov optimization algorithm increases the system transfer rate to reduce the buffer queue, thereby ensuring the stability of the entire system.

Another conclusion was that the queue length in the system was longer when $V = 300$ than when $V = 50$ or 150.

Figure 40.6 shows the changes in the average queue length Q and average transfer rate R with the number of users in the system using different existing algorithms. The Lyapunov optimization algorithm was compared with the minimal distance resource-allocation (MD-RA) and best channel state information resource-allocation (BCSI-RA) algorithms [50].

From Fig. 40.6a, it can be seen that with the increase in the number of users, the average queue length of the system gradually increases. Compared with the MD-RA algorithm and BCSI-RA algorithm, the queue length under the Lyapunov

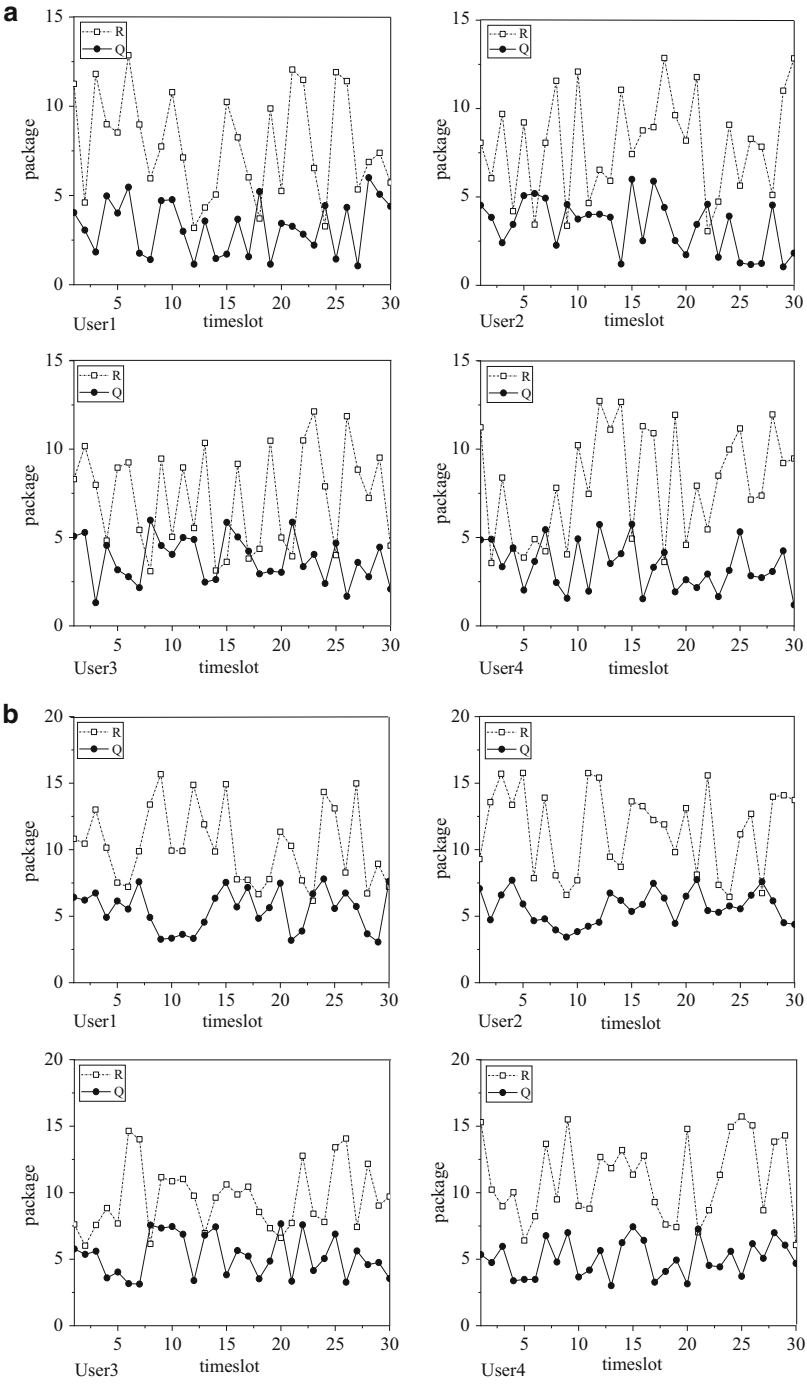

Fig. 40.5 Change in the instantaneous transmission rate and queue length of each user. (**a**) $V = 50$. (**b**) $V = 150$. (**c**) $V = 300$

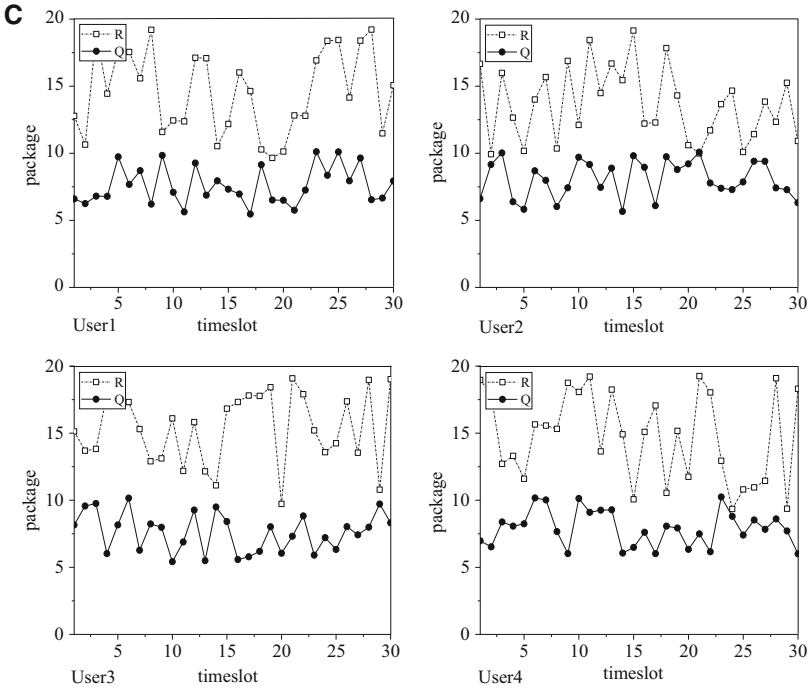

Fig. 40.5 (continued)

optimization algorithm is smaller and the growth rate is slower, indicating that the system has better stability when using the Lyapunov algorithm.

It can be seen from Fig. 40.6b that as the number of users in the system increases, the average transmission rate also increases, and the average transmission rate under the Lyapunov optimization algorithm is significantly higher than those of the MD-RA and BCSI-RA algorithms. The average transmission rate increases significantly when the number of users is greater than six.

Figure 40.7 shows the average queue length versus the average transfer rate as a function of the number of users, considering the interrupt probability, and compares the system performance using the three algorithms.

Suppose p represents the probability of LOS availability in the VLC system and a random number is generated between 0 and 1. If this number is greater than p, the LOS of the VLC AP is available; otherwise, the LOS is not available. The study showed that the Lyapunov optimization algorithm can achieve higher transmission rates while ensuring that the average queue length of the system is low; that is, the algorithm provides better system performance.

As shown in Fig. 40.8, as the penalty parameter V increases, the average queue length Q and average transmission rate R in the uplink communication link for different numbers of users also increase. This is because increasing the penalty

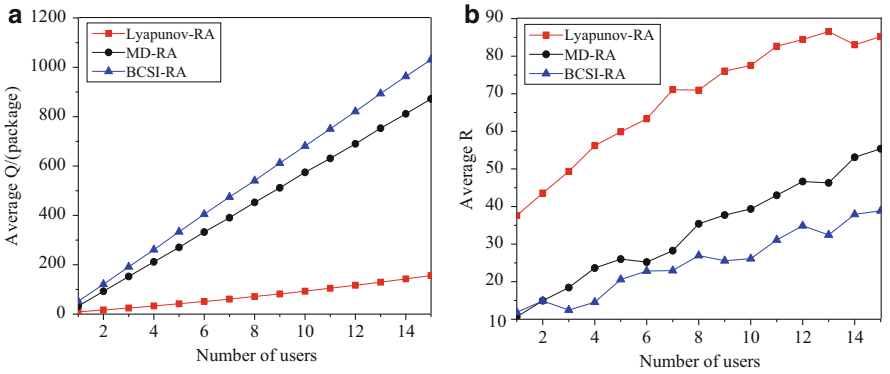

Fig. 40.6 (**a**) Relationship between the average queue length Q and number of users under the three algorithms. (**b**) Relationship between the average transmission rate R and number of users under the three algorithms

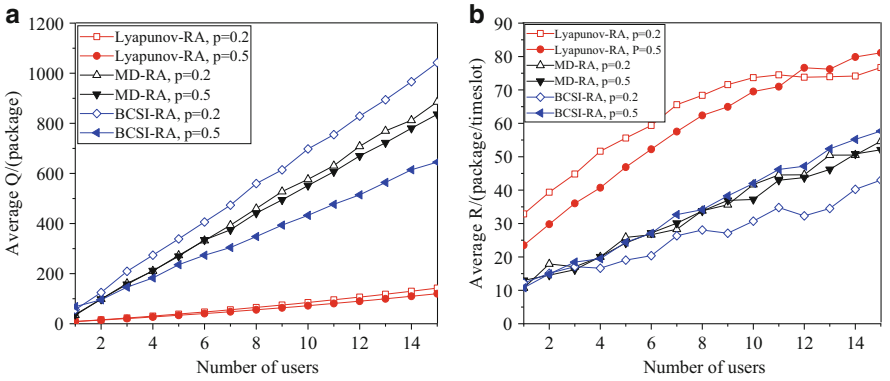

Fig. 40.7 (**a**) Relationship between the average queue length Q, interrupt probability, and number of users for the three algorithms. (**b**) Relationship between the average transmission rate R, interrupt probability, and number of users for the three algorithms

parameter causes the system to allocate more resources to the user, thereby optimizing the system performance.

In addition, as shown in Fig. 40.8a, as the number of users increases, the queue backlog in the system increases at an accelerated pace. An increase in the number of users leads to a decrease in the uplink communication rate, which affects the performance of the entire system. To balance the relationship between the queue length and transmission rate, an appropriate penalty parameter V can be selected to stabilize the system communication.

Figure 40.8b shows that the average transfer rate gradually increases as the number of users increases. Changes in both Q and R indicate a decrease in the communication rate of the upstream RF link. This is because, with limited spectrum

resources and base station processing power, users must share resources, resulting in network congestion and transmission delays, which in turn reduces the communication rate of the entire system.

Figure 40.9 shows the average queue length Q and average transmission rate R in the OFDMA-VLC/RF and VLC/RF systems as functions of the number of users. As shown in Fig. 40.9a, the queue-extrusion speed in the VLC/RF system using OFDMA technology is significantly slower than that in the VLC/RF system without OFDMA technology. The Q-value change in the OFDMA-VLC/RF system is relatively stable, indicating that the system is highly stable.

As shown in Fig. 40.9b, as the number of users increases, the average system transmission rate gradually increases; when the number of users increases to 15, the

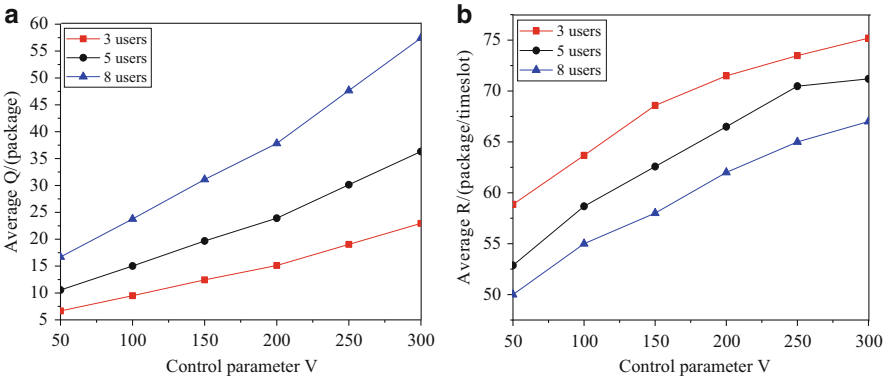

Fig. 40.8 (**a**) Relationship between the average queue length Q and penalty parameter V for different numbers of users in the uplink RF link. (**b**) Relationship between the average transmission rate R and penalty parameter V of the uplink RF link for different numbers of users

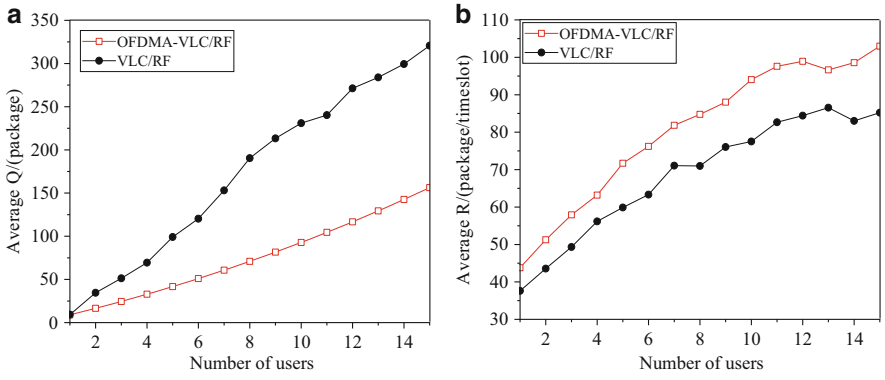

Fig. 40.9 (**a**) Comparison of the average queue length Q of the system. (**b**) Comparison of the average transmission rate R of the system

average transmission rate of the OFDMA-VLC/RF system increases by 17 packages, compared with the VLC/RF system. This is because the OFDMA technology increases the capacity of the entire communication system, thereby increasing the system transmission rate.

Conclusion

In this study, the resource-allocation problem in an indoor OFDMA-VLC/RF system was investigated, and an allocation strategy based on the Lyapunov optimization algorithm was proposed. The purpose of this study was to solve the resource-allocation problem by maximizing the average transmission rate of the system under the constraints of system stability and an average power budget.

1. To find the optimal resource-allocation strategy, we formulated a random-optimization problem that considered the stability constraints and average power budget of the system, and used the average system transmission rate as the optimization goal.
2. Using the Lyapunov optimization algorithm, the stochastic optimization problem was decomposed into three independent subproblems, and their optimal solutions were provided. The effectiveness of the proposed resource-allocation strategies were verified through simulation.

The results showed that this strategy significantly improved the average transmission rate of the system, while maintaining the system stability. This means that our approach can improve the system performance by making more efficient use of limited resources in indoor OFDMA-VLC/RF systems. This study has practical significance for improving the performance of indoor wireless communication systems and provides a valuable reference for further research.

Abstract

A new fingerprint-location method based on a clustering algorithm was proposed to address the problem of large positioning errors in an indoor boundary area. This clustering-based method embodies the idea of a rough location and then a fine location. First, the edge regions of the received signal strength (RSS) samples, which are greatly affected by reflection, are divided using the k-medoids algorithm. Then, the center part is clustered using density-based spatial clustering of applications with noise (DBSCAN). In the actual location-estimation stage, the points to be measured can only be located in one of the classified areas and are combined with the weighted-optimum k-nearest-neighbor algorithm (WOKNN) to match the location. The results showed that the average positioning error of the algorithm was 13 cm in an indoor environment measuring 5 m × 5 m × 3 m. Compared with the traditional method without clustering, the positioning accuracy of the edge area increased by 21%, and the overall

improvement was 33.8%. This proves that the proposed algorithm effectively improves the efficiency of real-time indoor-positioning accuracy.

Introduction

With increasing improvements in the Internet of Things, the application of location-based services has attracted considerable attention. Large-scale indoor construction is increasing gradually, and the demand for indoor positioning is increasing rapidly. In recent years, indoor positioning has been widely used in urban construction, medical services, construction sites, chemical metallurgy, power plants, and other fields. In the architecture field, the main applications include emergency management [1], intelligent energy management [2], heating, ventilation, air-conditioning system (HVAC) controls [3], and occupancy detection [4].

Real-time accurate knowledge of the locations of people in a building is useful for a variety of applications. At present, indoor wireless-positioning technologies are being developed, including wireless local-area networks (WLANs), radio frequency identification (RFID), Bluetooth, ultrawideband (UWB), ultrasonic, and infrared. Among these technologies, WiFi-based and Bluetooth-based low-energy (BLE) location technologies have become the most commonly used and are widely deployed in current smart devices, mainly because they do not require a line-of-sight path between the transmitter and receiver [5].

However, WiFi location relies on the assumption that the signal strength at each point in space does not change with time or other obstacles, which is unrealistic in real-world scenarios, and WiFi-location results are often unreliable. Multiple-input multiple-output (MIMO) communication has long played an important role in RF-based communication. Using MIMO, data rates can be increased without increasing the bandwidth or power, thereby increasing the channel capacity and effectively supporting multiple users [6].

In contrast to the aforementioned indoor-positioning technologies based on radio frequency communication, visible-light positioning (VLP) technology is based on indoor visible-light communication (VLC) technology. Indoor positioning can be realized using light-emitting diode (LED) lamps for lighting. VLC has developed rapidly, owing to its advantage of being green, its resistance to electromagnetic interference, and its rich spectrum resources. It can be used to enhance future wireless communication systems and has great potential for providing reliable solutions to indoor-positioning problems.

Sejan studied VLC technology in a MIMO communication environment and considered a machine learning method for MIMO VLC [7]. To construct a VLP system, methods such as the angle of arrival (AOA), time of arrival (TOA), and

received signal strength (RSS) can be used. TOA requires the strict synchronization of transmission and reception, whereas AOA requires more complex hardware. Therefore, methods based on RSS have attracted extensive attention, owing to its low cost and simple hardware [8].

Previous research based on VLC ignored the reflections of ceilings, walls, and indoor objects, making the positioning effect too ideal and inconsistent with results in an actual environment. In 2016, Aminikashani demonstrated the influence of multipath reflections and found that the central area of a room was almost unaffected. In contrast, other areas (viz., corners and edges) had very poor effects [9]. Saadi M observed that using a clustering algorithm before the location process meant that the process of querying the closest point only occurred in one area, which shortened the total execution time and improved the location accuracy [10].

In 2016, Saadi used only two LEDs and the k-means clustering method and obtained an average localization error of 31 cm, which was the best accuracy achieved in any practical environment using LEDs [11]. At present, k-means is widely used in indoor positioning; however, its initial centroid selection is random, which causes the clustering to find a local optimal solution, resulting in poor clustering results.

In 2018, Wang studied a visible-light positioning system model based on the binary k-means clustering method, which improved the clustering effect and simplified the computational complexity [12]. Dividing by region guaranteed the signal integrity in each region; however, the fingerprint points in the edge region of the cluster could be divided into incorrect clusters. In 2022, Ren proposed a hybrid localization algorithm based on an extreme learning machine (ELM) and density-based spatial clustering of applications with noise (DBSCAN) to solve the problem of large boundary errors between edges and corner clusters. Through comparison, it was found that the DBSCAN clustering algorithm was the best maximum-likelihood localization algorithm [13].

In the same year, Martínez proposed a new VLP system with RGB LEDs for multicell networks. It used the Euclidean distance and RGB LED position to estimate the position of the receiver through a trilateration algorithm. This system could be extended to multiple units based on the application scenario and had practical applications [14]. In 2023, to better realize real-time positioning, Long divided the positioning points into ordinary points, edge points, and blind spots and used corresponding models to handle the different types of points. This was the first study to consider the different effects of multipath effects in different areas of a room and realized centimeter-level positioning [15].

Improving the accuracy of indoor visible-light positioning systems using a simple, real-time, and robust approach has been a challenge in recent research [16]. In this study, we consider a VLC channel model that includes line-of-sight (LOS) and nonline-of-sight (NLOS) components. Considering that the randomness of k-means clustering greatly destabilizes the location, a fusion method combining k-medoids clustering with DBSCAN is proposed. It has low algorithm complexity and can ensure that fingerprints in the same environment, at different times and at the same location, have high similarity. Then, the fusion clustering algorithm was

compared with the weighted-optimum k-nearest-neighbor (WOKNN) algorithm to discuss the localization of different regions and verify the robustness and effectiveness of the algorithm.

Indoor Model and Algorithm Principle

System Model

An indoor visible-light positioning system based on RSS is mainly composed of an LED light source, a visible-light channel, and a photodetector (PD) array, as shown in Fig. 41.1. In this study, the room size was set to 5 m × 5 m × 3 m, and four LED arrays were evenly and symmetrically installed on the ceiling. They were used as emission sources and located at (1, 1, 3), (1, 4, 3), (4, 1, 3), and (4, 4, 3). The receiving end faced horizontally upward from any position on the ground.

Channel Model

In this study, considering the actual indoor environment, a line-of-sight (LOS) link and a nonline-of-sight (NLOS) link with primary wall reflection were considered. The communication link is shown in Fig. 41.2.

Assuming that the luminous intensity of the LED follows the Lambert radiation model, the channel gain in the LOS link can be expressed as [17]

$$H_{\mathrm{LOS}}(0) = \begin{cases} \dfrac{(m+1)A_r \cos^m(\phi)\cos(\varphi)}{2\pi \mathrm{d}^2} \mathrm{T}(\varphi)\mathrm{g}(\varphi) & 0 \le \varphi \le \varphi_{\mathrm{FOV}} \\ 0 & \varphi > \varphi_{\mathrm{FOV}} \end{cases}, \tag{41.1}$$

where A_r is the physical area of the photodetector (PD) and m is the Lambert radiation order. d is the distance between the LED and PD, φ is the incident angle,

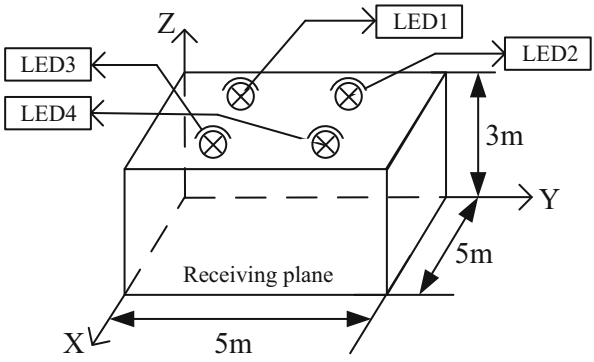

Fig. 41.1 Indoor VLC system model [16]

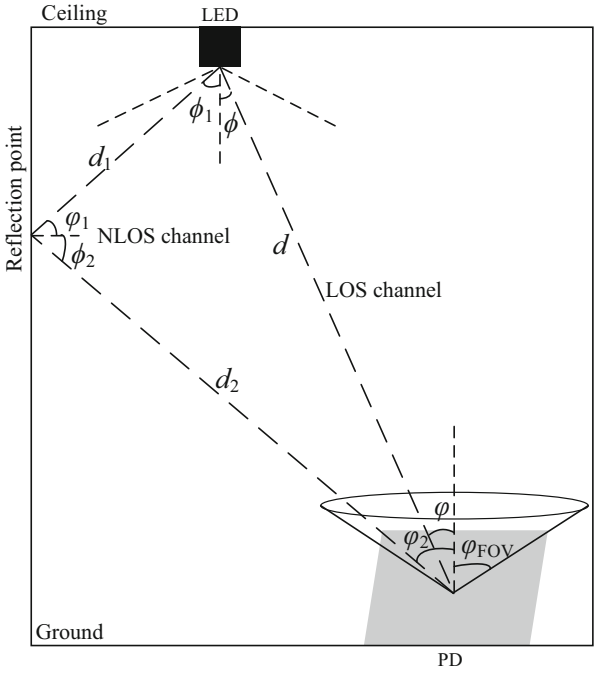

Fig. 41.2 Indoor visible-light channel [18]

ϕ is the irradiance angle, and φ_{FOV} is the field of view of the receiver. $T(\varphi)$ and $g(\varphi)$, respectively, represent the gains of the optical filter and optical condenser of the receiver, which can be expressed as

$$g(\varphi) = \begin{cases} \dfrac{n^2}{\sin^2(\varphi_{\mathrm{FOV}})} & 0 \le \varphi \le \varphi_{\mathrm{FOV}} \\ 0 & \varphi > \varphi_{\mathrm{FOV}} \end{cases}, \tag{41.2}$$

where n is the refractive index of the optical concentrator.

Assuming that the wall consists of many diffuse mirrors with area $\triangle$A and reflectivity $\mathrm{R_W}$, the channel gain of the first-order reflection is given by the following formula:

$$H_{\mathrm{dif}}(0) = \begin{cases} \sum\limits_{\mathrm{Wall}} \dfrac{A_{\mathrm{r}} \Delta A R_{\mathrm{W}}(m+1)}{2\pi^2 d_1^2 d_2^2} \cos^m(\phi_1)\cos(\varphi_1)\cos(\phi_2)\cos(\varphi_2)T(\varphi_2)g(\varphi_2) & 0 \le \varphi_2 \le \varphi_{\mathrm{FOV}} \\ 0 & \varphi_2 > \varphi_{\mathrm{FOV}} \end{cases}, \tag{41.3}$$

where d_1 and d_2 are distances, φ_1 and φ_2 are incident angles, ϕ_1 and ϕ_2 are irradiance angles, R_W is the reflectivity of the wall, and $\triangle$A is the area element of the reflection point of the wall.

The final total received power is expressed as

$$P_{\mathrm{rs}} = \{RP_{\mathrm{t}}[H_{\mathrm{LOS}}(0) + H_{\mathrm{dif}}(0)]\}^2 + \sigma^2_{\mathrm{noise}}, \tag{41.4}$$

where P_{rs} is the received power, P_t is the transmitted power, R is the responsivity of the receiver, and $\sigma^2_{\mathrm{noise}}$ is the variance of the total noise.

In a typical VLP system, LEDs are modulated to transmit signals, and time division multiplexing (TDM), frequency division multiplexing (FDM), or code division multiplexing (CDM) is used to allow multiple accesses from different LEDs. Therefore, intersymbol interference (ISI) can be avoided and background noise can be filtered out. The variance of noise can be expressed as [19]

$$\begin{aligned}\sigma^2_{\mathrm{noise}} &= \sigma^2_{\mathrm{shot}} + \sigma^2_{\mathrm{thermal}} \\ &= (2qRP_{rs}B) + \left(\frac{8\pi kT_k}{G}\eta A_r I_2 B^2 + \frac{16\pi^2 kT_k \Gamma}{g_m}\eta^2 A_r^2 I_3 B^3\right),\end{aligned} \tag{41.5}$$

where q, B, and k represent the charge, equivalent noise bandwidth, and Boltzmann constant, respectively, $k = 1.38 \times 10^{-23}$. T_k, G, and η represent the absolute temperature, open loop voltage gain, and fixed PD capacitance, respectively. Γ and g_m represent the field-effect transistor (FET) channel noise figure and FET transconductance, respectively. I_2 and I_3 are 0.562 and 0.0868, respectively.

The signal-to-noise ratio is expressed as [20]

$$SNR = \frac{P_r^2}{\sigma^2_{\mathrm{noise}}} = \frac{\{RP_t[H_{\mathrm{LOS}}(0) + H_{\mathrm{dif}}(0)]\}^2}{\sigma^2_{\mathrm{shot}} + \sigma^2_{\mathrm{thermal}}}, \tag{41.6}$$

where P_r^2 is the signal power of the receiver.

Fingerprint-Location Method

The fingerprint-location method infers the final location of the target through the physical-location coordinates and its signal characteristics (such as the RSS value). It uses a matching algorithm, which better inhibits the multipath effect and nonline-of-sight signal propagation [21]. It includes offline (training) and online (testing) modes, as shown in Fig. 41.3.

The main task of the offline mode is to collect the RSS from all fingerprints; each physical location should have a unique and distinguishable fingerprint. Then, noise reduction, regional division, and training are carried out in turn, and a fingerprint database is established according to certain rules. The online mode uses the training data in the offline stage to predict the current position of the PD. Existing matching algorithms include the nearest neighbor (NN), k-nearest neighbor (KNN), weighted k-nearest neighbor (WKNN), neural network, and support vector machine (SVM) [23].

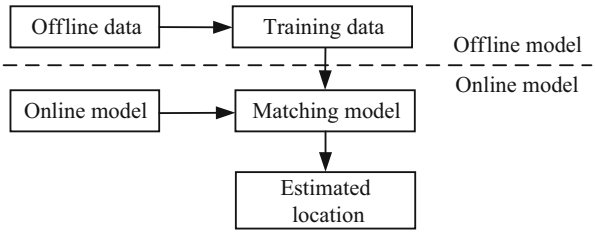

Fig. 41.3 Indoor-positioning system based on a fingerprint [22]

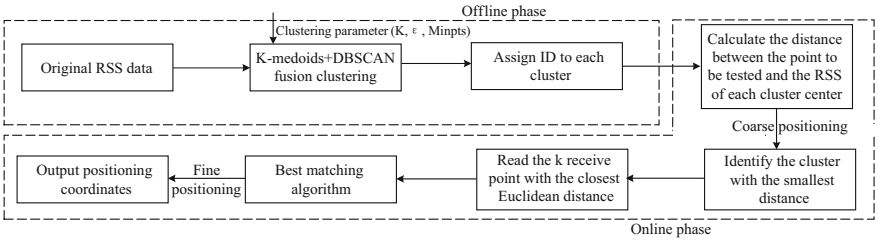

Fig. 41.4 Block diagram of the proposed algorithm

Improved Fingerprint Method

Research on fingerprint technology can be divided into two topics: establishing a fingerprint database in the offline stage and optimizing the matching algorithm in the online stage. A block diagram of the proposed algorithm is shown in Fig. 41.4.

Considering the comprehensive characteristics of the RSS in the offline stage, a fusion clustering algorithm was proposed. In the online-positioning stage, the Euclidean distance between the point to be measured and the RSS value of the central node of each cluster was calculated. The positioning area was narrowed to the area where the cluster closest to the central node was located, and the coordinate information of the positioning point was estimated using the best matching model to complete the positioning.

Offline Phase

The purpose of offline clustering is to reduce the space and computational complexity of a fingerprint search. The most important aspect is to improve the correctness of the fingerprint matching and location accuracy [24]. The proposed fusion clustering is as follows. The k-medoids algorithm divides the edge and middle regions, and the DBSCAN algorithm distributes the middle part according to the light intensity distribution characteristics. Feature extraction is important in NLOS recognition and mitigation.

The clustering effect is often measured using the Davies–Bouldin (DB) index, silhouette index (SI), and the sum of squares error (SSE). The smaller the DB or SSE, or the larger the SI, the closer the data objects are to their centroids, and the better the clustering effect [25].

K-medoids Algorithm

The k-medoids algorithm was optimized using k-means clustering. K-means takes the center point as the average of all data points in the current cluster, whereas k-medoids selects the point with the smallest distance to all other points in the current cluster as the central point. This solves the problems of sensitivity to abnormal points and being greatly affected by extreme values.

The algorithm flowchart is shown in Fig. 41.5, and the detailed steps are as follows [26]:

Randomly select k points from the total n sample points as medoids. Assign each of the remaining n-k points to the class of the closest medoid. For each point in class i, except the medoid point, calculate the value of the cost function. Repeat this with the other classes. Then, for each class, select the point with the minimum cost function as the new medoid. Repeat the first two processes until the medoid points no longer change or the set maximum number of iterations has been reached. Then, output the final k classes.

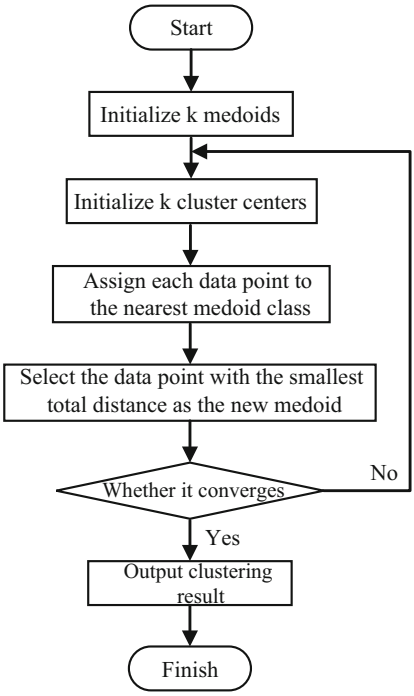

Fig. 41.5 K-medoids clustering algorithm flowchart

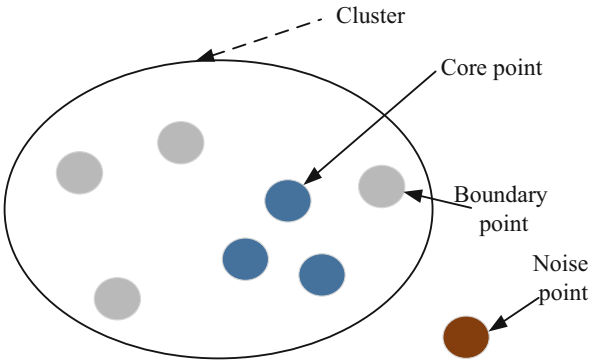

Fig. 41.6 Examples of core points, boundary points, and noise points [22]

DBSCAN Algorithm

DBSCAN, proposed by Ester in 1996, is a nonparametric density-based clustering algorithm. Its advantage is that it does not need to specify the number of clusters in advance. It divides high-density points into clusters and can effectively deal with low-density noise points [27]. Using the DBSCAN algorithm, the points of the fingerprint dataset were divided into core, boundary, and noise points. As shown in Fig. 41.6, the type to which each point belongs depends on the sample distribution, *Eps*, and *Minpts*. *Eps* is the radius of the region used to determine whether the data points are located in the cluster and *Minpts* specifies the minimum number of points required to form the cluster. The initial selection of *Eps* and *Minpts* greatly influences the clustering effect [28].

The DBSCAN process is as follows [29]: Starting from any point p in the database, retrieve all point densities reachable from p under the given *Eps* and *Minpts*; the point density is the compactness of the sample point distribution. If p is the core point, the process generates a cluster using *Eps* and *Minpts*, and the point is classified. If p is a boundary point, there is no point density reachable from p, and DBSCAN accesses the next unclassified point in the database [30]. Because DBSCAN defines clusters based on density, it is relatively noise resistant and can find clusters of arbitrary shapes. Therefore, DBSCAN can identify clusters that k-means clustering cannot.

Online Phase

The offline clustering results are stored in a new location fingerprint database. In the positioning stage, the distance between the label to be tested and the central node of each subregion is obtained for rough positioning. Subsequently, fine positioning is completed by matching the coarse positioning area. Current matching algorithms include NN, KNN, WKNN, and simple weighted k-nearest neighbor (SWKNN) [31]. To maximize its advantages, this study implemented a weighted optimal

k-nearest neighbor (WOKNN) algorithm in the positioning stage. This is the method for selecting the best matching algorithm and its best k value for different regions.

The flow of the SWKNN algorithm is as follows:

1. The receiver obtains the RSS value and calculates its Euclidean distance d_i:

$$d_i = \sqrt{\sum_{i=1}^{4} (\mathrm{RSS}_{Ti} - \mathrm{RSS}_i)^2}, \tag{41.7}$$

where RSS_{Ti} represents the RSS value collected online at an undetermined site, RSS_i is the corresponding number from the offline fingerprint database, and i is the subscript of the LED.

2. The distances d_i are arranged in ascending order and the average value E_d of the nearest K distances are determined:

$$E_d = \frac{d_1 + d_2 + \cdots + d_k}{K}. \tag{41.8}$$

3. Each distance value d_i is compared with the average value E_d. Distances greater than the average value are removed, the remaining points are recorded as M, and the K value in WKNN is replaced with M.
4. The above process is repeated. The value of K is gradually reduced and gradually approaches the true value.

The estimated position coordinates of the target are

$$P = \frac{\frac{1}{d_1}L_1 + \frac{1}{d_2}L_2 + \cdots + \frac{1}{d_M}L_M}{\frac{1}{d_1} + \frac{1}{d_2} + \cdots + \frac{1}{d_M}}, \tag{41.9}$$

where P represents the coordinates of the target to be located and L_i is the position of the i^{th} fingerprint.

Simulation Verification

This section describes the simulation results obtained using the proposed method. Starting from the power distribution and considering the influence of diffuse reflections, the positioning error distribution in different areas of an indoor environment was studied to verify the effectiveness of the proposed algorithm. The additional conditions are summarized in Table 41.1. Figure 41.7 shows the indoor illumination

intensity distribution on the same plane, based on the Lambertian model. It conforms to the international standard for indoor office illumination between 300 and 1500 lx.

Fingerprint Method

The LOS channel is very important in almost all indoor VLC positioning systems because it receives most of the total optical power. Figure 41.8a shows the power distribution under the LOS link; the entire receiving surface presents a high center and low corners.

Table 41.1 VLP system simulation parameters

Parameters	Values
Emitting optical power	1 W
Half power angle	60°
Wall reflectivity	0.7
Receiver responsiveness	0.5 A/W
Receiver field-of-view angle	70°
Refractive index	1.5
Reflection coefficient	0.8
Signal-to-noise ratio (SNR)	30 dB

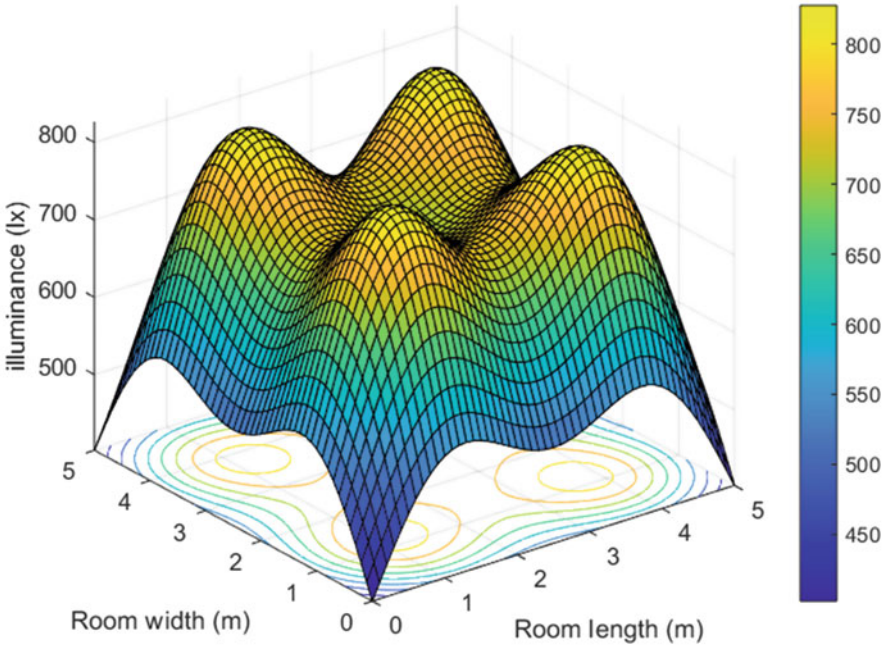

Fig. 41.7 Indoor communication receiving plane light intensity distribution

Figure 41.8b shows the optical-power distribution diagram of the NLOS. It can be seen that the distributions of the NLOS and LOS channels show opposite trends. Visible light always reflects in indoor environments, especially in narrow spaces with walls, ceilings, floors, and furniture. Therefore, most of the power added by the NLOS of the scattering part is concentrated near the walls of the room, with less in the center; the center receives the lowest scattered power. Compared with Fig. 41.8a, the scattering power near the edge of the wall is almost equal to that of the LOS component.

Figure 41.8c shows the distribution of the total received optical power. Compared with Fig. 41.8a, the overall power distribution of the room is wider, owing to the addition of NLOS energy.

When the SNR is 30 dB, the distribution of the positioning error of the 100 points to be measured is shown in Fig. 41.9. The numbers marked in the figure are the serial numbers of the points to be measured, which are evenly selected. It can be observed that the error in the middle area of the room is small, whereas the errors in the corner and edge areas are large. This is due to the increase in error caused by the gradual increase in the specific gravity of the scattering component; the multipath effect greatly increases the positioning error of the corners and edges.

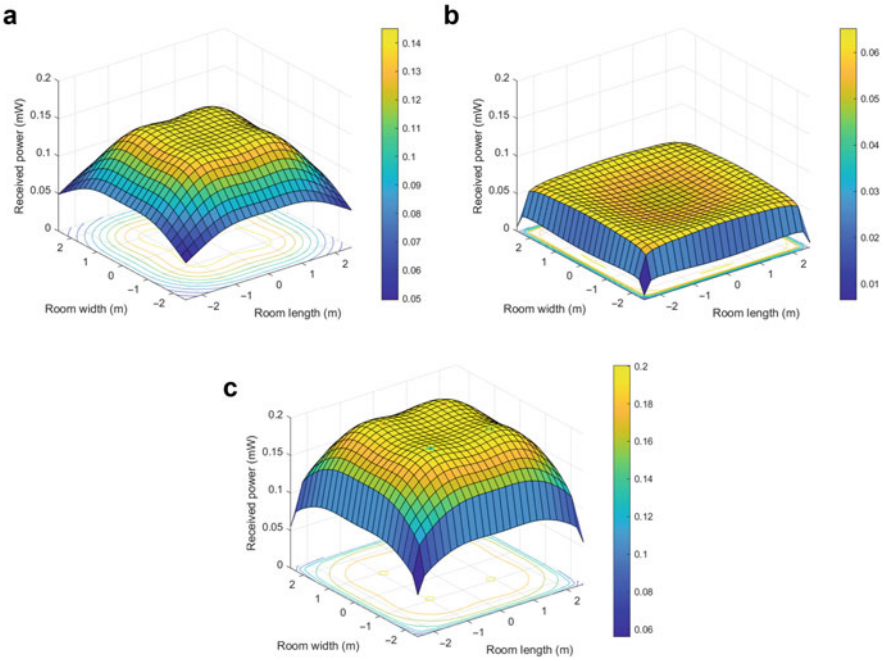

Fig. 41.8 Distribution of received optical power: (**a**) LOS channel, (**b**) channel with only one reflection, and (**c**) total channel

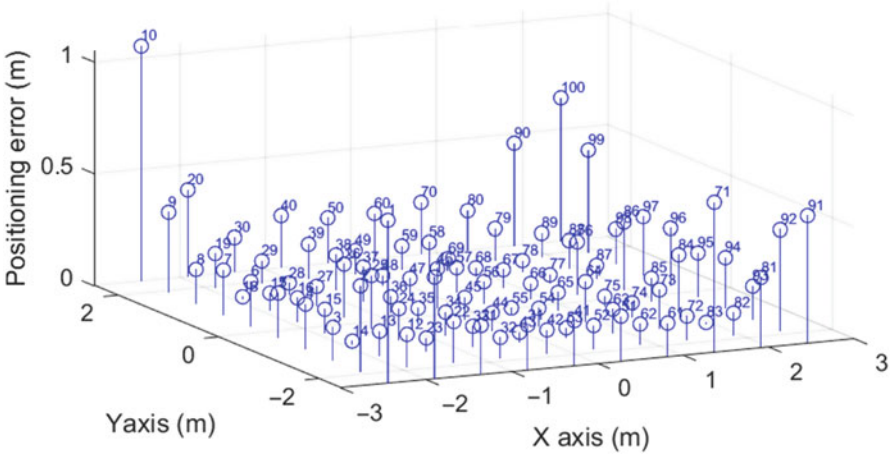

Fig. 41.9 Location error using the fingerprint method

According to the system simulation calculation, the average positioning error of the entire room was 20.26 cm, and the maximum error at the corners, which was greatly affected by the reflected light, was approximately 1.15 m. Thus, the traditional fingerprint positioning method was improved, and its performance was verified.

Improved Fingerprint Method

When correctly dividing clusters, the silhouette index (SI), elbow method, and sum of squares error (SSE) can be used as criteria for judging the clustering effect of k-medoids. They can be combined to determine the optimal number of clusters and initial K value. The initial selection of clustering centers is crucial to the clustering effect.

This study used the elbow method based on slope determination to determine the optimal number of clusters, k. The value of k in the K-medoids algorithm is three and the distance measure is a city block. In this case, the clustering effect was consistent with expectations and effectively distinguished between the center and edge areas.

For DBSCAN clustering, the clustering validity index was used to determine the optimal clustering result. The indices included the Davies–Bouldin (DB) index, silhouette index (SI), and sum of squares error (SSE). Among these, the SI index is widely used because of its simplicity, ease of use, and good evaluation capabilities. After simulation verification, the best clustering effect was determined. The final result was that when the number of clusters was five, the best *Minpts* value was 49 and the best *Eps* value was 1.5879×10^{-5}. These optimized parameters were used for DBSCAN clustering.

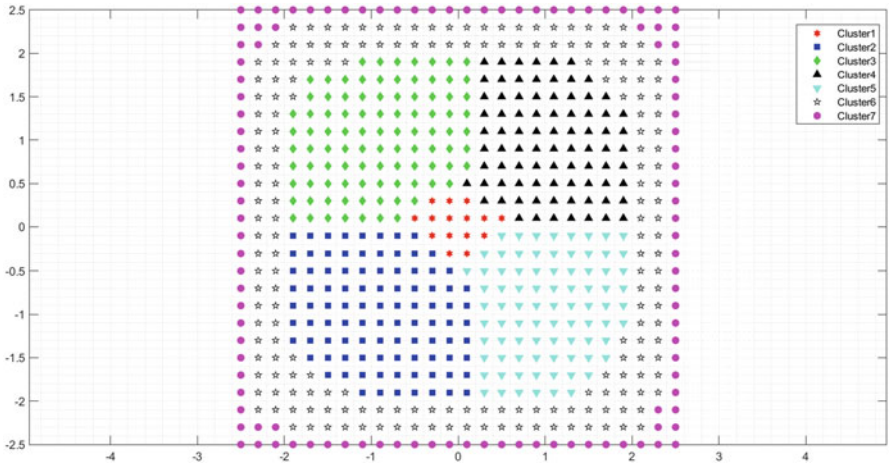

Fig. 41.10 Fusion clustering result diagram

The positioning effects differ in different areas. Therefore, VLC-based indoor-positioning technology must consider the reflected signals, and all receiving points are first positioned through fusion and clustering. Fusion clustering uses two algorithms to complement each other's advantages and improve the accuracy. The specific fusion clustering effect is shown in Fig. 41.10.

In the matching positioning stage, the value of k is manually selected and fixed [32]. The selected value may be well suited for one area, but other areas may require different values. Therefore, optimizing the number of nearest points in each region is a promising solution for improving positioning accuracy.

Subsequently, we simulated and analyzed the positioning error for different k values under different algorithms in each area, as shown in Fig. 41.10. For each cluster, from the perspective of overall positioning performance, SWKNN is the best, followed by WKNN and finally KNN. As the value of k increases, the error of the matching algorithm increases, which increases the positioning time; thus, the influence of the k value cannot be ignored. To minimize the average positioning error, it is necessary to determine the algorithm and its neighboring points with the minimum errors in each region.

Through cross-validation, the algorithm and k value with the best positioning effect in each cluster were determined. The results are summarized in Fig. 41.11 and presented in Table 41.2. From the center of the room to the edge, the average positioning error increases from small to large values, and the error in each area is reduced using the clustering algorithm.

Figure 41.12 shows the error distribution of the uniformly selected points to be measured. Compared with Fig. 41.7, it can be seen that the proposed algorithm effectively reduces the error of the edge part, with a maximum reduction of 0.49 m. It is more accurate for the edge region, partly because of clustering and partly because the cosine distance was used to measure the points to be measured instead of the

traditional Euclidean distance; this can make the estimated value closer to the real value.

The positioning accuracy is most obviously improved at the corners after adjustment. The positioning error in the central area of the room shows little improvement because it is not greatly affected by multipath reflection. This scheme can effectively solve the defects of large edge and corner errors in traditional RSS positioning, and the proposed algorithm greatly enhances the positioning performance based on VLP.

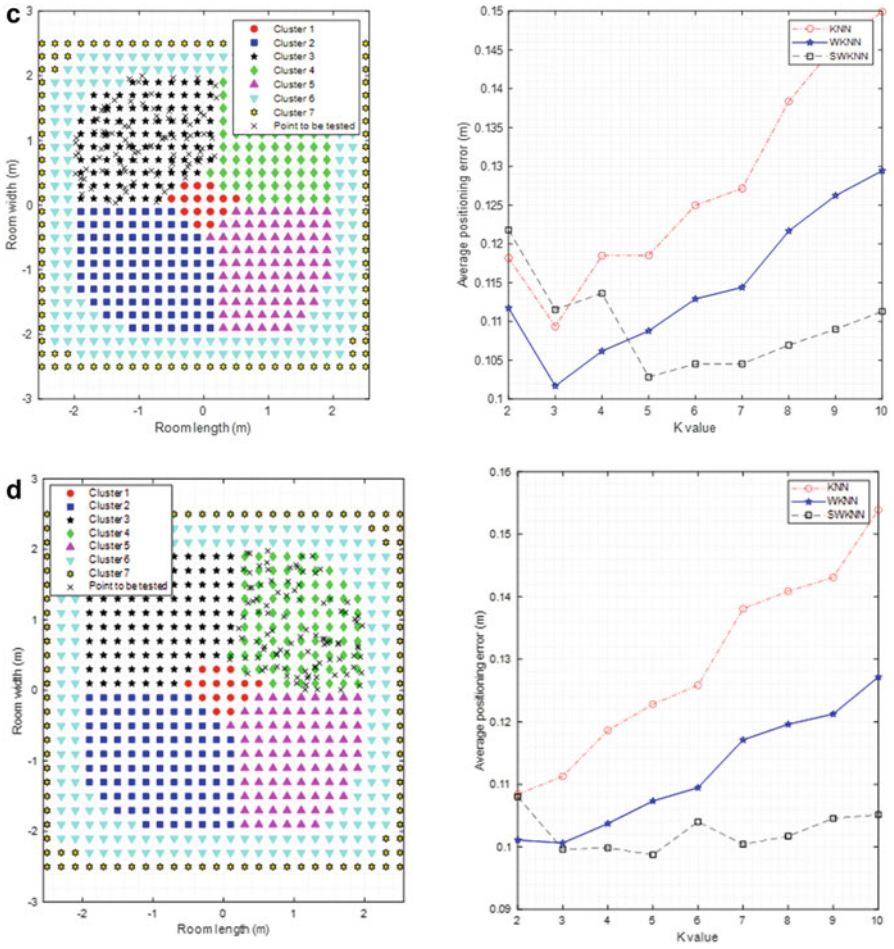

Fig. 41.11 (continued)

To further evaluate the localization performance of the proposed system, it was compared with classic algorithms. Figure 41.13 shows the cumulative distribution function (CDF) of the positioning errors for the different algorithms. The results show that the combination of the fusion clustering algorithm and WOKNN algorithm has a higher positioning accuracy than the other algorithms. When the cumulative positioning error distribution is 90%, the average positioning error of NN is 0.43 m, while the error distance of the proposed algorithm is 0.24 m. The positioning performance is improved by 44.2%, which is obviously improved as a whole.

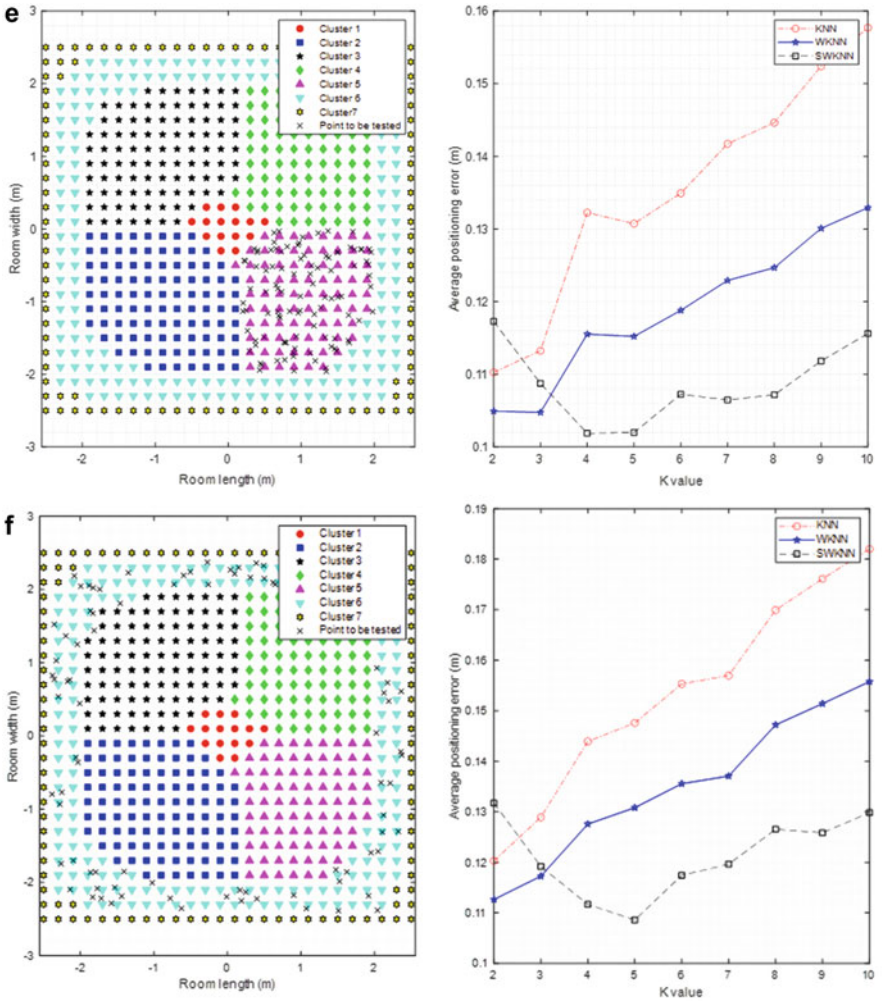

Fig. 41.11 (continued)

Table 41.3 indicates that the average positioning effect of the proposed algorithm is better than those of the other four more traditional algorithms. Using the proposed positioning algorithm, the positioning error at the training point can be effectively reduced, and the positioning accuracy of the entire receiving surface can be improved by 33.8%. This demonstrates the effectiveness of the proposed method. The improved algorithm proposed in this study greatly improved the clustering accuracy.

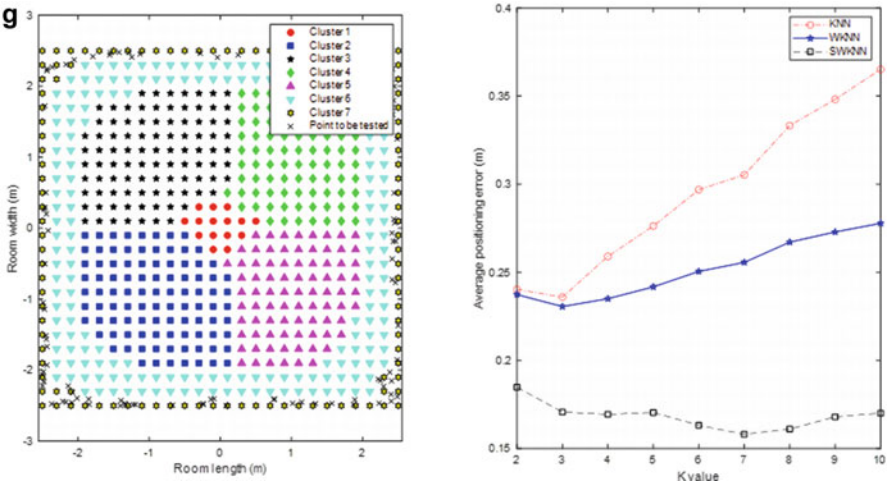

Fig. 41.11 (continued)

Table 41.2 Location results of different clusters

Region	Optimal algorithm	Optimum *k* value	Average positioning error (cm)
Cluster 1	SWKNN	4	6.92
Cluster 2	SWKNN	3	10.11
Cluster 3	WKNN	3	10.16
Cluster 4	SWKNN	5	9.87
Cluster 5	SWKNN	4	10.18
Cluster 6	SWKNN	5	10.86
Cluster 7	SWKNN	7	15.80

Discussion

The improved fingerprint method divides the research area into multiple clusters and analyzes each cluster separately to determine the optimal algorithm and k value. The algorithm proposed in this study is effective for most light source distributions with central symmetry. However, as indoor environments become more complex, the changing environment will definitely increase the failure of the fingerprint database. The focus should be on improving the maintenance and updating the efficiency of the fingerprint database. By selecting a special location as a monitoring point for detecting fingerprint data fluctuations, a backup fingerprint library for common environments can be developed to update the fingerprints over time.

Clustering is also conducive to the analysis of local features to a certain extent and can provide a reference for future compensation schemes. Therefore, to improve the practicability of indoor visible-light positioning, fingerprint database maintenance and updating technologies should be strengthened in the future.

Conclusions

In this study, a novel fusion clustering positioning model using visible light was proposed. By combining k-medoids with the DBSCAN clustering algorithm, the high localization performance of the k-medoids algorithm was used to solve noise problems. This method of clustering followed by positioning is suitable for complex indoor environments.

Coarse positioning improved the positioning efficiency and fine positioning ensured high accuracy, which significantly improved the overall performance. The positioning performance of the whole room was improved by 31% compared with traditional algorithms. The accuracy of this method was verified through simulations and algorithm comparisons.

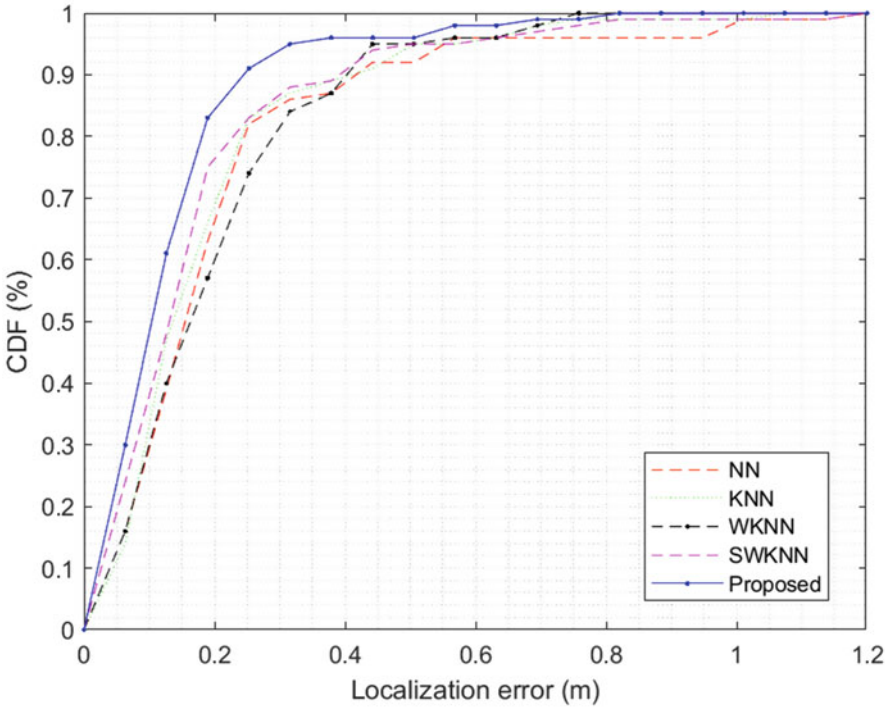

Fig. 41.13 Cumulative probability of errors in different algorithms

Table 41.3 Comparison of positioning accuracy of different positioning methods

Algorithm	Average positioning error (cm)
NN	20.26
KNN	18.51
WKNN	19.87
SWKNN	17.37
Proposed	13.4154

In future work, we should consider an adaptive calibration method to improve the positioning effect of corners and better integrate different positioning technologies to overcome the limitations of a single positioning technology.

Abstract

To apply visible-light communication (VLC) systems in different scenarios, this study utilizes a temperature-adjustable light source equipped with RGB light-emitting diodes (LEDs) and applies it to a visible-light communication system. It utilizes color-division multiplexing technology to achieve three-channel communication, thereby improving the communication bandwidth of the system. The communication system adopts three constant-current driving circuits to control the duty cycle of the pulse-width modulation (PWM) of each channel, thereby changing the proportion of RGB LEDs and obtaining different color temperatures to control the color for mixed-color LEDs. The experimental results show that when adjusting the color temperature, the change in luminous flux is very small, with fluctuations of less than 2.24%. When adjusting the brightness, the color-temperature fluctuation is within 40 K, which is less than the 50-K color-temperature limit that the human eye can distinguish, and the average color-temperature

error is 0.609%. A color tolerance less than 5.5×10^{-3} indicates a good dimming effect. The communication performance of the system is better in the high color-temperature range, which is significantly superior to the low color-temperature range. When the error rate is below 3.8×10^{-3}, the total modulation bandwidth of the three channels reaches 11.7 MHz.

Introduction

When a white light-emitting diode (LED) is used for the dual functions of lighting and communication, it is important to consider the impact of the color of the light source on the human eye, in addition to considering its communication performance. The lighting environment can have positive or negative psychological, physiological, and visual impacts [1, 2]. After a long period of natural selection, the continuous dynamic change in the color temperature of a natural light source feels the most comfortable to human beings. Color temperature is a physical quantity used in lighting optics to define the color of a light source. When a blackbody is heated to a temperature where the color of the emitted light matches that of a light source, the temperature at which the blackbody is heated is called the color temperature of the light source, also known as the color temperature.

The color temperature of sunlight is approximately 2500 K at sunrise. The color temperature rises to approximately 3500 K 1 h after sunrise and 5300–6500 K at midday. The color temperature then changes from high to low, reaching approximately 2800 K at sunset. The color temperature of the light source obviously affects people's cognition of the visual conditions around them. It plays a role in treating the symptoms of insomnia and alleviating the effect of jet lag, and has a significant impact on people's work efficiency [3].

The color temperature of the light source has a significant impact on the human nerve center [4], and cold light sources are prone to stimulate the nervous system. In a high color-temperature environment, the human heart rate increases, pulse rate accelerates, blood pressure rises, and the mind feels exuberant. In contrast, warm-colored light sources soothe emotions, reduce pressure, and lower the heart rhythm and pulse rate [5]. In terms of psychological perception, low-color-temperature light sources (warm light) make people feel warm, whereas high-color-temperature white light (cool light) makes people feel cold [6].

The light-source chromaticity must be quantitatively controlled to dynamically change the LED color temperature. It is important to study LED light sources with adjustable color temperatures in visible-light communication systems to adjust the color temperature of the LEDs according to the environment to create a healthy light environment in which people feel comfortable. In general, the color-temperature

range of indoor lighting is 3000–6500 K [7]. Light sources with different color temperatures are used on different occasions to meet people's psychological and physiological needs. Therefore, adjusting the color temperature of the light source in a visible-light communication system and controlling its chromaticity is a hot topic in current research.

Visible-light communication (VLC) in an indoor environment must not only provide communication functions, but also meet the lighting needs. Some areas, such as bars and photography studios, not only require the light source to be white, but may also require the color and chromaticity to be adjustable. Therefore, controlling the mixing and chromaticity of a multicolor transmission system should also be considered for VLC light sources.

In this study, controlling the chromaticity of a light source in a visible-light communication system of red-green-blue (RGB) LEDs was investigated and analyzed. By controlling the duty cycle of each channel's pulse-width modulation (PWM), and thereby changing the ratio of red, green, and blue LEDs, different color temperatures can be obtained to control the chromaticity of mixed-color LEDs. They can then be combined with existing communication technology to for communication.

Multicolor VLC-System Model and Foreign and Domestic Research Progress

System Model

A traditional visible-light communication system model mainly includes a sender, a free-space transmission channel, and a receiver. A diagram of a common visible-light communication system is shown in Fig. 42.1. The visible-light communication process can be described as follows: First, the signal generator generates the signal to be sent, passes it through the driving circuit to cause the LED light source to emit light, and modulates the generated signal onto the LED light source. After passing through the indoor free-space channel, it reaches the receiving end. The photodetector at the receiving end detects the received optical signal and converts it into an electrical signal, which is then processed by the receiving circuit and displayed on an oscilloscope.

The principles of baseband modulation and photoelectric signal transformation in visible-light communication systems involve loading the original signal onto the

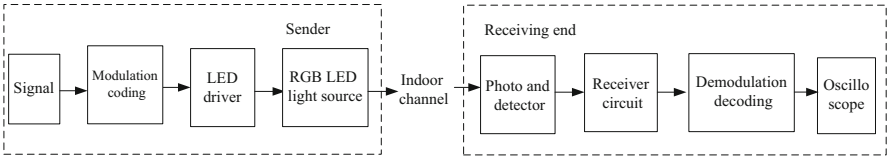

Fig. 42.1 Block diagram of a visible-light communication system

optical signal through an LED driver module after baseband modulation and digital-to-analog transformation. Then, the signal is transmitted from the sending end using the high-speed flashing changes of the LED light and transmitted through indoor channels to reach the receiving end of the system.

The driving circuit of an LED generally includes signal-amplification and DC-bias modules. The signal-amplification module appropriately amplifies the baseband signal, based on the dynamic range and communication requirements of the LED. The DC bias adds a DC component to the AC signal, allowing the LED to operate in a linear region. At the sending end, the electrical signals are converted into optical signals, whereas at the receiving end, photoelectric detectors are used to convert the optical signals into electrical signals. The receiving circuit filters, amplifies, reshapes, and demodulates the converted electrical signal before outputting it.

When a visible-light communication system has specific requirements for the transmission distance of a free-space channel, optical lenses may need to be added to focus the optical path to improve the signal-to-noise ratio (SNR) of the system.

Domestic Research Progress

In research on visible-light communication systems, fluorescent-powder LEDs that met both daily lighting needs and communication-system functions were first used. They had good performance and a simple structure; therefore, they were favored in the early research stages. However, phosphor-based LEDs have a slow response time, which limits the modulation bandwidth of the devices. Therefore, in recent years, research on high-speed visible-light communication has tended to use RGB LEDs as emission light sources. RGB LEDs have a faster response speed and a larger modulation bandwidth, and provide multiple optical-communication channels with different wavelengths. Color-division multiplexing can be used to superpose the modulation bandwidth.

In the visible-light communication field, an increasing number of scholars are studying multicolor visible-light communication systems to improve their performance through various hardware-improvement design schemes and modulation-coding techniques. In 2006, Ke et al. [8] investigated visible-light communication and its key technologies. The following year, the team [9] designed and simulated the light-source layout of a visible-light communication system and designed and verified the optimal layout of the four light sources.

To improve the communication speed, visible-light communication systems have developed from single-channel communication to multi-channel communication. In 2013, Wang et al. [10] used RGB LEDs and phosphor-based LEDs as emitting light sources, and conducted multiplexing experiments using wavelength-division multiplexing (WDM). The experimental results showed that when the communication distance was 66 cm and the BER was lower than 3.8×10^{-3}, a visible-light communication transmission with a 225-Mbps uplink communication rate and 575-Mbps downlink communication rate was achieved.

In the same year, Wu et al. [11] established a visible-light communication system using commercial RGB LEDs mixed with white light as the emission light source, using carrier-free amplitude-phase modulation and wavelength-division multiplexing technology. They successfully conducted visible-light communication experiments with a 25-cm communication distance and 3.22-Gbps data-transmission rate for the three channels, and an error rate of less than 10^{-3}.

In 2015, Wang et al. [12] established a high-speed visible-light communication system using red-green-blue-yellow (RGBY) LEDs as light sources, high-order carrier-free amplitude phase modulation, and mixed equalizers. The experimental results showed that the total communication rate of the three channels was 8 Gbps, the error rate was less than 3.8×10^{-3}, the communication distance was 1 m, and the illumination value of the receiving surface was 450 lx.

In the same year, Huang et al. [13] successfully demonstrated a gigabit-per-second visible-light communication transmission experiment based on RGB LEDs in free space at an 80-cm communication distance. Single-carrier 64-way quadrature-amplitude modulation (64QAM), 64QAM-orthogonal frequency-division multiplexing (OFDM), and bit-power loaded OFDM (BPL-OFDM) signals were demonstrated on an 80-cm free-space transmission at communication rates of 1.05 Gbps, 1.05 Gbps, and 1.42 Gbps, respectively, with error rates less than 3.8×10^{-3}. Compared with systems without equalizers, the bit-error rate performance improved by at least one order of magnitude. For BPL-OFDM modulation signals, the overall data rate increased from 1.13 Gbps to 1.42 Gbps by deploying equalization circuits.

In 2015, Ke et al. [14] constructed an RGB-LED visible-light communication video-transmission system and conducted experiments on video data-stream transmission with a 2-m communication distance and 1.5-Mbps data-transmission rate.

In 2016, Zhang et al. [15] considered the impact of color combinations on the communication rate based on RGB LEDs and increased the transmission rate to 10.4 Gbps using a rate-adaptive OFDM modulation method. In the same year, Chi et al. [16] proposed a new phase-shifted (PS) Manchester code based on eight-way pulse-amplitude modulation (PAM-8), and their experiments proved that this code could reduce noise and distortion. In a visible-light communication system based on RGB LEDs, with the help of PS Manchester encoding and wavelength-division multiplexing, information was transmitted over a 1-m communication distance, with a 3.375-Gbps total data rate and an error rate of less than 3.8×10^{-3}.

In 2017, Chen et al. [17] proposed a new Manchester-coded PAM-8 modulation scheme based on a hybrid time–frequency domain equalization scheme and applied it to a visible-light communication system based on RGB LEDs. The experimental results indicated that the overall data rate reached 4.05 Gbps. In the same year, Lu et al. [18] established a visible-light communication system using RGB LEDs combined with OFDM modulation. The experimental results showed that when the link was in single-input single-output mode, the system achieved a total communication rate of 3.48 Gbps. When the link was in multiple-input multiple-output mode, a 6.36-Gbps communication rate, 3.8×10^{-3} bit-error rate, and 1-m communication distance were successfully achieved.

In 2017, Kong et al. [19] implemented a wavelength-division multiplexing visible-light communication system based on RGB LEDs using 32 orthogonal-amplitude mapping (OAM) OFDM modulation in visible-light communication experiments. The experimental results showed that the data-transmission rates achieved by the red, green, and blue channels in a 10-m underwater channel were 4.17 Gbps, 4.17 Gbps, and 1.17 Gbps, respectively.

In 2018, Zhu et al. [20] used red-green-blue-cyan-yellow (RGBCY) LEDs as emission light sources and conducted experiments on indoor visible-light communication systems using wavelength-division multiplexing. The experimental results showed that at a 1-m communication distance, the total system communication rate was 10.72 Gbps, and the error rate was less than 3.8×10^{-3}.

In 2019, Deng et al. [21] proposed a multipulse position modulation (MPPM) dimming control scheme that supported different dimming target values. The proposed scheme improved the throughput and transmission efficiency of visible-light communication systems. In the same year, Zuo et al. [22] considered reliable data transmission and lighting quality when transmitting signals in visible-light communication systems and proposed a block-coding-based dimming scheme to construct a codeword set. The dimming was controlled by changing the ratio of the two levels through modulation using a key control. The experimental results showed that under different dimming levels, the scheme maintained good error performance and a constant transmission efficiency. They conducted communication experiments with a 2.5-m communication distance, 2.3-Mbps transmission rate, and a bit-error rate of less than 10^{-4}.

In 2020, Hu et al. [23] proposed a WDM visible-light communication transmission system based on 4×4 LED arrays using a discrete multi-tone (DMT) modulation technique and achieved a total communication rate of 20.09 Gbps with almost error-free communication experiments over a 1.2-m underwater link. In addition, for future LED-based WDM visible-light communication systems, the authors proposed a silicon-based multi-color LED array chip and a feasible filter scheme.

In 2022, Zhang [24] used white LEDs as the emission light source in a visible-light communication system using on–off keying (OOK) modulation. At a 3-m communication distance and 56-kbps data-transmission rate, he completed communication experiments that achieved both lighting effects and low-bit-error-rate signal transmissions. In the same year, Qiu et al. [25] successfully achieved a 25.2-Gbps communication rate and an almost error-free visible-light communication experiment with three LEDs and five micro-LEDs, using WDM technology at a 25-cm communication distance.

In 2023, Min [26] used color shift-keying modulation technology in a multi-color LED communication system. By testing the frequency response and high-speed communication performance of a four-color visible-light communication system, a single-color analog bandwidth on a 120-MHz communication system was achieved. The communication performance under various lighting indicators was analyzed, and a communication experiment with a communication rate of 50 Mbps and good lighting performance was conducted.

Foreign Research Progress

To prove that LEDs could simultaneously serve both lighting and communication functions, scholars from the Nakagawa Laboratory in Japan conducted a theoretical analysis and system simulation of visible-light communication system channels in 2000. Two years later, researchers conducted further studies on the characteristics, channel model, noise model, signal-to-noise ratio (SNR), and other performance indicators of LED light sources [27]. Some unknown interference may exist, owing to the free space of the visible-light communication system channel. Modulation technology can be used to improve the system's interference resistance.

In 2010, Vucic et al. [28] implemented a visible-light wireless point-to-point communication link with a total transmission rate of 513 Mbps, based on commercial thin-film high-power phosphorescent white LEDs and orthogonal amplitude modulation. Additionally, obstacles to improving data rates and potential remedial measures were discussed. If these obstacles were overcome, data rates exceeding 1 Gbps could be achieved under the same settings and experimental conditions.

In 2011, Kottke et al. [29] utilized RGB LEDs as emission light sources in visible-light communication systems using WDM and DMT modulation. At a 12-cm communication distance and a 1000-lx light intensity, they achieved communication rates of 293.7 Mbps, 232.4 Mbps, and 286 Mbps for three channels, with a total communication rate of 803 Mbps and an error rate of less than 2×10^{-3}.

The following year, the team [30] utilized RGB LEDs to mix white light and achieved communication rates of 376 Mbps, 439 Mbps, and 430 Mbps for the red, green, and blue channels, respectively, based on WDM and DMT modulation. The total communication rate was 1.25 Gbps, and the communication distance was 10 cm. Moreover, the illumination value at the receiving end met the working-environment indicator of 1000 lx, and the error rates of all three channels were below 10^{-3}.

In 2012, Cossu et al. [31] achieved a 1.5-Gbps single-channel communication rate on commercial RGB white LEDs using multicarrier modulation. Combined with WDM, the total system communication rate under illumination reached 3.4 Gbps at a 30-cm communication distance, and the system's BER was less than 2×10^{-3}.

In 2014, the team [32] again implemented a bidirectional visible-light communication system using WDM. The experimental results showed that when the communication distance varied from 1.5 m to 4 m, the uplink communication rate of the system varied in the range of 1.1 Gbps to 1.5 Gbps, and the range of the downlink communication rate varied in the range of 5 Gbps to 5.6 Gbps. The range of the light intensity ranged from 120 lx to 720 lx, and the BERs were all less than 3.8×10^{-3}. In the next year, the team [33] achieved four-channel information transmission in a visible-light communication system, when the BER of each channel was less than 3.8×10^{-3}. They achieved a data rate greater than 5 Gbps for the downlink communication and greater than 1.5 Gbps for the uplink communication over a transmission distance of 1.5–4 m indoors.

In 2014, Sung et al. [34] proposed an RGB-LED dimming scheme based on DMT modulation that could control the color in a high-speed visible-light communication

system. The authors conducted experiments and analyses under various modulation conditions and transmission distances. The experimental results showed that at a 30-cm transmission distance and a 512-point fast Fourier transform, a total transmission rate of 103.5 Mbps for three channels was achieved, with an error rate of less than 3.8×10^{-3}.

In 2016, Lee et al. [35] optimized and improved the traditional variable pulse-position modulation (PPM), ensuring that LEDs could stably transmit data, even in environments with rapid changes in light intensity. A visible-light communication system test bench with rapidly changing brightness and variable PPM was designed. The system light source was composed of 30 white LED chips, achieving a communication rate of 200 kbps at a 6-m communication distance, and bit-error rate of 6×10^{-3} in communication experiments.

In 2017, Sewaiwar et al. [36] proposed a high-performance time-division multiplexing-based multiuser multiple-input multiple-output (MIMO) system for efficient indoor visible-light communication. The transmitting light source in this system used RGB LEDs for parallel data transmissions. Simulation results showed that the proposed scheme provided an approximately 6-dB gain in the signal-to-noise ratio at a BER of 3×10^{-5} compared to a conventional single-input single-output system. In addition, the data rate reached 66.7 Mbps at a BER of 10^{-3}.

In 2018, Bian et al. [37] used RGB LEDs mixed with white light as the light source and used OFDM and WDM techniques in visible-light communication systems. The communication distance was 50 cm, the data-transmission rate was 10.2 Gbps, and the error rate was less than 3.8×10^{-3} in high-speed visible-light communication experiments. The following year, the team [38] used four different colored LEDs as emission light sources in a visible-light communication system and used OFDM modulation to complete a VLC transmission experiment with a communication rate of 15.73 Gbps and almost no error codes on a 1.6-m communication link.

In 2019, Jain et al. [39] used RGB LEDs as the emission light source for visible-light communication systems using a color shift-keying modulation method. They proposed a new adaptive nonlinear equalizer based on multivariate-kernel least squares to alleviate the intersymbol interference and nonlinearity of RGB LEDs. The simulation results showed that the system had a lower symbol error rate than existing technologies.

In 2020, Viñals et al. [40] designed a linear precoder for the downlink of visible-light communication systems that simultaneously served multiple users. The emission light source of this system used RGB LEDs to modulate three independent data streams on the three RGB channels and used multilevel PAM to conduct communication experiments with a modulation bandwidth of 15 MHz and a bit-error rate below 10^{-6}.

Multichannel visible-light communication systems using multiple monochromatic LEDs have achieved high communication rates; however, no color-control mechanism exists. The color of the light emitted by multiple LEDs poses a threat to the human eye, and many scholars have investigated this [41, 42].

Theoretical Basis

To analyze the LED color rendering, the Gaussian mathematical model (Y-model) proposed by Ohno et al. is in good agreement with the actual LED spectral distribution and has been widely recognized. This model can be represented as [43]

$$S_{\mathrm{LED}}(\lambda, \lambda_0, \Delta\lambda_{0.5}) = Y_c \frac{g(\lambda, \lambda_0, \Delta\lambda_{0.5}) + 2g^5(\lambda, \lambda_0, \Delta\lambda_{0.5})}{3} \tag{42.1}$$

where $g(\lambda, \lambda_0, \Delta\lambda_{0.5}) = \exp\left[-((\lambda - \lambda_0)/\Delta\lambda_{0.5})^2\right]$; λ is the wavelength; Y_c is the spectral power at the peak wavelength λ_0; and $\Delta\lambda_{0.5}$ is the half peak width.

The tristimulus value of a light source refers to its basic optical characteristics, which are typically used to describe and measure its color. According to the spectral mathematical model of the LED, the tristimulus values X, Y, and Z of the light source to be tested can be calculated using the following formula [44]:

$$\begin{cases} X = K_m \int_{380}^{780} S(\lambda)\bar{x}(\lambda)d\lambda \\ Y = K_m \int_{380}^{780} S(\lambda)\bar{y}(\lambda)d\lambda \\ Z = K_m \int_{380}^{780} S(\lambda)\bar{z}(\lambda)d\lambda \end{cases} \tag{42.2}$$

where $K_m = 683lm/W$ is a constant; $S(\lambda)$ is the relative spectral power distribution; $\bar{x}(\lambda)$, $\bar{y}(\lambda)$, and $\bar{z}(\lambda)$ are the color-matching function, which is the average data of the CIE 1931 Standard Observer, also known as the spectrum triple-stimulation function [44].

In the actual calculation, the CIE 1931 standard-chromaticity tristimulus value of the light source was obtained using discrete summation and approximate integration calculations. The expression can be expressed as

$$\begin{cases} X = K_m \sum_{380}^{780} S(\lambda)\bar{x}(\lambda)\Delta\lambda \\ Y = K_m \sum_{380}^{780} S(\lambda)\bar{y}(\lambda)\Delta\lambda \\ Z = K_m \sum_{380}^{780} S(\lambda)\bar{z}(\lambda)\Delta\lambda \end{cases} \tag{42.3}$$

where $\bar{x}(\lambda)$, $\bar{y}(\lambda)$, and $\bar{z}(\lambda)$ can be determined using lookup tables, and a spectral sampling interval of $\Delta\lambda = 1$ is often used.

The corresponding color coordinates can be determined according to the three obtained light-source stimulus values. After normalizing X, Y, and Z, the color coordinates x, y, and z of the light source can be obtained as follows:

$$\begin{cases} x = \dfrac{X}{X+Y+Z} \\ y = \dfrac{Y}{X+Y+Z} \\ z = \dfrac{Z}{X+Y+Z} \end{cases} \tag{42.4}$$

In lighting systems, the color temperature is a physical quantity used to define the chromaticity of a light source, and can indicate its lighting quality. The relevant color temperature of the light source can be calculated from the chromaticity coordinates; the formula for calculating the color temperature is as follows [45]:

$$T = -437n^3 + 3601n^2 - 6861n + 5514 \tag{42.5}$$

where $n = \frac{x-0.3320}{y-0.1858}$ and x, y is the color coordinate.

The color index is a parameter used to evaluate the degree to which a light source restores the true color of an object. It is generally believed that, under natural light, the color presented by objects is the most authentic, with a color index of 100. The color index of the light source for a standard sample can be expressed as [46]

$$R_i = 100 - 4.6\Delta E_i \, (i = 1, 2, 3, \cdots, 14) \tag{42.6}$$

where ΔE_i is the color difference between the sample under the reference light source and the light source to be tested, and can be obtained from the chromaticity coordinates.

The average color index of the light source for color samples 1–8 is called the general color index R_a:

$$R_a = \frac{1}{8}\sum_{i=1}^{8} R_i \tag{42.7}$$

Research on RGB LED Dimming

Dimming and Calculation Methods

Dimming technology has become an important aspect of LED driving, and three LED dimming methods are commonly used: DC, PWM, and thyristor dimming [47]. When the current is too small, the thyristor will disconnect, making the dimming effect unstable and unsuitable for use in visible-light communication systems [47]. DC dimming is achieved by changing the driving peak current of the LED to alter the luminous flux. This dimming method can affect the chromaticity shift and color-temperature change of the LED [48].

PWM dimming is achieved by changing the duty cycle of the LED light source, thereby changing the average luminous flux. The dimming performance is flexible

and can accurately control the luminous flux, thereby accurately controlling the brightness change of the LED and reducing the effect of current changes during amplitude modulation on the stability of the light source [49]. In engineering practice, color differences caused by PWM dimming are often ignored [50].

In the PWM-dimming method, the peak value of the driving current remains unchanged and the LED is dimmed by adjusting the duty cycle of the PWM. The expression is as follows:

$$I_{\text{avg}} = I_{\text{peak}} \cdot D \tag{42.8}$$

where I_{avg} represents the effective value of the driving current, I_{peak} represents the magnitude of the driving peak current, and D represents the PWM duty cycle.

For the convenience of calculation, it is usually assumed that the PWM duty cycle of the input driver module is directly proportional to the luminous flux output of the light source [51], which satisfies

$$\Phi = D\Phi_{\text{Max}} \tag{42.9}$$

where D is the duty cycle of the input PWM signal, $D < 1$; Φ_{Max} is the maximum output luminous flux; and Φ is the luminous flux of the output signal.

Glassman's law of color mixing provides a three-color mixing-output luminous-flux formula [52]:

$$\Phi = D_r\Phi_r + D_g\Phi_g + D_b\Phi_b \tag{42.10}$$

where D_r, D_g, and D_b are the input duty cycles of the PWM; Φ_r, Φ_g, and Φ_b are the maximum output luminous fluxes of each light source; and Φ is the output luminous flux of the mixed light.

The CIE-1931 standard colorimetric system specifies that the stimulus value Y is equal to the luminous flux; therefore, in the following text, it can be changed to Y. According to the principle of color mixing and the CIE 1931 color-coordinate calculation method, the color coordinates after mixing with the three light sources should satisfy the following [53]:

$$x = \frac{R_r D_r x_r + R_g D_g x_g + R_b D_b x_b}{R_r D_r + R_g D_g + R_b D_b} \tag{42.11}$$

$$y = \frac{R_r D_r y_r + R_g D_g y_g + R_b D_b y_b}{R_r D_r + R_g D_g + R_b D_b} \tag{42.12}$$

where x and y represent the color coordinates of a mixed light source consisting of three types of light sources; (x_r, y_r), (x_g, y_g), and (x_b, y_b) represent the color coordinates of red, green, and blue LEDs, respectively; $R_r = \frac{Y_r}{y_r}$, $R_g = \frac{Y_g}{y_g}$, and $R_b = \frac{Y_b}{y_b}$ represent the sum of the three stimulus values of the light source under full current operation; and D_r, D_g, and D_b represent the PWM input duty cycles of red, green, and blue LEDs, respectively.

From Eqs. (42.10), (42.11), and (42.12), the duty cycles of the three channels are obtained as follows:

$$D_r = \frac{\left(y_g - y_b\right)(x_b - x) + (y - y_b)\left(x_g - x_b\right)}{\left(y_g - y_b\right)(x_b - x_r) + (y_r - y_b)\left(x_g - x_b\right)} \cdot \frac{y_r Y}{y Y_r} \tag{42.13}$$

$$D_g = \frac{(y_b - y_r)(x_r - x) + (y - y_r)(x_b - x_r)}{(y_b - y_r)\left(x_r - x_g\right) + \left(y_g - y_r\right)(x_b - x_r)} \cdot \frac{y_g Y}{y Y_g} \tag{42.14}$$

$$D_b = \frac{\left(y_g - y_r\right)(x_r - x) + (y - y_r)\left(x_g - x_r\right)}{\left(y_g - y_r\right)(x_r - x_b) + (y_b - y_r)\left(x_g - x_r\right)} \cdot \frac{y_b Y}{y Y_b}, \tag{42.15}$$

where Y_r, Y_g, and Y_b are the respective maximum output luminous fluxes when the input duty cycles of the red, green, and blue light sources are 100%; Y is the output luminous flux of a hybrid light source; (x_r, y_r), (x_g, y_g), and (x_b, y_b) are the color coordinates of red, green, and blue, respectively; and (x, y) is the color coordinate of the mixed light source.

Simulation Analysis of Dimming

The duty cycle is proportional to the luminous flux, which determines the LED luminance. The larger the luminous flux, the brighter the LED luminance. Therefore, the duty cycle is directly proportional to the luminous brightness of the LED. The ratio of RGB LEDs with different brightnesses controlled by the circuit were calculated and simulated. The brightness ratio of a single LED was changed, and the changes in color temperature and color coordinates of the RGB-LED hybrid light source were observed through simulation.

The arrangement of the three types of LEDs is shown in Fig. 42.2, with an observation-surface size of 500 mm × 500 mm and a distance of 100 cm from the emitter. In the simulation, the distance remained unchanged; only the brightness ratio of the LED was changed. The total luminous flux of the LED was 100 lm.

Simulating Color-Coordinate Changes

When the control circuit adjusts the luminous-flux ratio of RGB LEDs, different color temperatures can be obtained. The changes in different color temperatures and corresponding color coordinates were simulated, based on the ratio calculated from Eqs. (42.11) and (42.12). As shown in Fig. 42.3, color coordinate x shows a decreasing trend with increasing color temperature, whereas color coordinate y fluctuated with increasing color temperature. The fluctuation is greater during the low-color-temperature stage and smaller during the high-color-temperature stage.

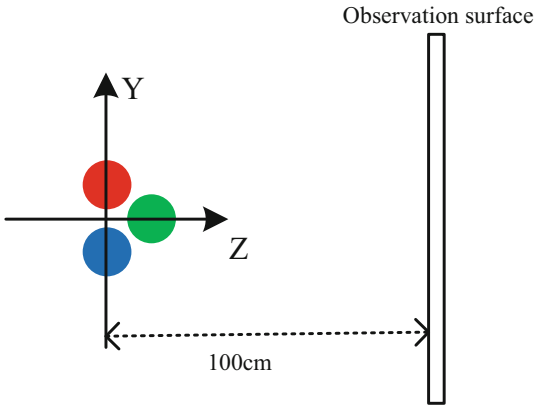

Fig. 42.2 Arrangement of three types of LEDs

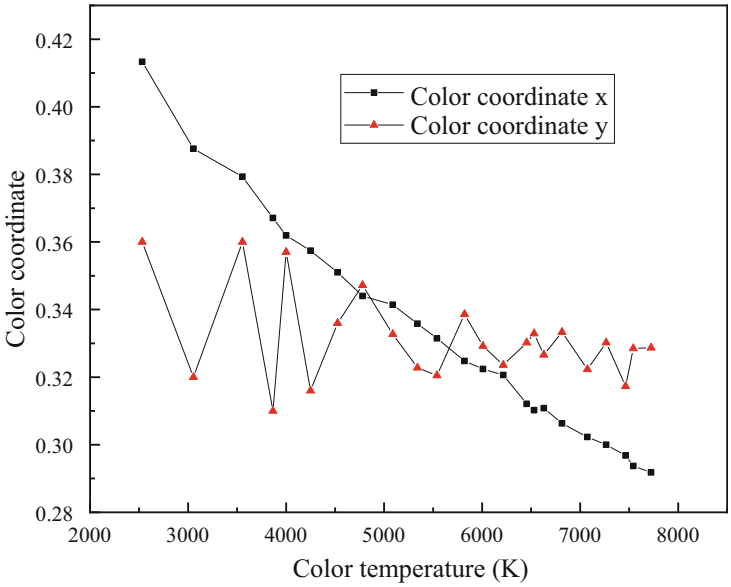

Fig. 42.3 Curves of the color coordinates changing with the color temperature

Figure 42.4 shows the mixed light source on the observation surface when the duty-cycle ratios of the RGB LEDs are set to 0.6: 0.28: 0.12, 0.5: 0.32: 0.19, 0.47: 0.33: 0.2, and 0.45: 0.34: 0.21. At this time, the color temperatures of the mixed light source are 3470 K, 5677 K, 6528 K, and 7265 K, respectively. The color coordinates are (0.4044, 0.3847), (0.3286, 0.3334), (0.3116, 0.3336), and (0.3038, 0.3099), respectively, and the total amount of light is approximately 88 lm.

The simulation showed that the proportions of the RGB LEDs had a significant impact on the color coordinates and temperature of the synthesized white light, with

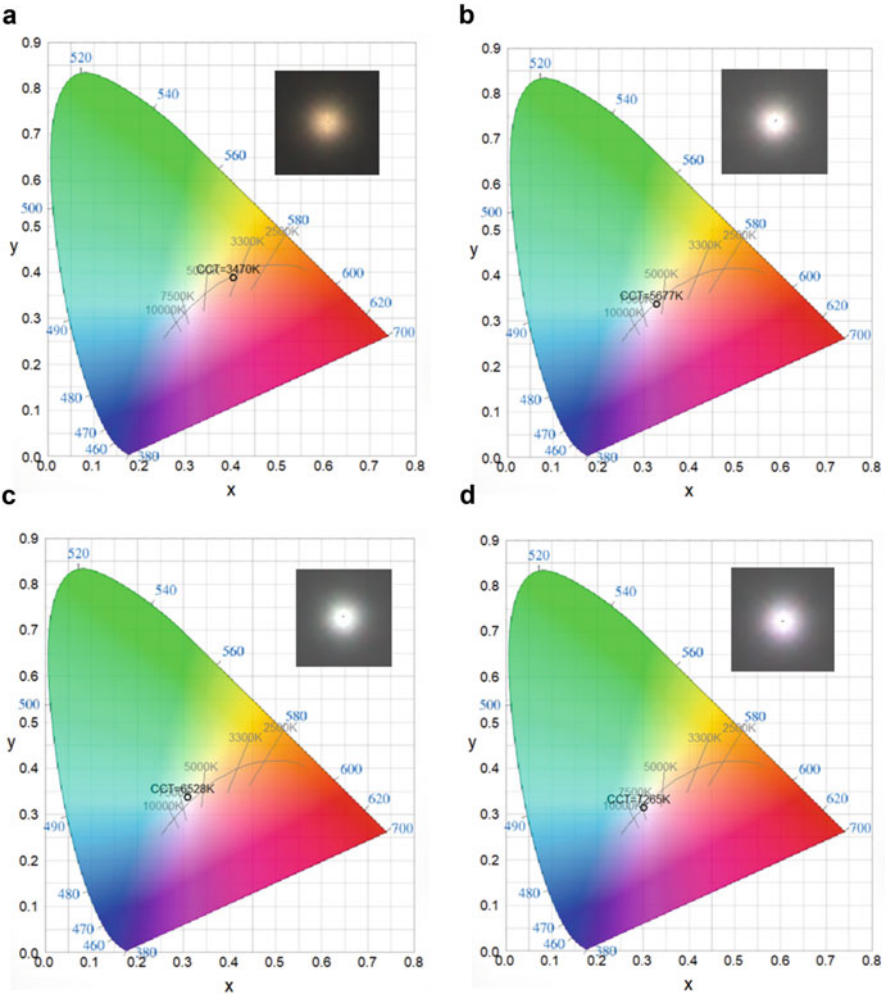

Fig. 42.4 Simulating light sources at different color temperatures. (**a**) 3470 K. (**b**) 5677 K. (**c**) 6528 K. (**d**) 7265 K

a relatively small impact on the luminous flux. By changing the duty cycle of the red, green, and blue LEDs, the hybrid white light source changed from warm white to cold white.

Simulating Color-Temperature Changes

A constant distance of 100 mm was maintained between the receiving surface and light source, and the changes in the average light intensity of the receiving surface under different color temperatures were simulated. As shown in Fig. 42.5, the average light intensity of the receiving surface at different color temperatures was

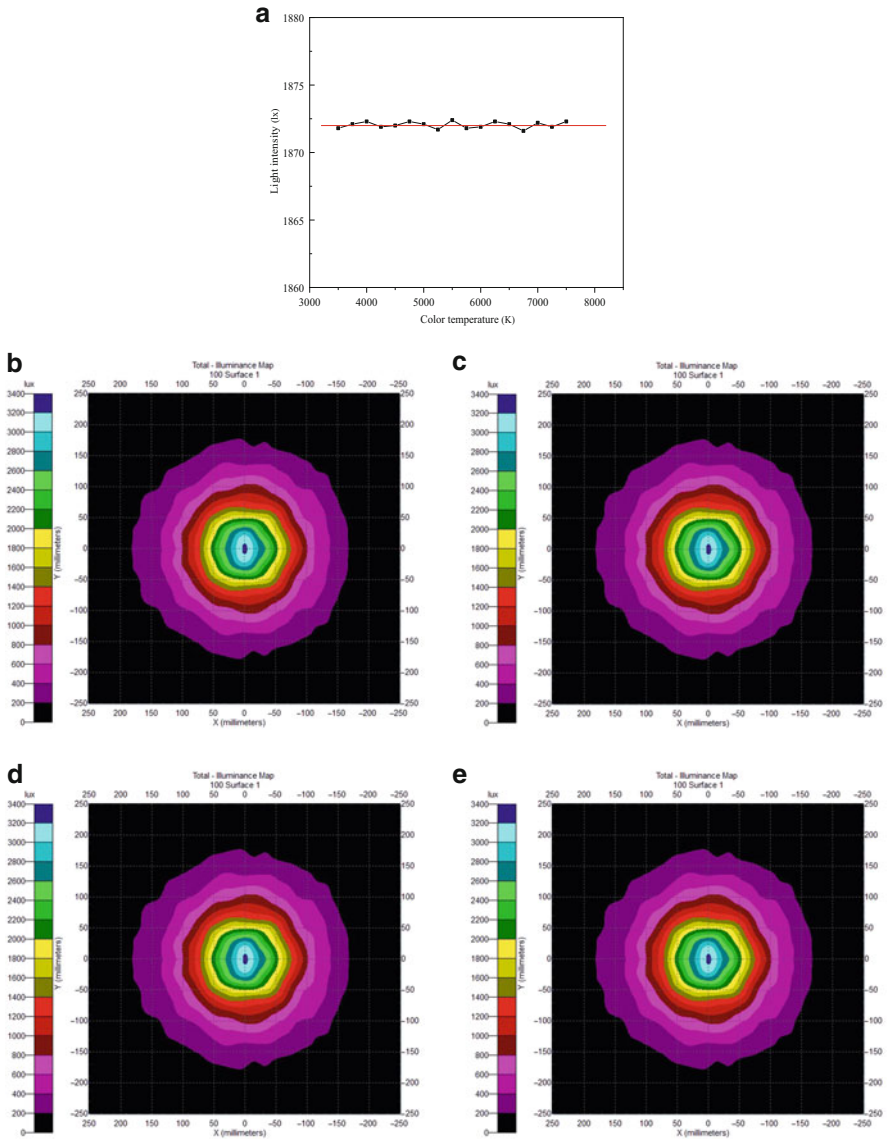

Fig. 42.5 Light intensity distribution under different color temperatures. (**a**) The variation of light intensity with color temperature; (**b**) Color temperature is 3500 K; (**c**) Color temperature is 5500 K; (**d**) Color temperature is 6500 K; and (**e**) Color temperature is 7300 K

approximately 1872 lx, with an error of less than 5 lx between the maximum and minimum values. When the color temperatures were 3500 K, 5500 K, 6500 K, and 7300 K, the simulated average light-intensity distribution of the receiving surface showed almost no difference. In summary, as the color temperature of the light

source changes, the change in the illumination intensity of the receiving surface becomes very small and can be ignored.

Simulating Different Transmission Distances

A color temperature of 6500 K was fixed and the light intensity on the receiving surface at different distances was simulated. As shown in Fig. 42.6, the energy received by the receiving surface was increasingly less dispersed as the distance between the light source and the receiving surface increased. When the distance between the light source and the observation surface was 50, 100, 200, and 300 cm, the simulated light-intensity map of the receiving surface showed that the energy dispersion increased with increasing distance. In summary, as the distance increased, the light intensity on the receiving surface decreased, and the distance had a significant effect on the light intensity on the receiving surface.

Dimming Experiment

This experiment used hexagonal RGB LED beads to form a luminescent light source; an HP350 spectrophotometer produced by Hangzhou Double Color Intelligent Testing Instrument Co., Ltd. was used to measure the light color parameters. Table 42.1 lists the light-color parameters when the three-color LED was operated at full current, where FWM is the full width at half maximum. Figure 42.7 shows the relative spectral power distribution.

The duty cycle of the LED was adjusted and its brightness was measured. Figure 42.8 shows the variation curve of the measured LED brightness with the duty cycle. The brightness of the green light changed significantly with the duty cycle, whereas the changes in the red and blue lights were relatively similar, with relatively small changes compared to the green light.

The dimming device consists of a switching power supply, control system, driving circuit, and red, green, and blue LED light sources. Figure 42.9 shows a block diagram of the dimming device. The control system sends instructions to the driving circuit to drive a three-channel LED, obtaining white light with different color temperatures based on the different duty cycles, thereby adjusting the LED color temperature.

RGB LEDs can be mixed in different proportions to obtain a color-temperature range of 2500–8500 K. To study the optimal color-rendering performance of the light-source module during the dimming process, 12 sets of combinations with good color-rendering performance were selected. The mixed-light parameters measured using an HP350 spectrophotometer are listed in Table 42.2.

From Table 42.2, it can be seen that, compared with the measured color temperature, the color deviation calculated according to Eq. (42.5) is lower than the 50-K color-temperature limit that can be resolved by the human eye. The average color-temperature error was 0.609%, and the difference between the measured and calculated values was small. Therefore, the color-temperature adjustment in the experiment was relatively stable.

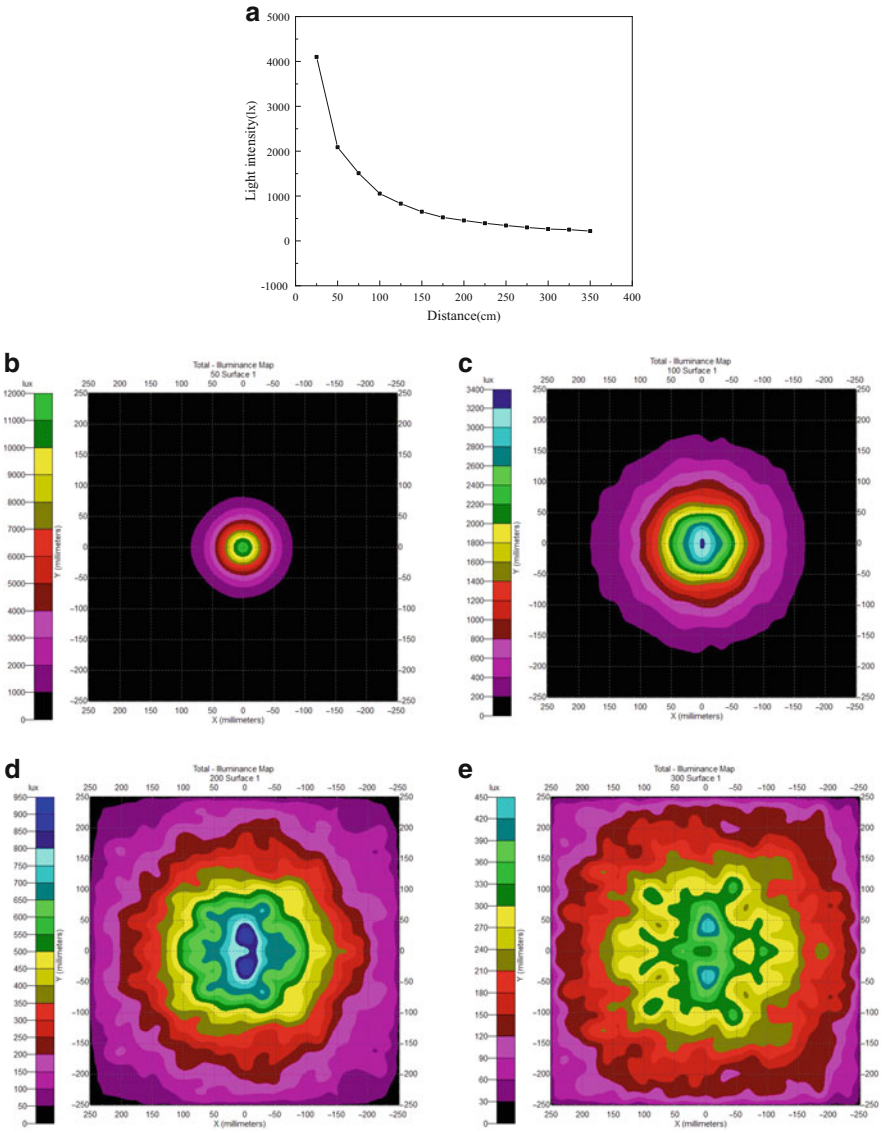

Fig. 42.6 Light intensity distribution at different distances. (**a**) The variation of light intensity with distance; (**b**) Distance is 50 cm; (**c**) Distance is 100 cm; (**d**) Distance is 200 cm; and (**e**) Distance is 300 cm

The theoretical color coordinates of the synthesized light source were obtained from Eqs. (42.3) and (42.4), and the actual color coordinates were measured using a spectrophotometer. Figure 42.10 shows the variation curves of the measured and

Table 42.1 Three LED parameters

LED type	Chromatic coordinates	Peak wavelength (nm)	FWHM (nm)	Luminous intensity (cd)	Luminous flux (lm)
Red	(0.6894, 0.3099)	630	20	1.8–2.0	67.9
Green	(0.1689, 0.7232)	520	20	5.0–6.0	178.1
Blue	(0.1434, 0.0416)	460	20	1.0–1.5	29.0

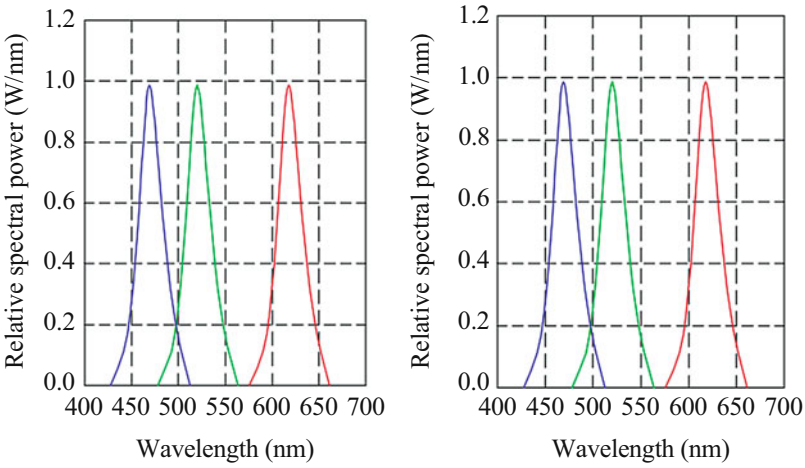

Fig. 42.7 Relative spectral power-distribution curves of three types of LEDs

calculated color coordinates with the color temperature. The error of the calculated color coordinate x was less than 0.0007, and the error of the color coordinate y was less than 0.0014. The measured color coordinates agreed well with the calculated color coordinates. The color coordinates have a significant impact on low-color-temperature light sources, whereas they have a relatively small impact on high-color-temperature light sources, which is consistent with the simulation results mentioned above.

The duty cycles of the RGB LEDs obtained from Eqs. (42.13), (42.14), and (42.15) can produce mixed white light with different color temperatures. As shown in Fig. 42.11, the duty cycles of the red, green, and blue LEDs varied with the color temperature. As shown in Fig. 42.11, as the color temperature increases, the duty cycle of the red LED decreases, whereas those of the green and blue LEDs increase.

An HP350 spectrophotometer was used to measure the luminous flux, irradiance, color tolerance, light intensity, and color index of the mixed light source. Figure 42.12 shows that the maximum luminous flux set in the experiment was 100 lm, and the luminous flux of the mixed light varies between 92 lm and 100 lm. The resulting luminous flux of the mixed white light is relatively high,

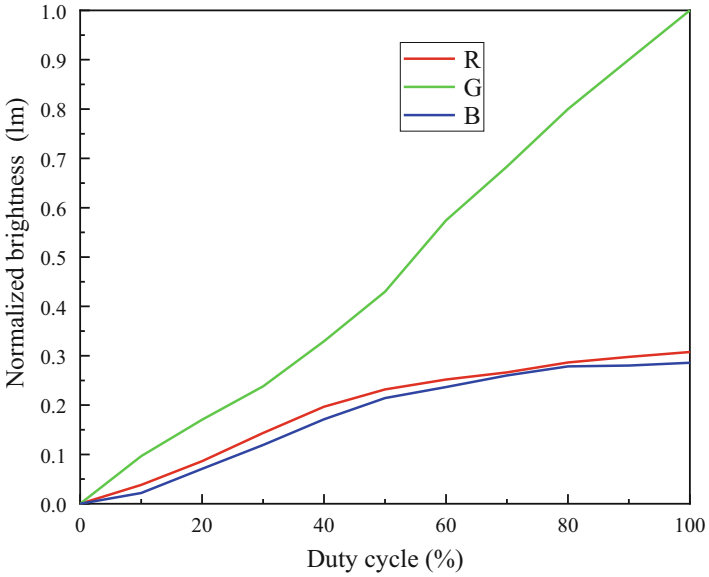

Fig. 42.8 Changes in the LED brightness with the duty cycle

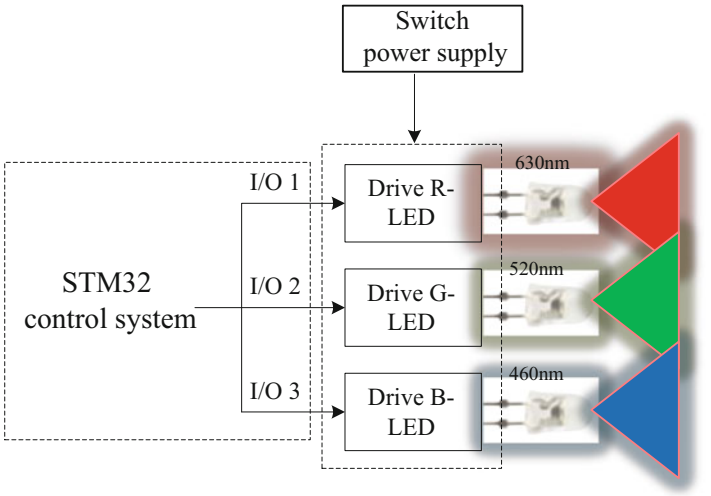

Fig. 42.9 Block diagram of the dimming device

and when the color temperature is adjusted, the fluctuation in the luminous flux is very small, with a fluctuation of 2.24%. Therefore, the influence of the color temperature on the luminous flux was relatively small, which is consistent with the simulation results.

Table 42.2 Comparison between measured and calculated data

RGB proportion	Measured color temperature (K)	Calculated color temperature (K)	Color temperature difference (K)
0.557: 0.301: 0.142	2539	2500	39
0.502: 0.280: 0.218	3030	3000	30
0.476: 0.347: 0.177	3525	3500	25
0.439: 0.304: 0.257	4012	4000	12
0.417: 0.370: 0.213	4532	4500	32
0.405: 0.323: 0.272	5023	5000	23
0.382: 0.361: 0.257	5510	5500	10
0.364: 0.356: 0.281	6032	6000	32
0.347: 0.363: 0.290	6526	6500	26
0.336: 0.355: 0.308	7036	7000	36
0.313: 0.382: 0.305	7540	7500	40
0.302: 0.381: 0.317	8032	8000	32

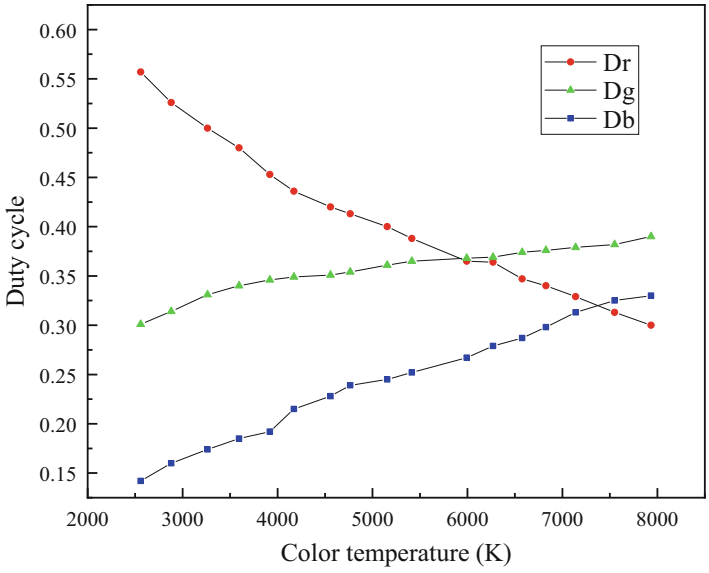

Fig. 42.10 Curve of color coordinates changing with color temperature

The irradiance range of mixed white light is 3.4–4.2 W/m^2. When the color-temperature range was 5000–6500 K, the irradiance reached its maximum and the lighting effect was optimal. The color tolerance *Duv* is stable around 0, which is specified to be less than 5.5 $\times$ 10^{-3}, and can meet the lighting standards [54]. Figure 42.13 shows that the illumination value fluctuates less with the change in color temperature, with a difference of only 8.2 lx between the maximum and minimum values. The change in color temperature has a small impact on the illumination intensity, which confirms the conclusion of the simulation.

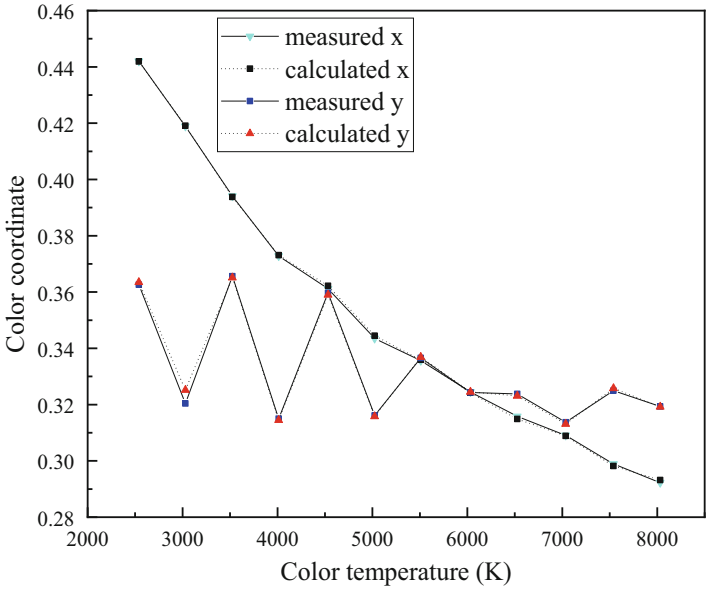

Fig. 42.11 Change of RGB duty cycle with color temperature

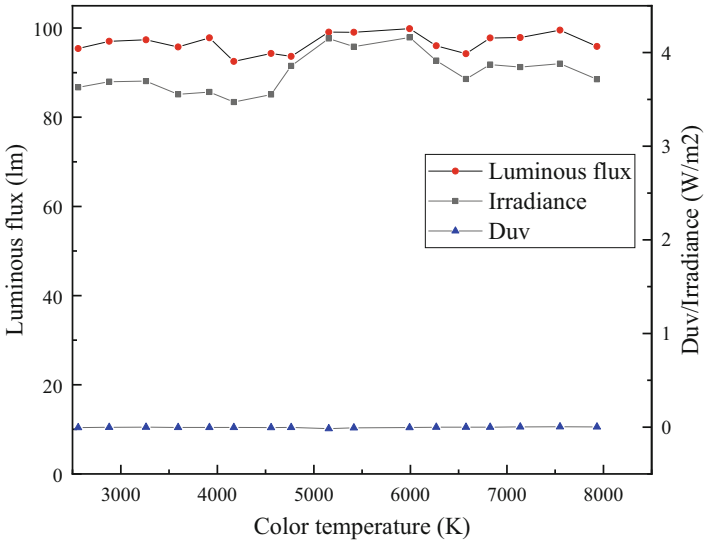

Fig. 42.12 Variation of luminous flux, irradiance, and color tolerance with color temperature

In Fig. 42.13, a comparison between the calculated color index and the measured color index according to Eqs. (42.6) and (42.7) shows that the theoretical value of the color index is in good agreement with the measured value. The color index is greatly

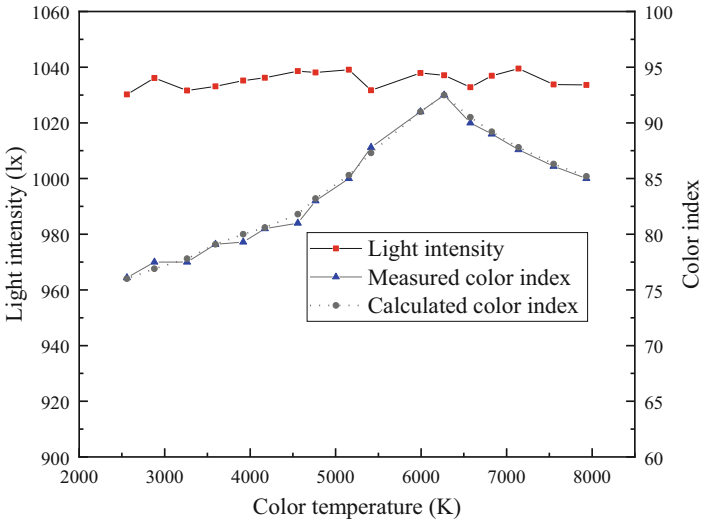

Fig. 42.13 Variation of illuminance and color index with color temperature

affected by the color temperature. When the color temperature is within the range of 5500–6500 K, the color index is optimal. This color-temperature range represents the light and color temperatures at noon. The effect of restoring the color of the object itself is the best, which also conforms to natural laws. A light source with a color index greater than 75 is of high quality [55]. The color index of the mixed white light is greater than 76 within the adjustable color-temperature range, and the maximum color index is 92, indicating that the experimental mixed white light has a good effect.

Figure 42.14 shows the light-intensity curves with distance at different color temperatures after using the HP350 spectrophotometer to measure the light intensity at different color temperatures and distances. The light-intensity curves with distance at each color temperature almost overlap, indicating that the influence of the color temperature on the light intensity is not significant. However, as the distance increases, the light intensity decreases, indicating that the distance has a significant impact on the light intensity, verifying the conclusions obtained from the simulation.

Figure 42.15 shows the light intensities at different positions on the receiving surface; they were measured at a distance of 50 cm. The light intensity is the highest under direct light. The light intensity is the lowest at the edge of the receiving surface, with a maximum illumination value of 1500 lx. The illuminance value on the receiving surface is uniform at 400–1500 lx, which meets the 300–1500 lx illuminance value formulated by the International Organization for Standardization with uniformity and lighting effects.

To verify the correctness of the simulation results, the proportions of the RGB LEDs were adjusted to 0.6: 0.28: 0.12, 0.5: 0.32: 0.19, 0.47: 0.33: 0.2, and 0.45: 0.34: 0.21, using a driving circuit, which were consistent with the simulation

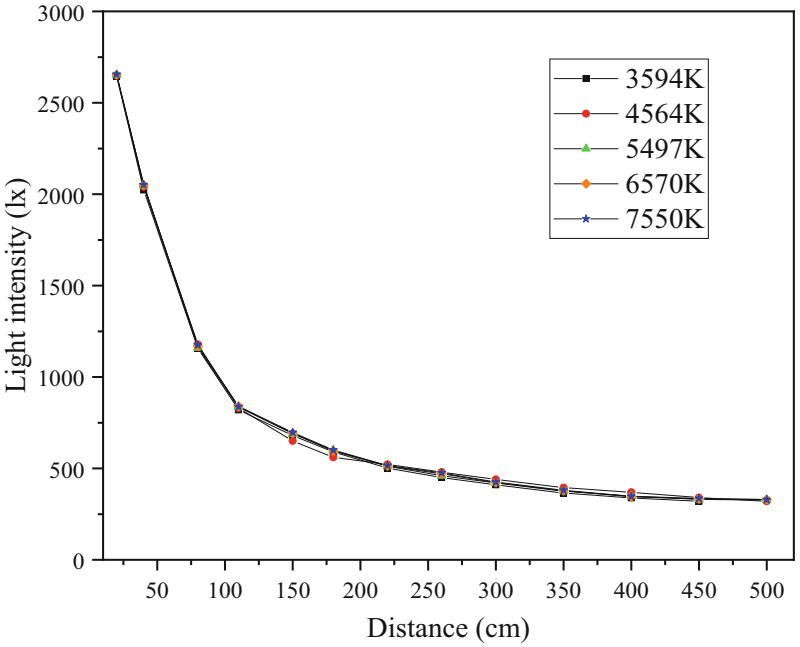

Fig. 42.14 Change of light intensity with distance under different color temperatures

proportions. The color temperatures of the mixed white light measured using the HP350 spectrophotometer were 3472, 5670, 6530, and 7260 K, which were almost equal to the simulated color temperatures. Figure 42.16 shows the measured spectrogram and Fig. 42.17 shows the position information of the mixed white light on the CIE 1931 chromaticity map. The chromaticity coordinates were (0.4043, 0.3846), (0.285, 0.3333), (0.3117, 0.3335), and (0.3038, 0.3098), which are very close to the simulated chromaticity coordinates, indicating that the mixed white light has a good effect.

Design and Experiment of an RGB-LED Visible-Light Communication System

System Working Principle and Experimental Device

The visible-light communication system consists of three parts: a sender, an indoor channel, and a receiver. Figure 42.18 shows the structural diagram of the visible-light communication system. The light emitted by the three differently colored LED chips at the sending end can be regarded as three channels; therefore, color-division multiplexing was used for multiplexing transmissions, thereby improving the system communication performance.

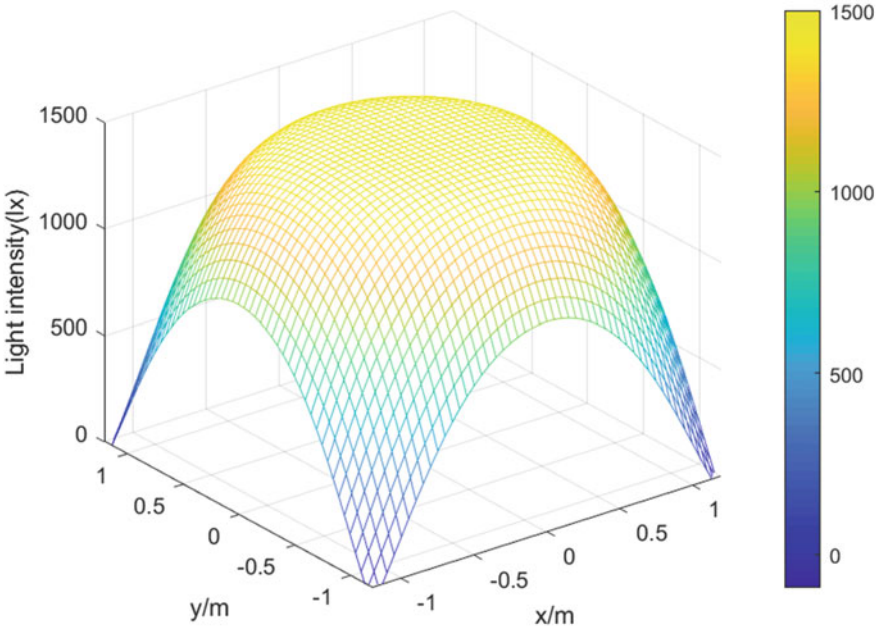

Fig. 42.15 Distribution of light intensity on the receiving surface

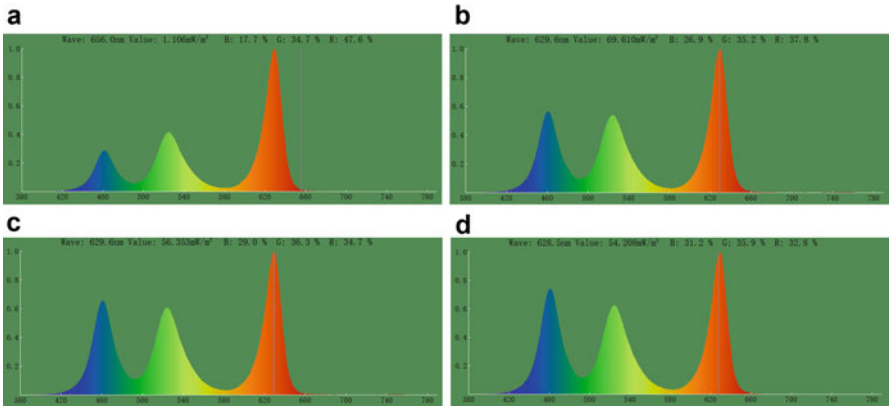

Fig. 42.16 Measured spectrograms at different color temperatures: (**a**) color temperature is 3470 K, (**b**) color temperature is 5670 K, (**c**) color temperature is 6530 K, and (**d**) color temperature is 7260 K

Three PWM channels are generated by the STM32 microcontroller to drive the three types of LEDs. The three colors are then mixed into white light in a certain proportion for output and transmission in the indoor channel. At the receiving end, monochromatic radiation is separated from the white light with corresponding

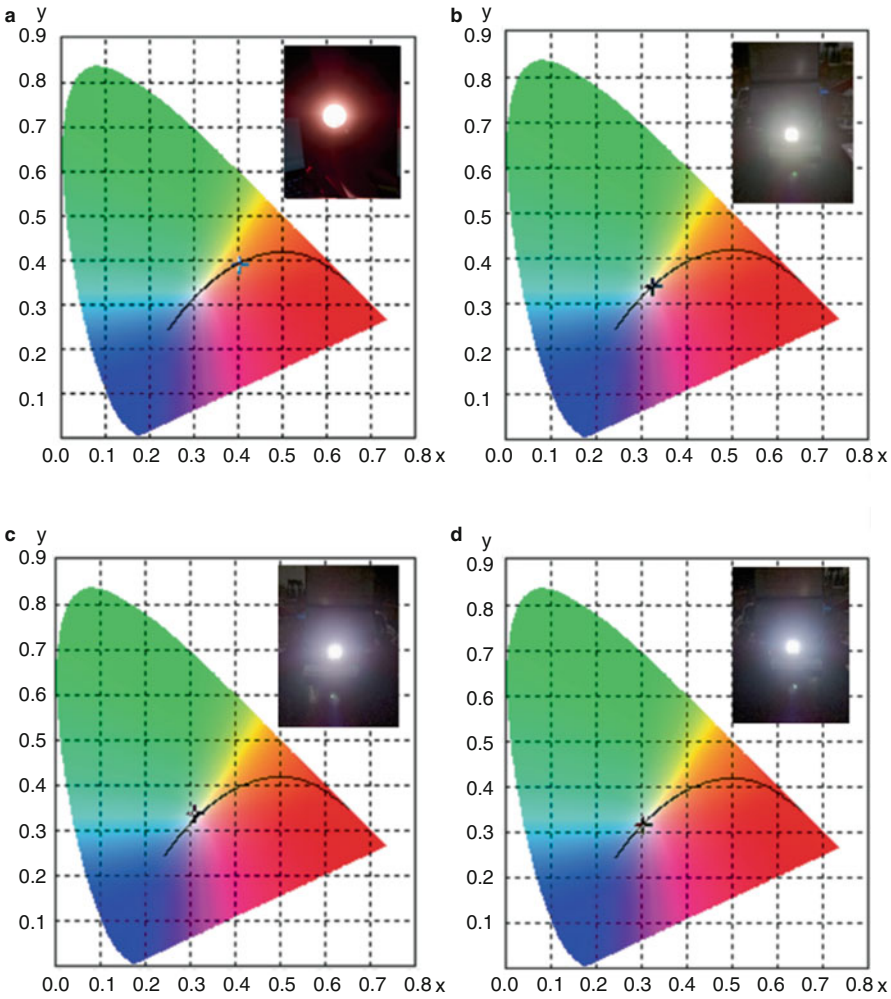

Fig. 42.17 CIE 1931 chromaticity chart at different color temperatures. (**a**) 3470 K. (**b**) 5670 K. (**c**) 6530 K. (**d**) 7260 K

filters to form three channels. The detector is used to receive signals and display them on the oscilloscope. The received optical power is measured using an optical power meter and the data are recorded using a computer. Finally, the color temperature and light intensity of the mixed white light are measured using a spectrophotometer. The RGB LED visible-light communication system designed in this study achieved high-speed data communication through three parallel signals and used the PWM dimming method to output white light to control the chromaticity.

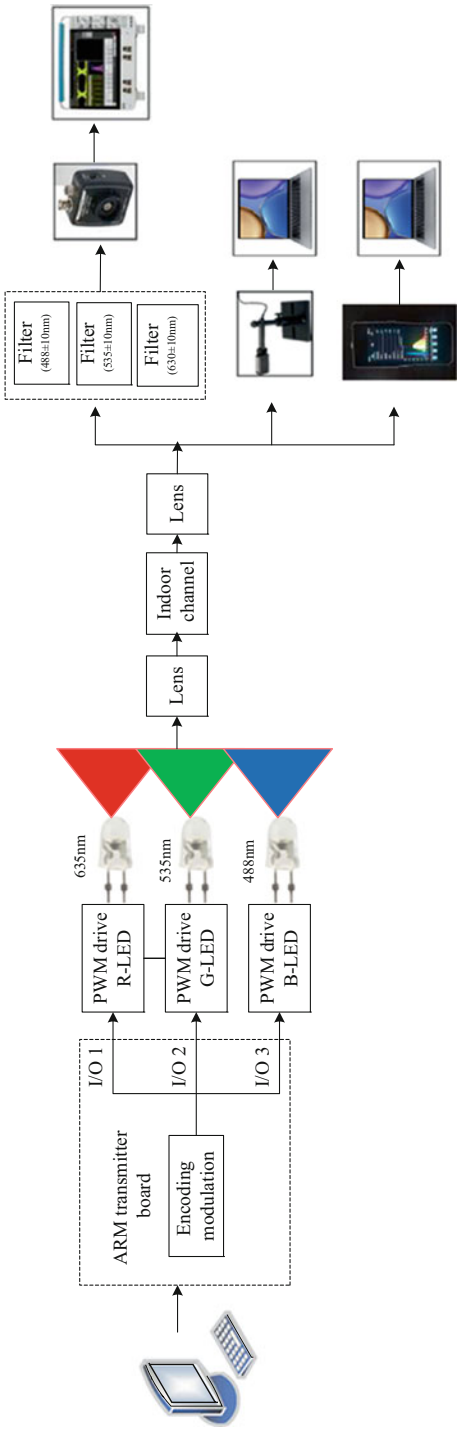

Fig. 42.18 RGB LED visible-light communication system

Analysis of Experimental Results

Because lighting and communication are integrated in this system, it is necessary to separately analyze the received light power and light intensity. The light source was vertically illuminated onto the receiving surface, and the color temperature of the light source was adjusted according to the mixing ratios obtained from the dimming experiment: 0.6: 0.28: 0.12, 0.5: 0.32: 0.19, 0.47: 0.33: 0.2, and 0.45: 0.34: 0.21. An OPHIR-PD300-UV optical power meter was used to detect changes in the light power at different distances, as shown in Fig. 42.19.

It can be observed from Fig. 42.19 that the optical power decreases with increasing distance. When the distance is less than 180 cm, the optical power rapidly decreases as the distance increases. When the distance exceeds 180 cm, the optical power decreases slowly as the distance increases. These five groups of curves generally conform to exponential-decay trends. The receiving-surface light power of the warm color temperature is relatively low, whereas the light power of the cold color temperature is higher. However, when the distance is greater than 320 cm, the light powers of the five color temperatures tend to be consistent.

Next, when the distance was 100 cm, the distribution of light power on the receiving surface under the five color temperatures was measured. The analysis shows that the distribution trend of light power on the receiving surface is consistent

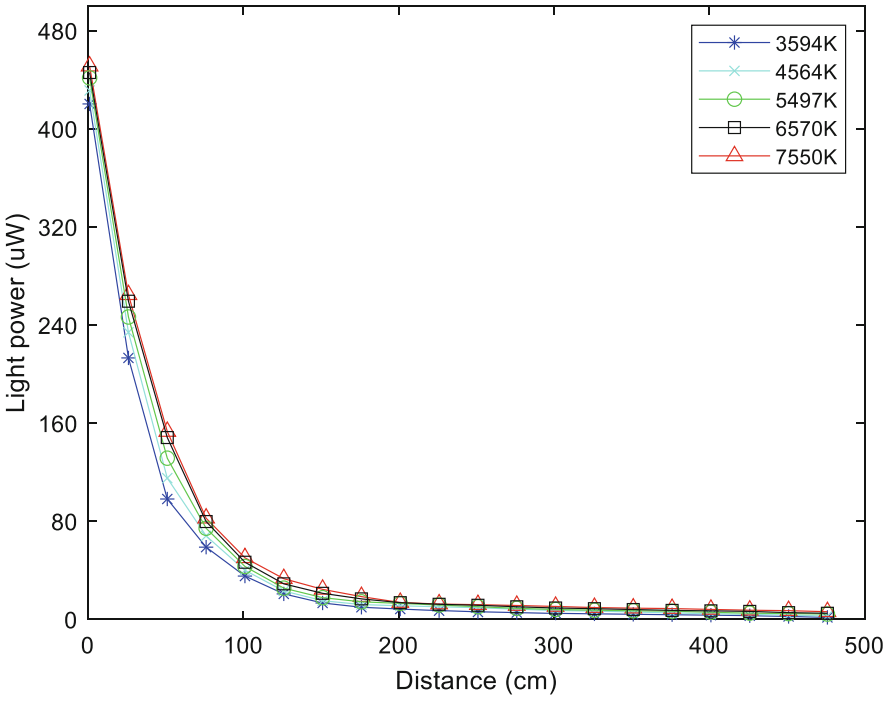

Fig. 42.19 Changes in optical power with distance

among the five color temperatures. Taking a color temperature of 6570 K as an example, as shown in Fig. 42.20, the value of the light power is the highest at the center position and decreases sequentially around the four positions.

The distance between the transmitter and receiver remained fixed, the modulation bandwidth was changed, and the error rate under different modulation bandwidths was calculated to obtain the maximum modulation bandwidth for reliable system transmissions. In the experiment, the communication distance was 250 cm, and the modulation bandwidths of the three channels were changed. The total modulation bandwidths at different color temperatures were recorded and synthesized, and the error rates were calculated.

Figure 42.21 shows the error-rate curve with the modulation bandwidth at five color temperatures: 3594 K, 4564 K, 5497 K, 6570 K, and 7550 K. As the modulation bandwidth increases, the bit-error rate also increases. When the error rate is below 10^{-3}, the maximum modulation bandwidth for the five color temperatures can reach 9.2 MHz, 10 MHz, 11 MHz, 11.5 MHz, and 11.7 MHz, respectively. The modulation bandwidth at high color temperatures is higher than that at low color temperatures. When the modulation bandwidth is 9 MHz, the error rate at all color temperatures is less than 3.8×10^{-3}, achieving reliable transmissions in visible-light communication systems.

When the modulation bandwidth is 8 MHz, the error rate curves of the five color temperatures of 3594 K, 4564 K, 5497 K, 6570 K, and 7550 K with distance are

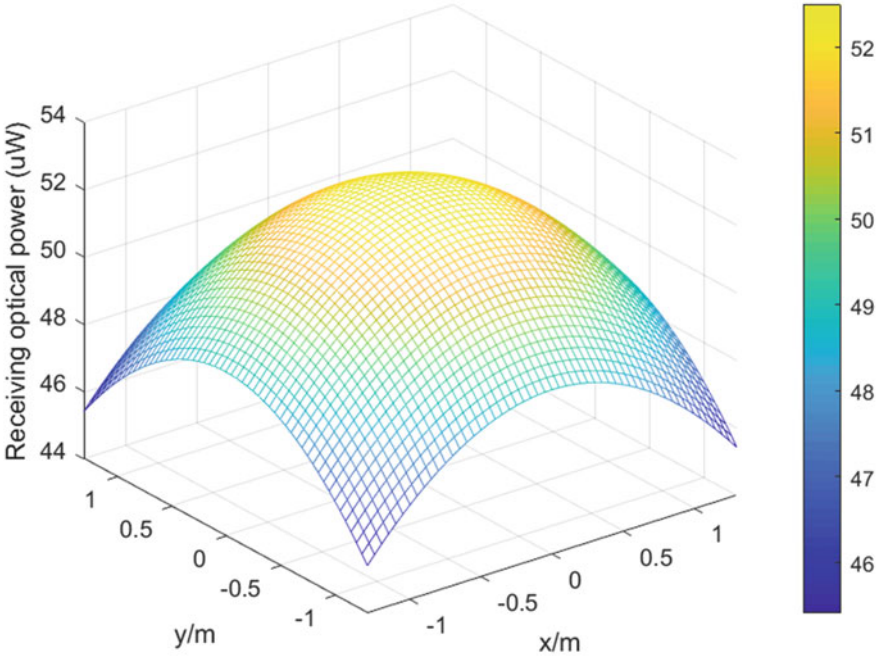

Fig. 42.20 Distribution of optical power on the receiving surface

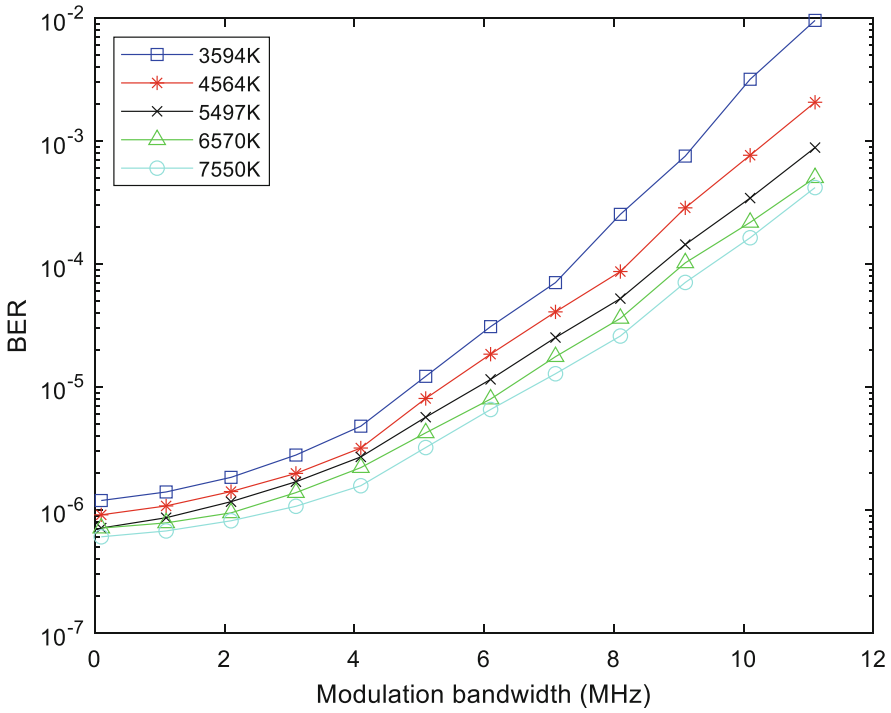

Fig. 42.21 Changes in bit-error rate with modulation bandwidth for different color temperatures

shown in Fig. 42.22. In the actual testing, as the distance increases, the error rate of the system also increases, and the speed of change increases. When the transmission distance is 350 cm, the error rate at each color temperature is lower than the limit error-rate value 3.8×10^{-3} for forward error correction. The bit-error rate of the cold white temperature is significantly lower than that of the warm white temperature.

It was concluded that as the color temperature increased, the communication performance of the system improved. However, when the color temperature exceeded 6500 K, the increase in the color temperature had a smaller impact on the communication system performance.

Conclusion

This study investigated the chromaticity control of light sources in visible-light communication systems. LED white-light sources with adjustable color temperatures were investigated through simulations and experiments. When the error rate of each color temperature was below 3.8×10^{-3}, the modulation bandwidth of the system reached 11.7 MHz, the farthest communication distance was 5 m, and the

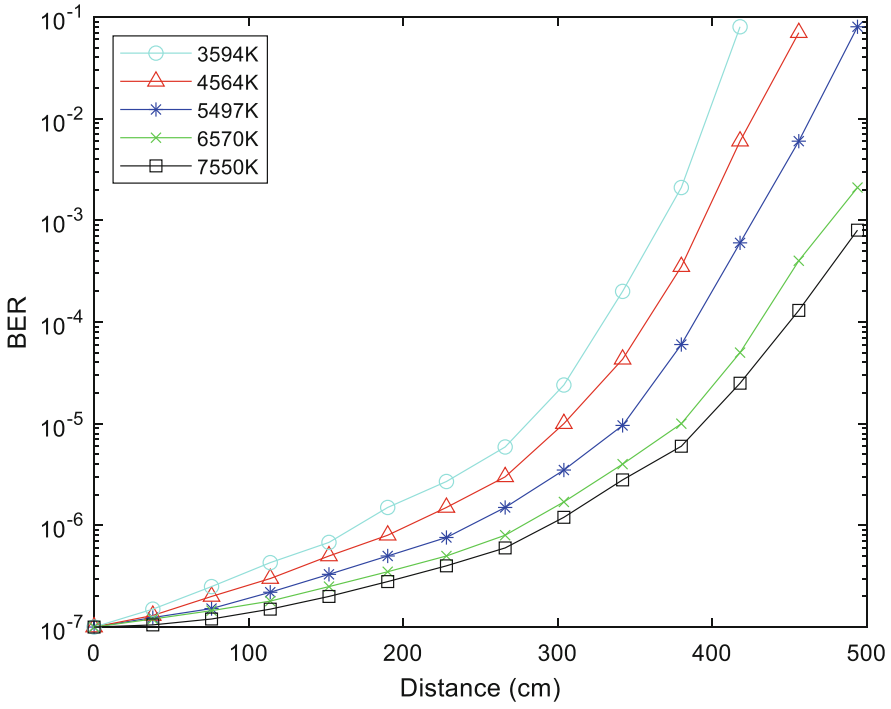

Fig. 42.22 Change of error rate with distance for different color temperatures

illumination intensity was above 400 lx. This enabled both the visible-light communication and lighting functions. The following conclusions were obtained:

1. Light sources with different color temperatures can be obtained by changing the ratio of red, green, and blue LEDs. The general color index of the light source with a color temperature between 5500 K and 6500 K was the best. The influence of the color temperature on the illumination intensity of the receiving surface at the same distance could be ignored. Distance had a significant impact on the illumination of the receiving surface. As the distance increased, the light intensity decreased rapidly.
2. The optical powers at different color temperatures and distances were measured. It was found that the color temperature had a small impact on the receiving power value, whereas the distance had a greater impact. As the distance increased, the optical power decreased exponentially.
3. Based on the communication experiments under different color temperatures, it was concluded that the communication performance of the system was better in the high-color-temperature range and significantly better than in the low-color-temperature range. As the distance increased, the communication error rates under different color temperatures continued to increase.

Abstract

Light communication channels sometimes have changing characteristics that are difficult to predict. This article proposes a structure based on a convolutional neural network (CNN) structure, with a balanced algorithm for a residual structure. The optical-channel balance-coefficient vector is a time sequence that reflects the channel noise characteristics and has memory characteristics. The balancer algorithm can accurately learn the complex channel characteristics and calculate the compensation coefficient, based on the channel characteristics, to restore the original transmission signal. In addition, this article discusses a method of compensating for the receiving terminal when in the mobile state.

Long short-term memory (LSTM) parameters are used to represent the sequence causal relationship in the memory channel, and the CNN and residual structure are used to refine the results to improve the reconstruction accuracy. The simulation results show that this algorithm can effectively eliminate the declining characteristics of the optical channel, improve the performance of the system-transmission error rate, solve the overall channel-damage problem, and accurately restore the original transmission signal at a faster convergence speed. In addition, compared with traditional competition-balance methods, this method achieves a better balance between performance and complexity, proving its potential and effectiveness.

Introduction

Humans are now entering the era of big data. The emergence of the concept of artificial intelligence and the popularity of mobile electronics have led to an increasingly crowded spectrum of resources in wireless communication networks. Visible-light communication (VLC) technology is fast, safe, and environmentally friendly, with no need for spectrum permits; it has become a research hotspot in the field of wireless communication.

Visible-light communication systems are susceptible to multidiameter effects, scattering noise, thermal noise from electronic devices [1], and other external factors. The intersymbol interference (ISI) phenomenon has increased, thereby increasing the system error rate. To reduce the system error rate, the balance of the light-communication channel-equilibrium technology directly corrects the communication-code elements, and eliminates direct and indirect problems between the codes.

The channel-balance algorithm is the core of the equilibrium and determines its calculation speed and performance. Traditional channel-balance algorithms include zero equilibrium, least mean square (LMS) equilibrium, recursive least squares (RLS) equilibrium, and minimum mean-square error (MMSE) equilibrium [2].

However, these traditional channel-balance algorithms have some deficiencies:

1. Relying on prior knowledge: Traditional equilibrium methods require prior knowledge, including channel-status information and noise-statistics information, which are difficult to accurately obtain in practical applications;
2. Strict assumptions about the signal model: The traditional equilibrium method usually makes strict assumptions about the signal and noise models. In actual applications, signals and noise often have unknown complex features, which may not fully meet these assumptions;
3. Sensitivity to noise conditions: Traditional equilibrium methods are more sensitive to noise conditions;
4. Require manual feature engineering: Traditional equilibrium methods usually require manual design-feature extractors to extract appropriate input features. This depends on the experience of field experts, and the feature selection and design may be difficult.

With the development of neural-network technology, a large number of intelligent equilibrium algorithms have been developed and applied to the VLC balance. Relevant research has achieved many results.

Deep learning automatically analyzes and learns data by simulating the neural network in the human brain. It can establish a more complex model through multiple levels of neural networks and identify and abstract information through a series of hierarchical learning and abstraction characteristics. Deep learning has achieved significant success in image semantic segmentation and characterization, natural language processing, and various computer science and engineering fields. In recent years, deep learning has been used for channel equilibrium and has achieved some important results.

In 2019, Lu et al. proposed a neural-network balancer based on long short-term memory (LSTM) to reduce the linear and nonlinear damage to the VLC system based on the pulse amplitude [3]. In 2021, Lin et al. proposed a nonorthodox multiple access VLC (NOMA-VLC) marker based on convolutional neural networks (CNNs) to compensate for and recover signals [4]. In a multiple-input multiple-output (MIMO) visible-optical communication system, Zhao et al. produced an adaptive artificial neural network (ANN), which was feasible and had low space complexity [5].

In 2022, Lu et al. proposed models to compensate for VLC systems based on Gaussian-based inputs and Bayesian time-domain learning [6]. Chen et al. proposed a new type of temporal–frequency attention-based convolutional neural network (TFCNN) and used it as a post-equalizer in an underwater VLC (UVLC) carrierless amplitude and phase (CAP) modulation system to compensate for the nonlinear distortion of the visible-light signal [7].

The steps abovementioned deep-learning system used to balance the channel include the following:

First, the data are pre-processed to standardize the input signal. Second, a network model is built and deep-learning technology is used to build a channel-balance

neural-network model. Third, the model is trained and evaluated with well-trained models. Fourth, the performance indicators of balanced channels are calculated, such as the misunderstanding rate for model training, to obtain pre-training models. Finally, the training model is deployed and applied to actual applications and the channel is balanced to improve system performance.

However, the CNN in the above method is a one-dimensional CNN that can be used to learn and capture the local spatial characteristics in the time-domain signal, such as frequency changes in the frequency domain or time changes in the time domain; however, changes in the information cannot be effectively tracked. A separate LSTM is suitable for modeling information, which can capture the dependency relationships between the different time steps.

However, it is difficult to effectively extract the local space characteristics of the light signal's time-domain signal. An effective method simultaneously combines the CNN-LSTM with convolution and cycling and uses the spatial locality and time-dependent relationships in the time-domain signals. Therefore, this study adds residual structures based on the CNN-LSTM and designs a type of neural-network equalizer for the receiving end. It is an active adaptive nonlinear time-domain neural network, to balance the receiving signal and suppress the intersymbol interference between the codes.

In response to the impact of the nonlinear and time-variable characteristics of indoor visible-light communication systems, an adaptive channel-equilibrium algorithm that integrates convolutional LSTM binding residual structures is proposed in this article.

Compared with the traditional channel-equilibrium method, the CNN-LSTM proposed in this study has the following advantages, in terms of the channel balance:

1. It has a data driver, which can process a large amount of data. The complex and nonlinear mapping relationship between them does not need to be prioritized; the characteristics are those of better capture signals.
2. It has better adaptability, and can better handle complex signals and noise conditions, as well as different signal models and data distributions.
3. The algorithm generally has strong universality and can be applied to different fields and tasks, including voice, image, and natural-language processing.

Compared with the ablation model, that is, the model with a separate CNN and LSTM, CNN-LSTM combines convolutional, residual, and circulating network structures and uses the local and time-dependent relationships between spaces in the time-domain signal. Among them, the CNN extracts the spatial characteristics in the time-domain signal through local perception, and the LSTM models the timing relationship through the memory unit and more comprehensively represents the information of the time-domain signal. Using the overall algorithm, the optical communication channel is more effective and balanced.

Research Progress

Status of Traditional Equilibrium-Technology Research

Equilibrium technology was used in the radio-communication field in the early stages to eliminate code interference caused by the unsatisfactory characteristics of the channel, such as the zero-forcing (ZF) [8], least mean square (LMS) [9], recursive least squares (RLS) [10], and blind equilibrium algorithms [11]. These equilibrium technologies are also applicable in visible-light communication.

Wolf et al. [12] analyzed the effect of the ZF equilibrium for a visible-optical communication system that used non-return-to-zero switch-keying control. In [13], Xie et al. discussed the multidiameter interference problem in the visible-light communication channel and studied the compensation effect of zero-forcing equilibrium, minimum equity error equilibrium, and judgment-feedback equilibrium. In [14], Komine et al. proposed an adaptive equilibrium system of LMS-based algorithms for differences in the light range between multiple light sources. The simulation results showed that the adaptive balance system reduced the impact of shadows.

In [15], Bandara et al. used the RLS equilibrium algorithm in a judgment-feedback balancer. This method reduced the length of the training sequence while maintaining the performance at the same bit-error rate (BER), thereby increasing the data-transmission rate. In [16], Chen et al. experimentally demonstrated the use of adaptive digital prebalancing technology in indoor VLC systems. The results showed that, using the proposed adaptive-balancing technology, the modulation bandwidth of the orthogonal frequency-division multiplexing (OFDM) signal could be optimized according to the estimated signal-to-noise ratio information to maximize the data rate of the VLC system.

In [17], Jin et al. applied a blind balancing scheme to the intersymbol interference of a visible-light communication system. Simulation results showed that the method effectively improved the data-transmission bandwidth and dynamically compensated for signal distortion. In [18], Cao et al. investigated the signal distortion caused by intersymbol interference in a visible optical communication system and proposed a blind balance scheme (the constant modulus algorithm (CMA)) based on the receiving signal power. An experiment was conducted to verify the effectiveness of this plan.

Balanced-Technology Research Status of Deep Learning

Machine-learning applications have demonstrated good robustness in many areas, including but not limited to medical treatment [19], finance [20], and industry [21]. Machine learning has been widely used in VLC systems and has achieved significant results. Examples include machine-learning-based light-emitting diode (LED) nonlinear compensation technology, machine-learning-based signal-detection

technology [22], machine-learning-based signal demodulation, visible-optical communication channel estimation with deep learning [23], machine-learning-based automotive visible-light communication-channel modeling [24], and machine-learning-based interior visible-light communication positioning systems [25].

Applying machine learning to VLC channel balancing has many advantages. The most significant advantage is that machine learning has strong adaptability and intelligence. It can automatically learn and adapt to the complex changes and interference of channels and improve the performance and stability of the visible-light communication system. In addition, the machine-learning balance can be trained using a large amount of data to improve the accuracy and robustness and achieve better results in practical applications.

In [26], Xiao et al. proposed a method for changing the long neural-network blind equilibrium to compensate for channel distortion caused by intersymbol interference in water acoustic communication. Simulation analysis showed that the proposed method had a good balancing effect. In [27], for the first time, Hairy et al. realized an artificial neural network (ANN) equalizer based on a visible-optical communication system considering the code performance. The results showed that the ANN equalizer had the best effect on indoor VLC systems. Furtes et al. [28] proposed a post-equilibrium method based on an underwater visible-light communication system and compared it with the Volterra-based equilibrium method. It had a better balancing effect.

Zhang et al. [29] proposed a non-data-based K-nearest neighbor (KNN) equilibrium technique to reduce the system damage to high-end modulation signals. Experiments in quadrature amplitude modulation (QAM) and 64-QAM coherent optical transmission systems showed that this method had low complexity and used zero-redundant optical-fiber nonlinear equilibrium technology that effectively improved the system performance.

In [30], Wang et al. proposed a nonlinear phase-noise discrimination method based on support vector machines (SVMs), and introduced nuclear functions to create nonlinear decision-making boundaries. Compared to the maximum-likelihood estimation algorithm, the SVM had a lower code rate at the same transmitting power, and the method complexity was lower.

In [31], Ma et al. proposed a balanced scheme based on the K-means algorithm for the nonlinear distortion caused by the components in the visible-light communication system, and an experiment was performed using the VLC system. The results showed that this method effectively compensated for the nonlinear effects, and the error-rate was significantly improved.

Lu et al. [32] introduced a pre-disturbance solution based on the K-means algorithm to reduce the nonlinear distortion in a visible-light communication system. The experimental results showed that this method reduced the system error rate by at least 50%. In their study [33], Yu et al. proposed a signal decision-making method for the density-based spatial clustering of applications with noise (DBSCAN). This was the first time that DBSCAN had been successfully applied to a four-level pulse-amplitude modulation (PAM-4) VLC system. Through experiments, the Q-factor was increased by 3.9 dB in the PAM-4 VLC system.

In [34], Miao et al. proposed a nonlinear post-balancing scheme based on deep learning (DL) to deal with severe channel damage in a DC-biased optical (DCO)-OFDM system. The simulation results showed that the nonlinear distortion of the system could be effectively compensated, and the distorted symbols could be effectively recovered. In their study [35], Liu et al. proposed to integrate feedback neural-network and recursive neural-network (RNN) deep-learning frameworks to solve the problems of nonlinear distortions and linear symbols. Simulations showed that the DL-based detector effectively enhanced the signal detection when nonlinear and linear distortions existed.

In [36], Li et al. investigated a balance method using deep neural networks (DNNs) and LMS linear equilibrium and proved its effectiveness through experiments in a 64QAM VLC system. The results showed that a 2.4 Gbit/s data-transmission rate was successfully implemented in the 1.1-m indoor VLC system, and the mixed balancer exhibited better BER performance.

Costa et al. [37] proposed a convolutional neural network (CNN) equilibrium technology suitable for visible-optical communication OFDM systems. By evaluating the amplitude of the system's average error, code rate, and error vector, this method showed a better-balanced effect than the traditional minimum secondary method. In [38], Játiva et al. proposed a channel-equilibrium solution for VLC-based underground mining systems. The BER performance of this method was better than that of the zero-forcing balance algorithm.

The aforementioned domestic and foreign studies indicate that many equilibrium algorithms currently exist. Traditional balance methods include zero-forcing equilibrium, adaptive balancing, and blind equilibrium based on LMS and RLS. Although these methods can compensate for the signals, they have some shortcomings.

For example, zero-forcing equilibrium first requires the statistical characteristics of the signal, which are often difficult to acquire in practical applications. The convergence speed of the adaptive-equilibrium algorithm is slower, and it takes longer to reach the optimal state. Additionally, the blind balancing method must satisfy certain signal characteristics; otherwise, it may lead to a decline in performance.

With its rapid development, scholars worldwide have begun to study balanced technologies based on machine learning. Compared to traditional equilibrium methods, machine-learning balancing methods have more advantages. They can automatically learn and adapt to complex changes and signal interferences, thereby improving the signal-compensation effect in practical applications.

In addition, machine-learning balance methods can improve their accuracy and robustness through training data to achieve better results in practical applications. Therefore, machine-learning methods are commonly used for extensive research on channel equilibrium.

In summary, optical communication technology is emerging in today's communication field; however, the distortion caused by indoor visible-optical communication systems in China is a challenge. Balancing technology is important for

compensating VLC channels, and is the focus of current research and the research work in this article.

With its rapid development, deep learning has been widely used in various fields, including visible-light communication, and achieved good results. Moreover, applying deep-learning algorithms to VLC equilibrium also shows good robustness. Therefore, using deep-learning methods for balancing VLC systems has important research significance.

Channel Balancing in Visible-Light Communication Systems

Time-Domain Balance-Filtering Principle

In a VLC system, the sending LED driver circuit will prepare the LED to send the information, and it is launched in the form of a light signal. This modulation method can modify on–off keying (OOK) in light communication; that is, the light signal being on or off indicates binary information. "1" and "0" have a variety of modulation and encoding methods, which mostly use parallel communication [39].

The modulated visible-light signal reaches the receiving end after a space transmission. The photoelectric detector and signal-processing circuit of the receiving end perform photoelectric transformation, amplification, sampling, demodulation, and framework processing on the signal, and the original information sequence is finally restored [39].

The total impact response of the system is

$$h_i(t) = p(t) \otimes h(t) \otimes r(t) + n(t), \tag{43.1}$$

where $h_i(t)$ is the general channel impact response, $p(t)$ and $r(t)$ are nonlinear noises, such as the thermal noise of the sender and the receiving end of the electronic device, respectively, $h(t)$ is the noise of the multidiameter channel response, and $n(t)$ is the visible-light communication background noise.

The submissive response of the visible-light channel can be modeled as a random variable for multidiameter superpositioning. Figure 43.1 shows the normalized channel impulse response at different times, where *a*, *b*, *c*, and *d,* respectively, represent the channel characteristics at times T_0, T_1, T_2, and T_3. The corresponding parameter *d* is the straight-line distance from the light source to the acceptable end, *h* is the wall-reflection coefficient, *m* is the Langbo model: 1[$x = 1, y = 1, z = 3$], 2 [$x = 1, y = 4, z = 3$], and 3[$x = 4, y = 1, z = 3$].

Owing to the movement of the receiver, the multidiameter structure in the four subdiagrams changes; however, it can be seen from the figure that the overall

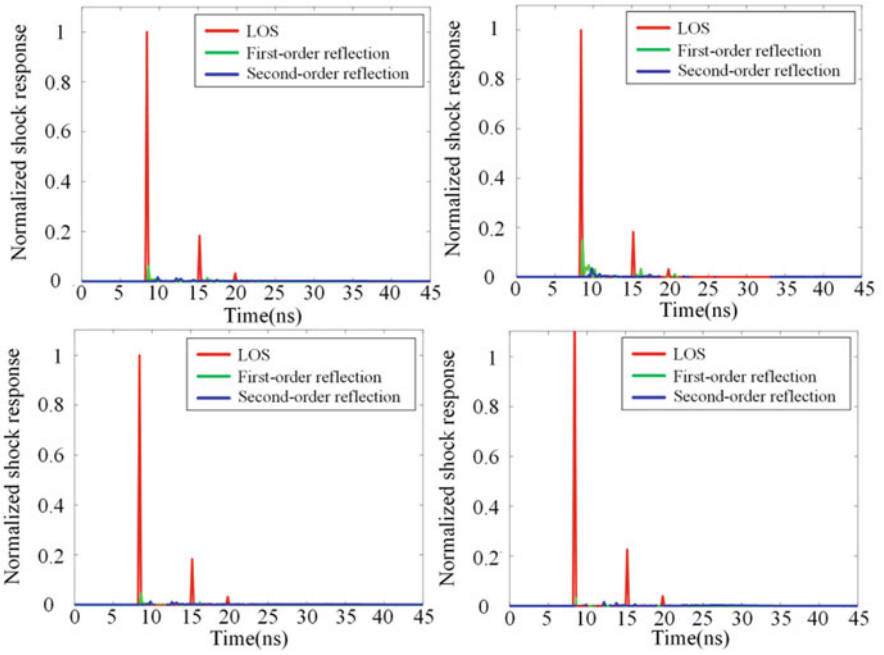

Fig. 43.1 Channel shock-response changes

structure of the visible-optical channel in different positions is relatively stable. This is because the scene established in this article is a closed indoor scene. The multidiameter component power is mainly derived from the wall reflection. Therefore, the channel is a quasi-static channel with low time-variant characteristics.

The general channel impact response of the system is distorted by various noises in the code. The principle of time-domain equilibrium is to use an adjustable-coefficient filter to adjust the impact response to satisfy the Nyquist theorem:

$$h_T(t) = \sum_{n=-\infty}^{+\infty} w_n \delta(t - nT_s), \tag{43.2}$$

where w_n is the balancing coefficient and T_s is the sampling interval. Therefore, the change in $h_i(t)$ adjusts the balancing coefficient. The tap coefficient can be determined using a filter and applied to the input signal. The filter structure is shown in Fig. 43.2.

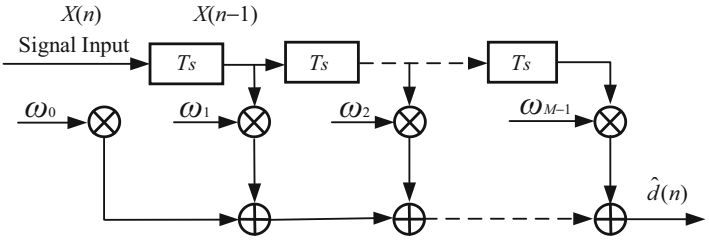

Fig. 43.2 Nonlinear horizontal time-domain filter

The input data of time n is

$$x(n) = [x(n), x(n-1), \cdots, x(n-M+1)]^T. \tag{43.3}$$

The balancer coefficient is

$$w(n) = [w_0(n), w_1(n), \cdots, w_{M-1}(n)]^T. \tag{43.4}$$

The output signal of the balancer can be represented as

$$r(n) = \sum_{n=-\infty}^{+\infty} w_i(n)x(n-i) = w^T(n)x(n). \tag{43.5}$$

The selection of the balancer coefficient directly affects the output result, which determines whether the signal can be judged correctly. In particular, if the equilibrium coefficient can adaptively change according to the channel characteristics, the balancer can dynamically correct the distorted waveform within the correction system.

Communication-System Analysis and Simulation

In a visible-light communication system, the channel capacity of the direct-current biased optical-OFDM (DCO-OFDM) transmission method is more capable than asymmetrically clipped optical OFDM (ACO-OFDM), has a doubled channel capacity, and very good application prospects. In addition, the data-transmission method of the equalizer experimental system, combined with 16QAM modulation, is used in this study. The basic principle of the DCO-OFDM system is shown in Fig. 43.3.

After the input source signal is modulated by 16QAM, a constellation mapping operation is performed. The mapping output of the DCO-OFDM system is

$$X(n) = [0, x(1), \cdots, x(N/2-1), 0, x^*(N/2-1), \cdots, x^*(1)]^T \tag{43.6}$$

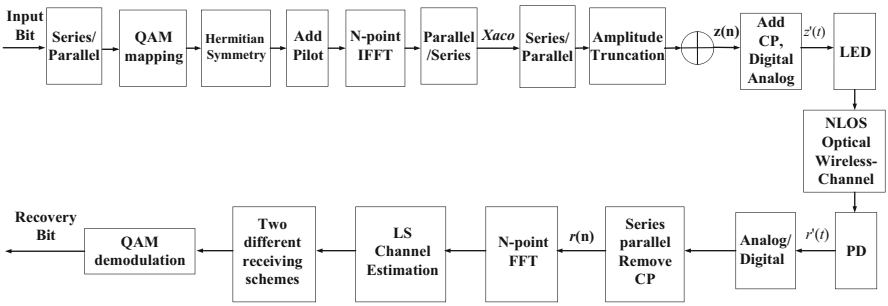

Fig. 43.3 DCO-OFDM signal-transmission principle

where N is the length of the fast Fourier transformation, * is the comortar operation, and the mapping signal meets Emi's symmetry. The next step is to use a Fourier transform on the frequency-domain mapping signal:

$$\begin{aligned} x_{\mathrm{IFFT}}(k) &= F^H X \\ &= \frac{1}{\sqrt{N}} X(0) + \frac{1}{\sqrt{N}} \sum_{n=0}^{N/2-1} X(n) \exp\left(\frac{j2\pi nk}{N}\right) + \\ &\frac{1}{\sqrt{N}} X\left(\frac{N}{2}\right) \exp(j\pi k) + \frac{1}{\sqrt{N}} \sum_{n=0}^{N/2-1} X^*(m) \exp\left(-\frac{j2\pi mk}{N}\right) \end{aligned} \tag{43.7}$$

where H represents the matrix conjugate transpose, and F is the $N \times N$ normalized discrete Fourier-transform matrix. In an intensity-modulation/direct-detection (IM/DD) system, the signal driving the LED must be a real non-negative signal; hence, the signal needs to be limited. The limited signal is converted into a parallel series and a cyclic prefix is added. After the protection interval is inserted, the digital-to-analog conversion drives the LED to emit an optical signal.

The optical signal is transmitted through the VLC indoor channel and is converted into an electrical signal by a photodetector at the receiving end. The electrical signal can be expressed as follows:

$$y(t) = h_i(t) \otimes x(t) + n(t), \tag{43.8}$$

where $h_i(t)$ is the channel impulse response proposed in section "Time-Domain Balance-Filtering Principle," $x(t)$ is the transmitted data signal, and $n(t)$ is background white-light noise. The indoor channel-noise model follows a Gaussian distribution with mean of 0.1 and variance of 1 [40]. The distribution of the Coriolis model is consistent with the background of visible-light communication in outdoor and vehicle networking.

The channel is composed of the direct and sequentially reflected channels, and its noise characteristics follow a Gaussian distribution. Because of the change in the

receiver position, the transmission distance of the channel will change. The distances of the direct channel are 2 and 2.5 m, and the distances of the reflected channel are 5 and 4.5 m, respectively. The mean values of the Gaussian distribution are 0.1 and 0.15, respectively. The variance is 0.2, 0.22.

The input signal is 182, a fast Fourier transform module and the output signal is a frequency domain.

$$Y = HX + HN_{\mathrm{DCO}}, \tag{43.9}$$

where $H = F\widetilde{h}(t)F^{H}$ is the frequency-domain expression of the channel impulse response; it is an $N \times N$ diagonal matrix. N is the Fourier transform of the additive white Gaussian noise (AWGN) vector. The 1–N/2–1 parts of the signal are extracted as the subcarrier modulation signal, and the extraction vector is

$$Y_{\mathrm{ex}} = [Y(1), Y(2), \cdots, Y(N/2-1)]^{T}. \tag{43.10}$$

The signal input to the filter is

$$Y_{\mathrm{sd_DCO}} = H_{\mathrm{sd_DCO}} X_{\mathrm{ex_DCO}} + \sigma_{\mathrm{AWNG}} H_{\mathrm{sd_DCO}} N_{\mathrm{ex_AWNG}}, \tag{43.11}$$

where $H_{\mathrm{sd_DCO}}$ is the (N/2–1) × (N/2–1) equivalent frequency-domain transfer matrix and $X_{\mathrm{ex_DCO}}$ is for X to obtain masks of $m = 1, 2, 3\ldots, N/2–1$ dimensions consisting of row elements. $N_{\mathrm{ex_AWGN}}$ is Gaussian noise with a mean of 0.1 and a variance of 1.

In the offline training phase, we used the DCO-OFDM signal-transmission mode. The model was trained in the IM/DD channel, including LED nonlinearity, optical propagation, and channel noise. First, random data were generated as transmitted symbols. After the symbols were modulated, mapped, and transmitted through the VLC channel, the received electrical signals were collected at different partial-discharge positions and divided into several short overlapping samples. Each short sequence and sample of the original transmitted signal were combined into the training data. In practical applications, it is necessary to collect a variety of training sets to improve the parameter-learning ability of the CNN-LSTM.

Performance Analysis of a VLC System in a Multipath Channel

An indoor visible-light communication system was simulated and modeled. The length, width, and height of each room were recorded as lR, bR, and hR, respectively. An LED lamp was installed at the center of the ceiling. The distance from the ceiling was marked as HLED, and its direction pointed vertically to the ground. The photodetector (PD) was located on the work plane, which was HPD from the ground, and its direction was vertically upward. The wall was divided into a grid of equal horizontal and vertical 0.1-m distances, and each cell was used as a reflection unit. The simulation parameters are listed in Table 43.1.

Table 43.1 Channel-simulation parameters

Parameter	Symbol	Numerical value
Room size	$l_R \times b_R \times h_R$/m	$6 \times 6 \times 4$
LED distance from the ceiling	H_{LED}/m	0.5
PD distance from the ground	H_{PD}/m	0.85
Monte Carlo simulation times	N_{MC}	10,000
Subcarrier number	N_{SC}	256
Cyclic prefix	N_{CP}	16
Modulation bandwidth of LED lamp	B_L/MHz	50
Photoelectric conversion coefficient	γ /(A/W)	1
PD area	A_R/cm^2	1
Area of the microreflection unit	ΔA/m^2	0.01
Wall reflectivity	ρ_i	0.8
PD field-of-view angle	Ψ_{FOV}/°	80
LED half-power angle	$\theta_{1/2}$/°	60

When the modulation bandwidth of the light source is 50 MHz, the symbolic period of the modulated signal is 10 ns. Relative to τ0, an optical signal with a delay greater than Tsp = 5 ns leads to ISI. The optical power of the receiver, line of sight (LOS), specular reflection, and other primary reflection signals exceeded 90%. Therefore, only the LOS, specular reflection, and primary reflection were considered in this experiment. In addition, considering the symmetry of the multipath effect in the room, the multipath effect of the PD on one quarter of the room was considered.

CNN-LSTM Neural Network Equalization Algorithm

Overall Structure

The convolutional neural-network–time-series memory-structure equalization algorithm can simultaneously compensate and equalize code errors caused by intersymbol interference and nonlinear noise. The basic algorithm structure is shown in Fig. 43.4. The CNN neural-network structure has a strong data-feature extraction ability; hence, it can effectively extract channel features and calculate and generate the tap coefficient $w(n)$. The process of generating the tap coefficient is also the process of classifying the 0 and 1 characters [41].

First, the channel-transmission symbols are sampled to obtain the original sequence $[X(n-(l+1))]$. As the block pilot is added during the sampling process, the sampling sequence is divided into a series of subsequences of length $2l+1$, and a two-dimensional sequence matrix is formed by the subsequences. The matrix is sent to the convolutional neural network to learn the channel characteristics and estimate the equalization coefficients [41]:

$$Z_i = w \cdot X + b, \tag{43.12}$$

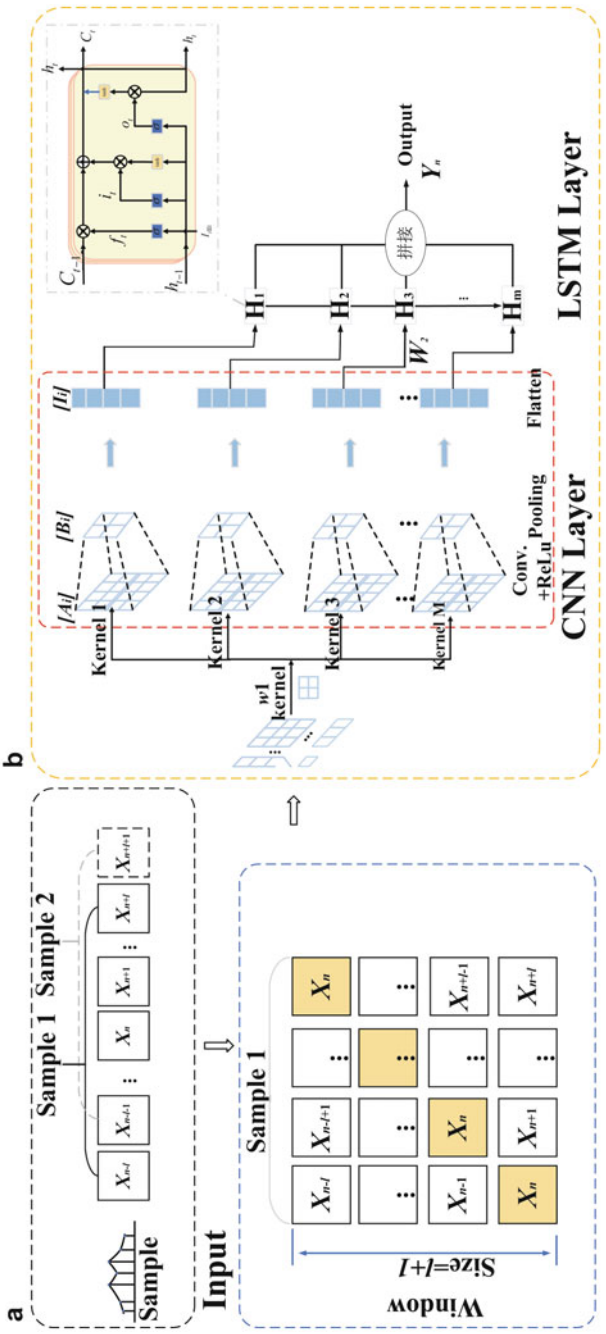

Fig. 43.4 CNN-LSTM channel equalization principle. (**a**) Pilot sampling process. (**b**) CNN-LSTM structure

where matrix X is the parameter-training matrix and b is the parameter offset vector. In addition, each neural-network layer determines the final predicted value according to the cost function. The selected cost function is the cross-entropy function:

$$L_i(w_h, w_r) = -\sum_{i}^{m} \left[w_r^i * \log\left(w_h^i\right) + \left(1 - w_r^i\right) * \log\left(1 - w_h^i\right) \right], \tag{43.13}$$

where L represents the training layer, w_h represents the predicted value, w_r represents the real sample value, and the sample w and bias b are random numbers at the initialization. Using the random gradient-descent algorithm, w and b were obtained using the minimum cost function.

In the random gradient-descent backpropagation process, the derivative of the loss function is gradually moved forward by the output layer [41]:

$$\frac{\partial L}{\partial w_h} = \left(-\frac{w_r}{w_h} + \frac{1 - w_r}{1 - w_h} \right) \cdot \frac{\partial w_h}{\partial Z^L}. \tag{43.14}$$

The existing predicted values were modified and updated according to the backpropagation and derivation results. The result of the output sequence entered the pooling layer, which sampled the result again, after reducing the sampling frequency and obtained the sampling result $[Z'_i]$. The flattening layer turns the two-dimensional matrix-sequence data into a one-dimensional vector $w_i(n)$, and each vector is input into the corresponding LSTM unit structure.

$$w_i(n) = [w_i(1), w_i(2), \cdots, w_i(n)]^T \tag{43.15}$$

The LSTM introduces a "gate mechanism" to extract the long-term memory time-series information. By controlling the input, forgetting, and output gates, the LSTM can add or remove present or past time-state information to or from the storage unit. The LSTM structure is composed of a forgetting gate, input gate, and output gate. The forgetting and input gates control the working state of the memory. The corresponding expressions are [42]

$$f_t = \sigma\left(W_f[x_t, h_{t-1}] + b_f\right) \tag{43.16}$$

$$i_t = \sigma(W_i[x_t, h_{t-1}] + b_i) \tag{43.17}$$

$$C_t = f_t C_{t-1} + i_t \tanh(W_c[x_t, h_{t-1}] + b_c), \tag{43.18}$$

where σ is an S-shaped function; W_f, W_i, and W_c represent the input weights corresponding to different doors; h_{t-1} represents the output of the previous state; and x_t represents the input of the current state. b_f, b_i, and b_c correspond to the bias matrices. The final output of the LSTM structure is

$$h_t = \tanh(C_t)(W_o[x_t, h_{t-1}] + b_o). \tag{43.19}$$

The output of the entire LSTM structure was finally activated using the rectified linear-unit (ReLU) function. After the backpropagation algorithm completed the training and optimization of the dataset, the equalizer obtained the equalization coefficient for the output-symbol equalization from the LSTM structure. It does not need to be constantly trained through the neural network, which greatly reduces the running time of the program.

When the equalization coefficient changes, owing to a change in the channel characteristics, the cost function of the LSTM structure activates the forgetting gate and neural network to re-learn the channel characteristics. The equalizer can independently adjust the equalization coefficient, according to the changes in the channel, for adaptive equalization. Based on the overall algorithm, a residual module was added to more effectively equalize the visible-light communication channel.

Robustness Analysis of the Algorithm

Visible-light communication channels vary over time. Based on the nonlinear composite channel-equalization principle of CNN-LSTM, an intelligent residual channel-equalization algorithm was proposed that could adaptively equalize the channel. However, when sampling the channel transmission symbols to obtain the original sequence $[X(n–(l+1))]$, there is often noise, and then there is a point in time when the actual input data of n is:

$$\begin{aligned} x(n) = {} & [x(n), x(n-1), \cdots, x(n-M+1)]^T \\ & + [\varepsilon(n), \varepsilon(n-1), \cdots, \varepsilon(n-M+1)]^T. \end{aligned} \tag{43.20}$$

The equalizer coefficient is

$$w(n) = [w_0(n), w_1(n), \cdots, w_{M-1}(n)]^T. \tag{43.21}$$

The output signal of the equalizer can be expressed as

$$r(n) = \sum_{n=-\infty}^{+\infty} w_i(n)(x(n-i) + \varepsilon(n-i)) = w^T(n)x(n). \tag{43.22}$$

From the above formulas, it can be observed that the selection of the equalizer coefficients affects whether the signal can be judged correctly. The original sequence sample will introduce all types of noise. The CNN has a self-learning ability to adapt to the generated noise; it balances the channel noise of different interferences in the data-feature extraction, and finally outputs a set of equalizer coefficients.

The LSTM structure further processes this group of equalizer coefficients to obtain ones that match the current channel, which improves the bit-error rate of the system transmission. In addition, a residual module is added so that the LSTM structure can better activate the CNN network structure to re-learn the group of equalizer coefficients, according to whether the input of the current equalization

coefficient matches the channel, and iterate the input to obtain the adaptive equalizer coefficients.

This design has good algorithm robustness. The normal channel-noise CNN self-learning structure can output a set of effective equalizer coefficients and the LSTM can directly handle the output. When there is abnormal noise interference, the LSTM structure will trigger the CNN self-learning structure to train again.

Simulation Analysis of the CNN-LSTM Model Performance

Structural Parameters of the CNN-LSTM Algorithm

In view of the characteristics of the time-domain signal of visible-light communication and the problems of the model, this paper proposes a deep-learning channel-equalization prediction model based on a convolutional long short-term memory network for feature fusion; it is called the CNN-LSTM equalizer for VLC channel equalization.

The channel-equalization calculation process of the CNN-LSTM equalizer is as follows: The input samples are extracted from the spatial domain by the CNN module, the resulting features are input into the LSTM for time-series feature screening, and finally, the regression layer is used for regression.

At present, there is no recognized optimal deep-learning model structure for channel equalization in visible-light communication, and different structures have a great impact on the results; therefore, choosing a good structure strongly affects the channel-equalization performance.

The LeNet-5 two-dimensional convolution neural network has been used in some fields, including image processing, and achieved good results. Therefore, this study designed the convolution layer of the CNN based on the LeNet-5 structure. It replaced the fully connected layer in the CNN with the LSTM layer, and introduced batch normalization, a pooling layer, and a discarding layer from reference [43]. The model structure is shown in Fig. 43.5.

The CNN-LSTM-equalizer model uses the signal after passing through the channel and optical medium, and outputs the received signal obtained after equalization before making a decision.

CNN-LSTM Model Parameter Settings

In this section, the performance of the proposed scheme is evaluated, based on simulation results. Modulated DCO-OFDM symbols containing 512 subcarriers with 16 quadrature amplitude modulation (16QAM) are randomly generated at the transmitter, and the normalized DC is set to 0.5. The sampling symbol is divided into a two-dimensional matrix using a block pilot, completing the data preprocessing.

The CNN-LSTM-equalizer structure consists of four CNN-LSTM-series structures. One pooling layer, one convolution layer, and one flattening layer are used in the CNN structure.

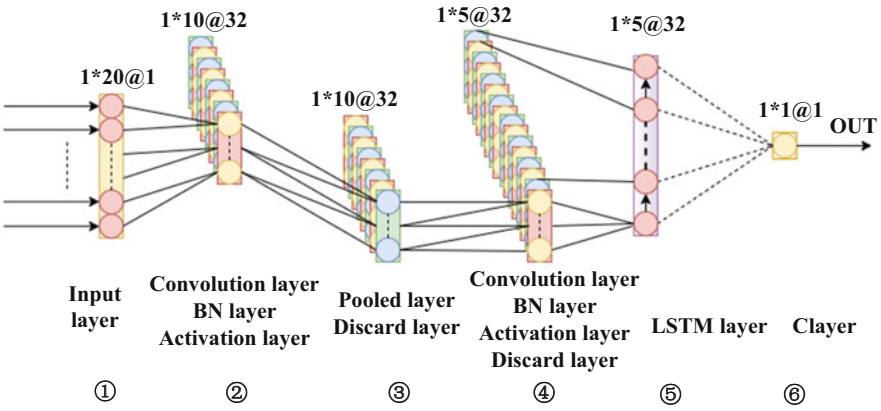

Fig. 43.5 CNN-LSTM structure diagram

Table 43.2 Equalizer simulation parameters

Parameter	Value
Modulation method	DCO-OFDM/QAM
Channel capacity	512 × 16
DC	0.5
Number of neurons in the pooling layer	32
Number of neurons in the convolutional layer	32

The numbers of neurons corresponding to the pooling layer and convolution layer are set to 32. The equalizer simulation parameters are listed in Table 43.2.

To compare all the models as closely as possible, they are run in an environment with the same training-process configuration, referring to the parameters commonly used in deep-learning model training [44]. The Kaiming method is used to initialize the weight coefficients of the CNN and full-connection layers [45]. The orthogonal method is used to initialize the weight coefficients of the LSTM layer [46], which is helpful for accelerating the model convergence.

In the network training process, the Adam optimizer makes the model converge faster and more robustly [47] and reduces the test of the verification set. The processed dataset was randomly scrambled and divided into a training set, verification set, and test set at 10:1:2, as shown in Table 43.3.

Simulation Analysis of the Structural Effectiveness of the CNN-LSTM Algorithm

Using the equalizer parameters listed in Table 43.1, the performance of the algorithm-only equalizer proposed in this study was simulated when the channel distance was 3.5 m, the normalized LED power was 1, and the power distribution

Table 43.3 LSTM, CNN, and CNN-LSTM model training-parameter configurations

CNN-layer initialization method	LSTM-layer initialization method	Full-connection-layer initialization method
Kaiming	Orthogonal	Kaiming
Optimizer method	Learning rate	Loss function
Adam	1e-3	Mean-squared error (MSE)
Number of training sets	Number of validation/test sets	Training wheels
1e4	1e3/1e3	100
Discard rate	Lot size	Activation function
0.4	32	ReLU

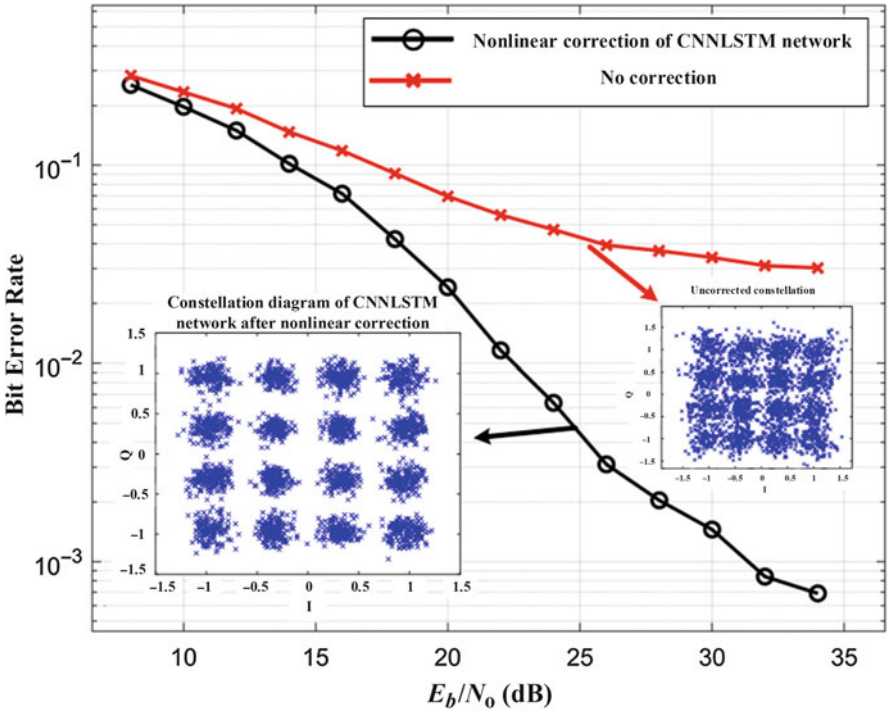

Fig. 43.6 Performance comparison of the CNN-LSTM network with and without correction

was 0.5. The simulation results are shown in Fig. 43.6. The BER change under a certain signal-to-noise ratio indicates the equalization performance [48].

In addition, this paper describes the output of the proposed scheme and ideal equalization for comparison, which reflects the channel characteristics, and compares the effect after equalization by the actual reception amplitude, ideal reception amplitude, and reception amplitude after equalization. The original Rx sequence and the sequence after equalization are shown in Fig. 43.7.

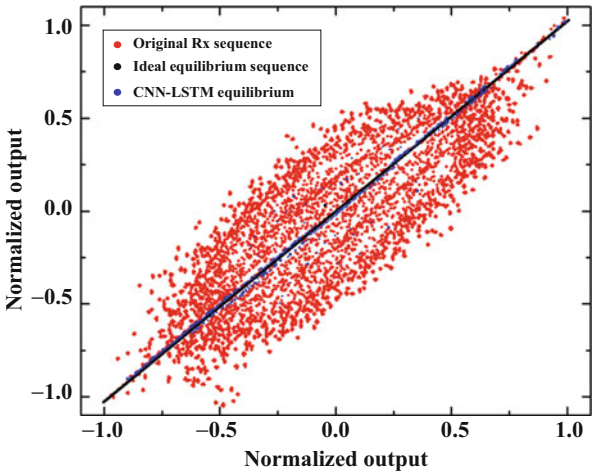

Fig. 43.7 Comparison of the normalization degree between the input and output signals

After mapping the amplitudes of x(n) and y(n), the signal-mapping amplitudes are shown in Fig. 43.7. Ideally, the receiver can fully measure the signal channel characteristics. We can observe that the originally received amplitude n deviates from a linear straight line and exhibits strong distortion. However, the proposed scheme differs slightly from the ideal case and shows excellent linearity for the same channel input. This indicates that the proposed CNN-LSTM can quasi-match the original input, thereby mitigating the general nonlinearity of the LED and optical radio channels.

Figure 43.8 shows the eye diagram of the VLC system with a 20 Mbit/s, 16QAM input signal with and without equalization. It can be seen that the eye diagram is almost closed before equalization, and the jitter and noise are relatively high, indicating that the BER is relatively high at this time. After equalization, the open eyes can be clearly observed, which indicates that the signal after equalization receives less interference from other sources, and the signal quality is higher.

Mobile Receiver-Compensation Method Based on the CNN-LSTM Algorithm Structure

In a visible-light indoor communication system, it is common for the receiver PD to receive a signal in the mobile state. Therefore, this study fully considers this scenario and aims to improve the understanding of the actual communication environment through an in-depth study to enable better design and optimization of the communication system.

By analyzing and exploring this scenario, we can encounter many types of the complex situations found in an actual communication environment, such as channel noise and multipath effects, to understand them more comprehensively. We then propose effective solutions to these problems to improve communication-system

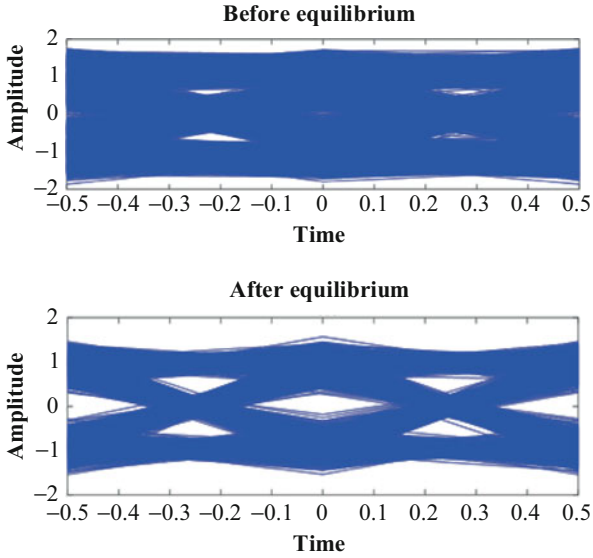

Fig. 43.8 Unequalized and equalized eye diagrams for VLC systems

performance and stability. On this basis, this study considers two typical mobile methods for indoor VLC.

Figure 43.9a shows the first movement path; the receiver PD moves from one wall corner to another wall corner in a straight line, that is, from the (0, 0, 0.65) position to the (6, 6, 0.65) position. In Fig. 43.9b, for the second movement path, the receiver PD moves along the right-angle path, that is, from the (1, 1, 0.65) position to the (5, 1, 0.65) position, and then to the (5, 5, 0.65) position.

When the receiver is moved indoors, the channel characteristics change over time, which has a significant impact on the system performance. In this method, the transmitted signal is a type of time-series data. To solve this problem, this study proposes a VLC-channel compensation method based on deep learning. The CNN-LSTM deep-learning algorithm was used in combination with the residual structure to predict the channel to compensate for the signal at the receiver and improve the performance and stability of the system.

The DCO-OFDM system was verified on a simulation platform, and the BER performance of this method under different SNRs in mobile scenes with 16QAM modulation was simulated and analyzed. Fig. 43.10a shows the trajectory of the receiver PD in space; i.e., the trajectory of the PD extending along a straight line from the starting coordinates (0, 0, 0.65) to the key coordinates (6, 6, 0.65).

Figure 43.10b shows the BER performance at a signal-to-noise ratio of $E_b/N_o =$ 10 dB. The abscissa represents the moving distance of the PD from the starting point, and the ordinate represents the bit-error rate of the system. It can be seen from the figure that the equalization method proposed in this article can effectively alleviate the distortion caused by the channel during movement. Figure 43.10c, d show the

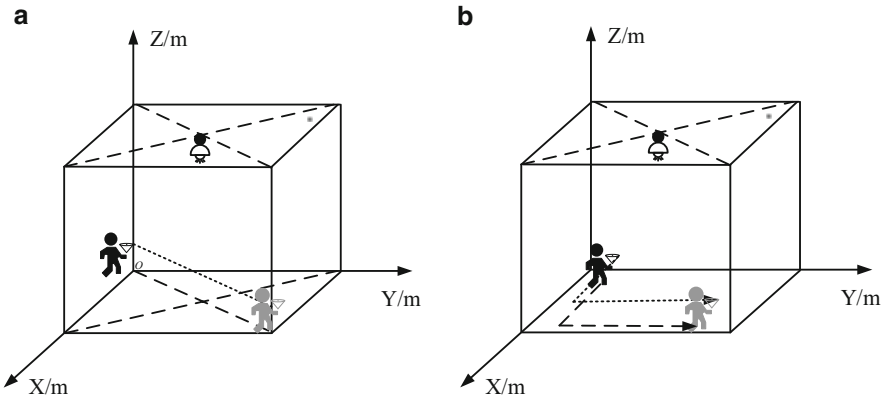

Fig. 43.9 Different movement paths in the VLC system. (**a**) Mobile path one. (**b**) Mobile path two

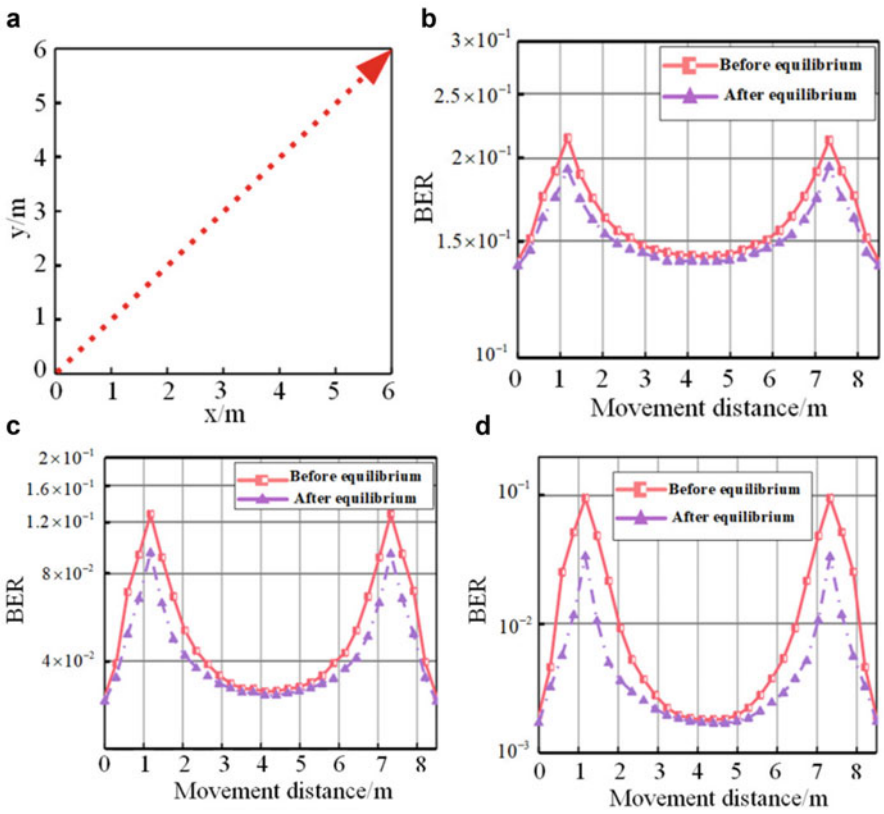

Fig. 43.10 BER performance of the DCO-OFDM system for the first mobile path. (**a**) Movement path. (**b**) $E_b/N_o = 10$ dB. (**c**) $E_b/N_o = 15$ dB. (**d**) $E_b/N_o = 20$ dB

BER performances of $E_b/N_o = 15$ dB and $E_b/N_o = 20$ dB, respectively, which also indicate that the equalization method proposed in this study has a lower bit-error rate.

Figure 43.11 shows the BER performance improvement of the DCO-OFDM system in the second mobile scenario. That is, the receiver PD moves from the starting coordinates (1, 1, 0.65) along a straight line to the coordinates (5, 1, 0.65) and then to the end point (5, 5, 0.65). The distance of the entire movement process was approximately 8 m.

Figure 43.11a shows the movement trace of the receiving PD in the spatial plane. The figure also shows that the influence of the channel on the system constantly changes during movement. The CNN-LSTM residual-structure balancing methods proposed in this article show better BER performance. Figure 43.11b shows the change in BER power as the PD moves from the start point to the end point, when $E_b/N_o = 10$ dB.

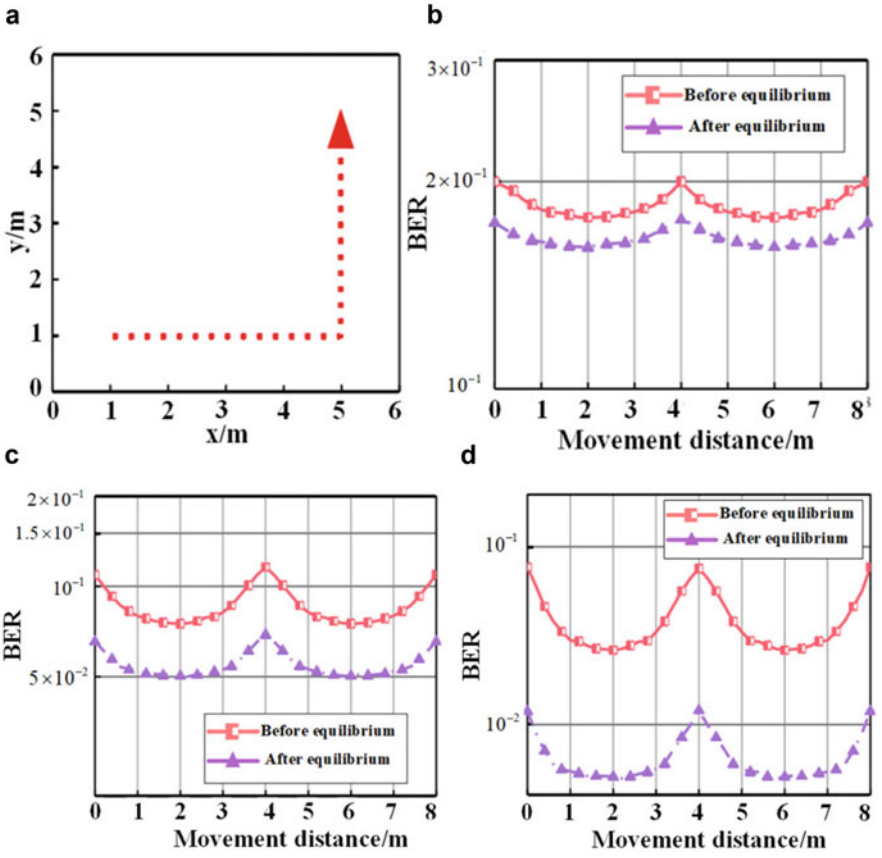

Fig. 43.11 BER performance of the DCO-OFDM system for the second path. (**a**) Movement path. (**b**) $E_b/N_o = 10$ dB. (**c**) $E_b/N_o = 15$ dB. (**d**) $E_b/N_o = 20$ dB

Figure 43.11c, d show the BER power changes at signal-to-noise ratios E_b/N_o = 15 dB and E_b/N_o = 20 dB, respectively. As shown in the figure, the CNN-LSTM residual-structure balancing method effectively alleviates the distortion caused by the channel during the entire movement process.

Comparative Simulation Analyses of Different Equalization Algorithms

To highlight the performance of the algorithm structure in this study, several existing and traditional equalization algorithms were selected for comparison. The algorithms considered in this study include the LSTM algorithm, DNN neural-network algorithm, Volterra equalization algorithm, and the proposed CNN-LSTM adaptive-equalization algorithm. The new energy of the equalization algorithm is highlighted by the change in BER under different SNRs. The BER simulation results for different algorithms are shown in Fig. 43.12, and the corresponding constellation diagrams are shown in Fig. 43.13.

Figure 43.12 shows the convergence curves of the CNN-LSTM equalizer, DNN equalizer, LSTM equalizer, and traditional Volterra blind equalizer. It can be seen from the figure that after the convergence of the CNN-LSTM equalization algorithm, the BER is much smaller than that of the LSTM, DNN, and traditional Volterra blind-equalization algorithms. This indicates that the proposed equalization algorithm has a smaller BER after convergence, higher stability, and better anti-noise performance.

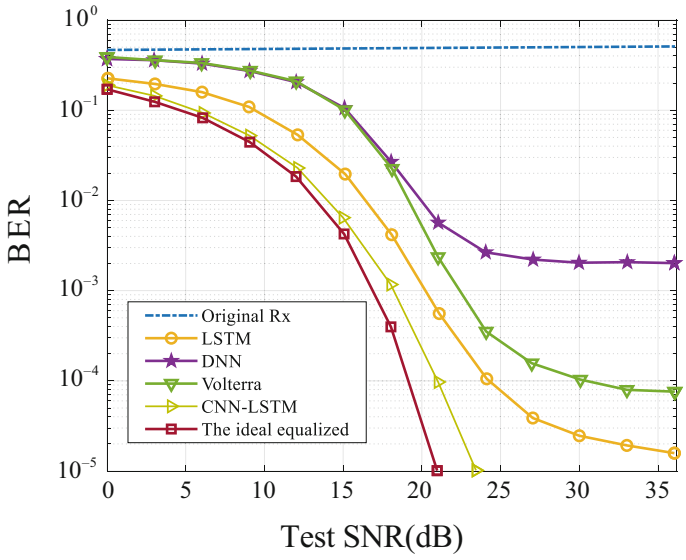

Fig. 43.12 Performance comparison of different equalization algorithms

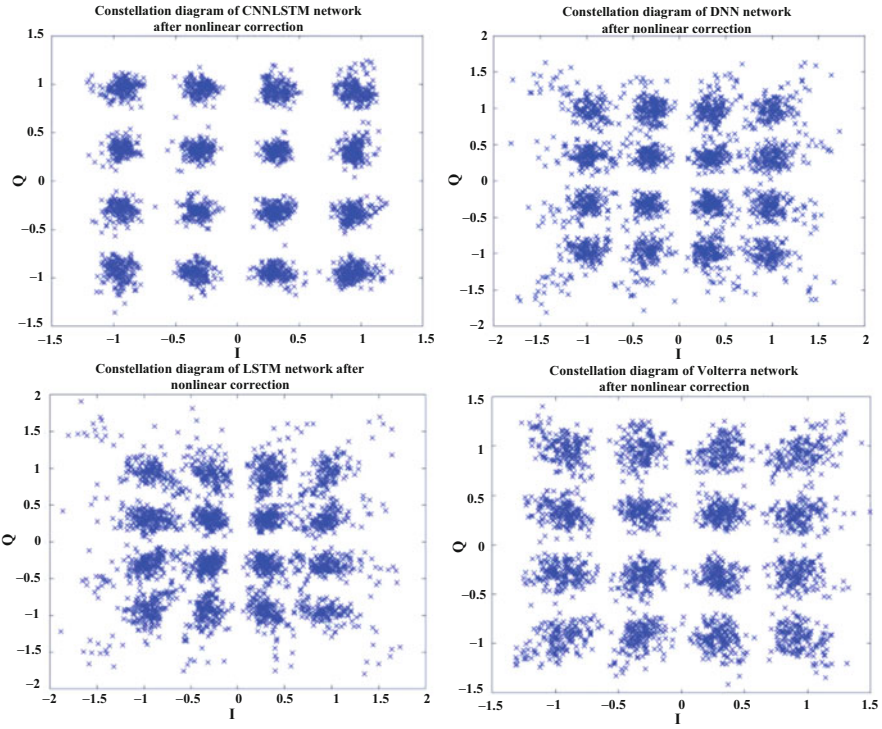

Fig. 43.13 Constellation diagrams after correction by different equalization algorithms

The correction accuracies of the DNN and LSTM algorithms converge after the signal-to-noise ratio exceeds 25 dB and the equalization performance reaches the limit. The algorithm proposed in this article is closest to the equalization curve of the ideal equalizer, does not converge, and is much better than some of the other intelligent-equalization algorithms, in terms of correction accuracy.

The effectiveness of the CNN-LSTM equalization method proposed in this article was verified using the experimental MATLAB platform. The BER performance of signals using a multipath channel, with CNN-LSTM, LSTM, DNN, and Volterra equalization in 4QAM and 16QAM DCO-OFDM systems were simulated and analyzed.

Figure 43.14 shows the BER performance of the different equalization methods in the DCO-OFDM systems. It can be observed that CNN-LSTM has the best BER performance and the same signal-to-noise ratio under both 4QAM modulation and 16QAM modulation. In contrast, the BER performances of the DNN and LSTM equalization are worse than that of the CNN-LSTM equalization, and the BER performance of the CNN-LSTM equalization is slightly better than that of LSTM equalization.

It can also be observed from the figure that as the modulation order increases, the bit-error rate increases; that is, the bit-error rate of the 16QAM modulation is higher than that of the 4QAM modulation. In addition, the equalization effect of various

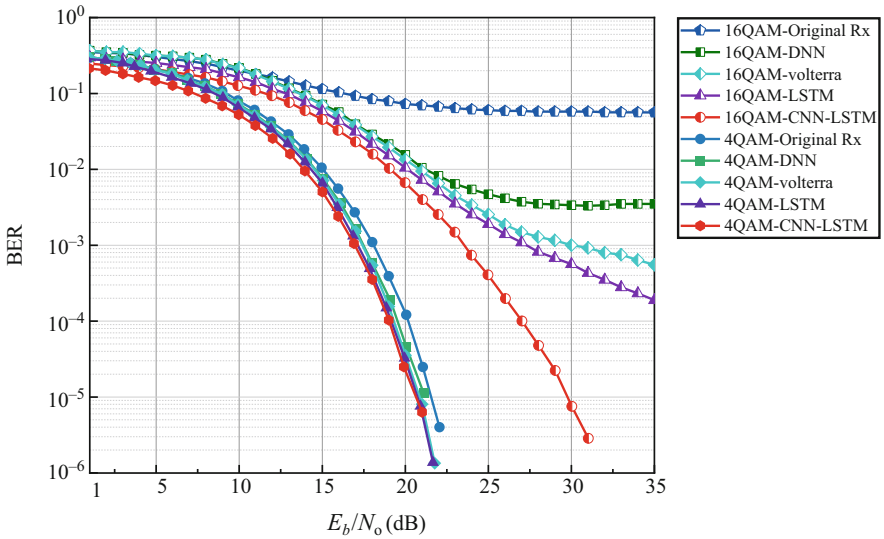

Fig. 43.14 Comparison of the BER performance of different equalization methods in a DCO-OFDM system

equalization methods is not ideal because of the strong signal distortion and high bit-error rate with a low SNR. As the signal-to-noise ratio increases, the effects of different equalization methods become apparent. In particular, the proposed CNN-LSTM method exhibits the best equilibrium effect.

Figure 45.15 shows the BER performance of the DCO-OFDM systems with 4QAM and 16QAM modulation and CNN-LSTM and LSTM equalization with different signal-to-noise ratios. As can be seen from the figure, the BER performance of the CNN-LSTM equalization method is basically the same as that of the LSTM equalization method. In addition, the BER performance of the CNN-LSTM equalization method was slightly better than that of the LSTM equalization method under different modulation orders.

Simulation Analysis of the Structural Parameters of the CNN-LSTM Algorithm

The step distance of the algorithm influences its computational speed and equalization performance. The CNN-LSTM algorithm was simulated with a fixed step size to analyze the influence of different step sizes on the bit-error rate of the algorithm. QAM modulation was adopted for the signal and the training-sequence length was 1000. The step sizes were 0.1, 0.01, 0.001, and 0.0001, and the simulation results are shown in Fig. 43.16.

As shown in Fig. 43.16, different step sizes affect the convergence speed and BER of the CNN-LSTM algorithm. From the convergence perspective, the step size

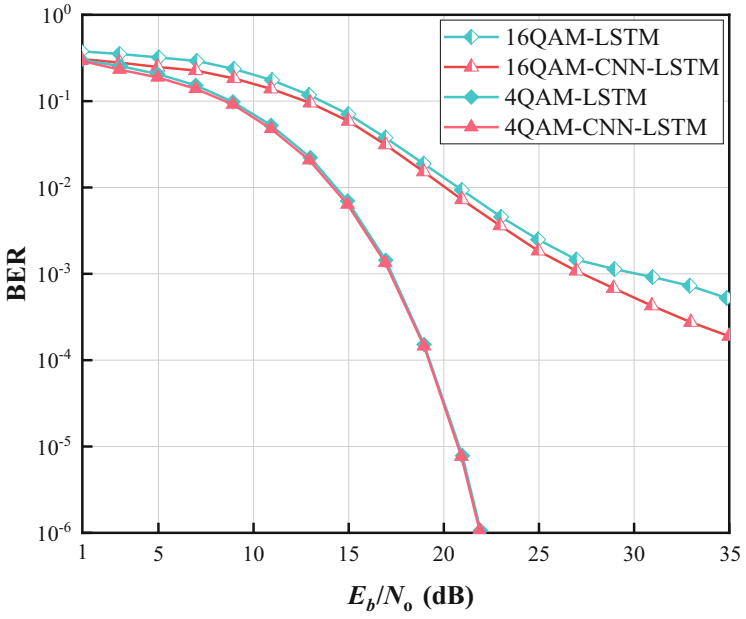

Fig. 43.15 Bit-error rate of CNN-LSTM and LSTM equalization in a DCO-OFDM system

of 0.1 converges the fastest, and a step size of 0.01 converges the next fastest. The smallest step size (0.0001) exhibits the lowest convergence.

The lowest BER was obtained when the step size was 0.0001, the next lowest was 0.001, and the highest was obtained when the step size was 0.1. From the above analysis, it can be seen that the CNN-LSTM algorithm has an inherent contradiction in the convergence speed and BER.

The distribution pattern of the LED light source and the power uniformity further increase the channel complexity, crosstalk between codes, and BER [18]. The performance of the equalizer was simulated under different light-source transparency conditions. The simulation results and constellation diagrams after balancing under the same LED transparency are shown in Figs. 43.17 and 43.18, respectively.

The transparency of the LED light source has a non-negligible influence on the performance of the equalizer: With a transparency of 0.3, the equalization residuals converge at 0.2 at an S/N ratio of 30 dB, and then stabilize. As the transparency increases, the residuals after equalization decrease and the curves converge and overlap at 0.6 and 0.8, which means that after 0.6, the transparency can be ignored and has a negligible influence on the equalizer performance.

In channel equalization, a connection exists between the channel distance and BER residuals. From Fig. 43.19, it can be seen that the BER is the lowest when the

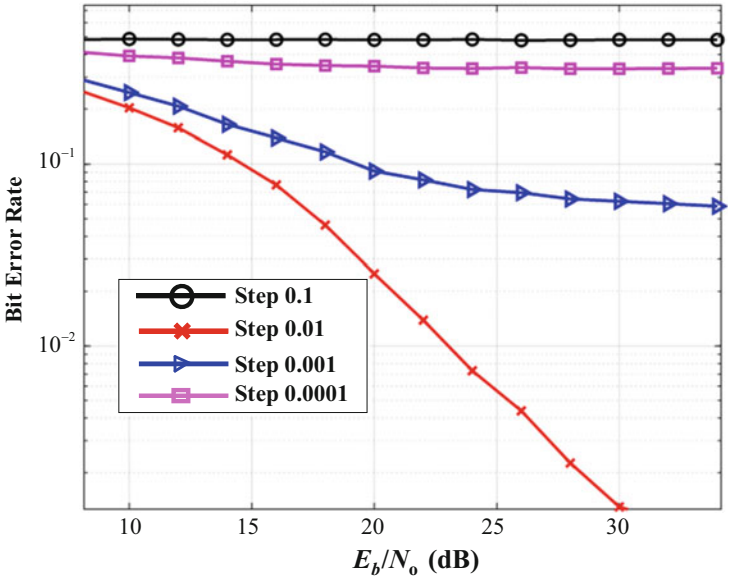

Fig. 43.16 Convergence speed as well as BER comparison of CNN-LSTM algorithms with different step sizes

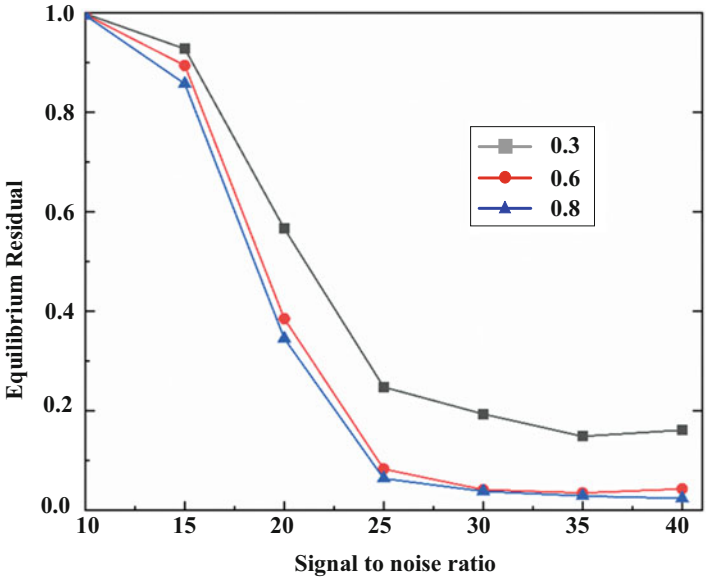

Fig. 43.17 Equalizer performance with different LED transparencies

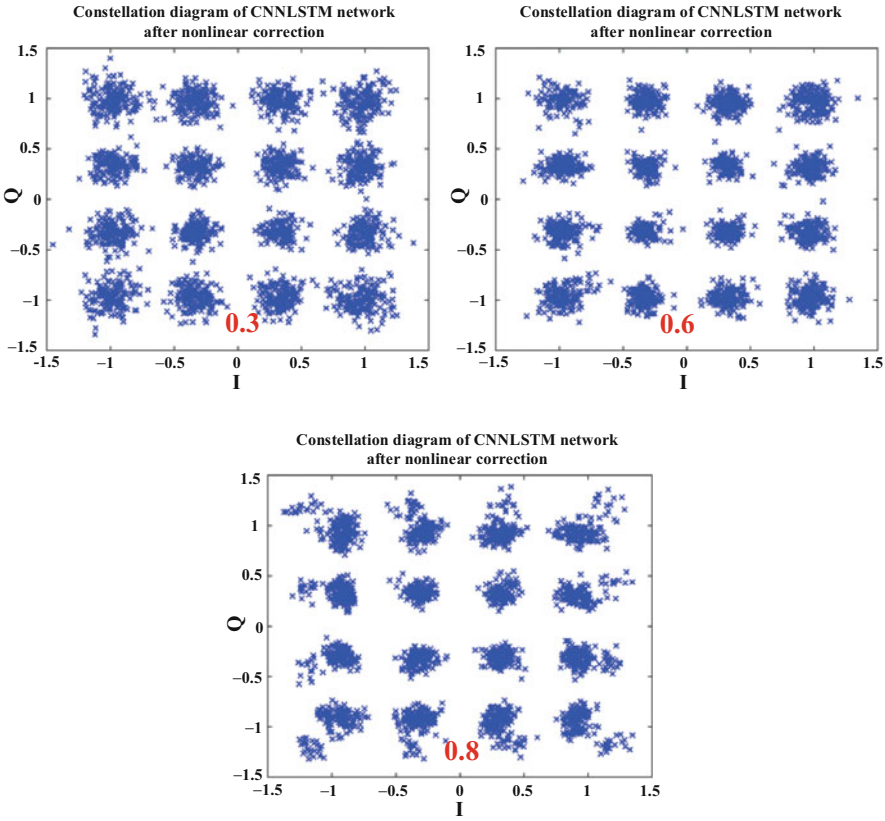

Fig. 43.18 Constellation diagrams after equalization with different LED transparencies

channel spacing is 2.0 m, whereas the BER is the highest when the channel spacing is 3.5 m. It can be clearly seen that as the channel distance increases, the BER residuals, i.e., the difference between the equalized BER and the ideal BER, increase. When the channel spacing increases from 2.0 m to 3.5 m, the BER increases; however, the equalizer always reduces the BER and meets the communication requirements after convergence (Fig. 43.20).

There is an inevitable relationship between the BER residuals and the signal-current threshold. From Figs. 43.21 and 43.22, we can see that as the signal-current threshold increases, the BER residuals decrease; however, the balanced residuals converge at an SNR of 20 dB. Then, the current threshold increases and the BER residuals tend to stabilize; hence, the SNR is optimal at 20 dB. It also shows that increasing the signal current improves the performance of the system and the quality of the signal (Fig. 43.23).

To check the robustness of the CNN-LSTM algorithm, random interference was artificially set into the channel with a certain threshold, according to the method

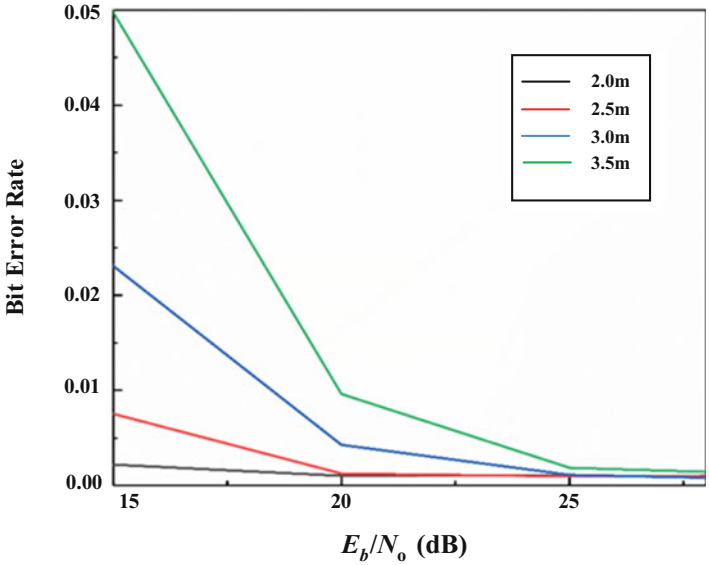

Fig. 43.19 BER residuals after equalization for different channel spacings

described in section "Robustness Analysis of the Algorithm." The simulation results showed that CNN-LSTM is more robust than the LSTM, DNN, and Volterra equalization algorithms.

Conclusion

In this paper, we proposed a convolutional neural network (CNN) fused with an LSTM time-series memory structure for a visible-light communication equalization algorithm. The CNN learns the channel features and converts them into a vector of tapped coefficients, which is described as a time-series feature and stored in the LSTM time-series memory structure. The structure can actively forget and wake up the CNN structure to re-learn the channel features to adjust the equilibrium when the channel is changed.

In this study, the channel-compensation performance of the equalizer was analyzed by numerical simulation. The simulation results indicated the following:

1. In the 35-dB signal-to-noise ratio, the receiver side of the BER reduced below 10^{-3}, to meet the communication requirements.
2. The mapped amplitude after equalization fit well with the ideal accepted amplitude, indicating that the accuracy of the equalization algorithm had been further improved. The widening of the eye diagram also indicated that the communication quality had been further improved.

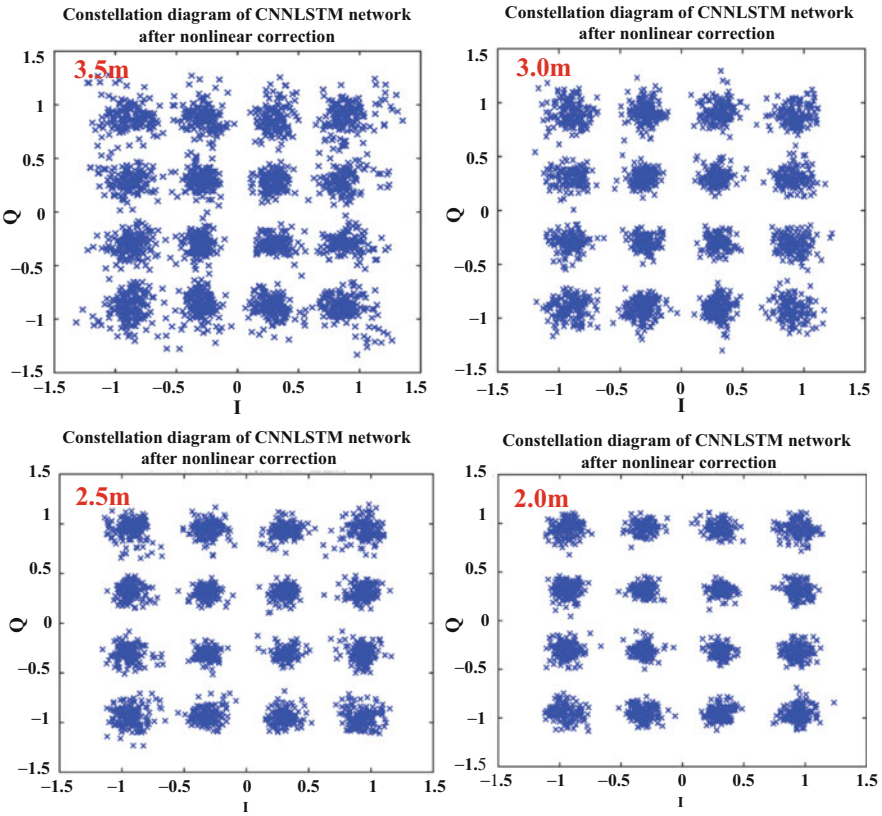

Fig. 43.20 Constellations of received signals at different channel distances

3. In the comparative analysis with existing algorithms, the proposed algorithm had the highest equalization accuracy and actively learned the parameters for channel changes and adaptive equalization.
4. The simulation results under different VLC parameters showed that the method was beneficial for improving the overall characteristics of the channel. A better BER performance was obtained at an affordable complexity cost, with an improvement of at least 2.8-dB SNR over the correction accuracy of the conventional method at a BER of 10^{-3}.

To solve the problem of channel characteristics changing with time with a mobile receiver in an indoor VLC system, this study considered two typical mobile-path models and analyzed the influence of interference factors, such as channel noise and multipath impact, on the BER performance of the system. Considering this scenario, a channel-compensation method based on the CNN-LSTM residual algorithm was proposed to reduce the influence of the channel on the system performance when the receiver moved. The simulation results showed that the proposed method could

effectively contain the signal distortion caused by the channel and improve the reliability and stability of the system.

Abstract

Ultraviolet technology has been widely used in military and civil fields, such as space detection, ultraviolet guidance, ultraviolet interference, corona discharge detection, and military communication. In this paper, the development of UV communication at home and abroad is introduced from the single and multiple scattering of UV light, the different links in UV communication are analyzed, the pulse broadening effect of non-direct view link UV communication and the influence of atmospheric turbulence are discussed, the UV self-organizing network is summarized, and the development of UV communication is also looked forward.

Introduction

Ultraviolet communication is gradually becoming a research hotspot because of its inherent advantages such as low solar background noise, non-direct vision, high confidentiality, and good concealment. The strong scattering characteristics of UV band in the atmosphere make it an ideal choice for Non-Line-of-Sight (NLOS) communication. And because the transmission process is affected by Rayleigh scattering and Mie scattering, the UV light intensity decays rapidly as the transmission distance increases, so the UV light signal can only be received within a certain range, making its communication difficult to be eavesdropped. UV light communication is usually short-distance communication under complex weather conditions, although the strong absorption of the atmosphere, but due to the haze weather, dust, battlefield, and other environmental aerosol density increases, will strengthen the scattering ability of UV light, but to improve the stability of the UV light system communication link.

Research Progress at Home and Abroad

Owing to its strong scattering properties in the atmosphere, the ultraviolet band is ideal for non-line-of-sight (NLOS) communication [1]. Because the transmission process is affected by Rayleigh scattering and Mie scattering, with the increase in transmission distance, the ultraviolet light intensity is rapidly attenuated; therefore, ultraviolet light signals can be received only within a certain range, thus avoiding eavesdropping. Ultraviolet communication is usually short-distance communication under complex weather conditions. Because of the increase in aerosol density owing to hazy weather, dust, battlefields, and other environments, the scattering ability of ultraviolet light is enhanced, and the stability of communication links of ultraviolet light systems is enhanced [1].

The ozone layer in the stratosphere has strong absorption characteristics for the 200–260 nm ultraviolet light band. Hence, the ultraviolet light in this band has very low radiation when it reaches the surface of the earth, which is called the solar-blind zone. The solar-blind zone creates a superior communication condition for communication systems working in this band [1].

Foreign Research Progress in Ultraviolet Optical Communication

In 1939, the US government discussed the Navy's ultraviolet communication system, including light sources, photodetectors, and ultraviolet filters, but did not conduct experiments [2].

In 1968, Sunstein et al. [3] built an optical communication link and provided experimental ultraviolet results for the system under different parameters. In 1976, under the new Standard Atmosphere model, Reilly proposed and developed a theoretical model for describing single scattering, based on ellipsoidal coordinate systems, and evaluated various combinations of absorption and scattering coefficients, anisotropic phase functions, and transmitter/receiver distances [4].

In 1985, Geller et al. [5] used a mercury lamp as an ultraviolet light source and a photomultiplier tube and a filter as a receiver to verify the feasibility of ultraviolet communication at a communication distance of 1 km. In 1991, Luettgen et al. [6] proposed a single-scattering model describing uniform scattering and dielectric absorption, and analyzed the pulse response time and path loss of short-range indirect communication systems.

In 2000, the General Telephone & Electronics (GTE) company, with funding from the US military, developed an indirect ultraviolet optical communication system with a 4.8-kbit/s transmission rate at a communication distance of less than 2 km, and a bit-error rate of 10^{-6}, which met the requirements for video transmission [7].

In 2005, Shaw et al. [8] conducted field experiments in various environments, such as open areas and under canopies. Measurements showed that solar-blind UV light-emitting diodes (LEDs) could be applied to short-range communication links.

In 2008, Xu et al. [9] used on–off keying (OOK) modulation in a communication system. The bit-error rate for different transmission elevation angles was obtained by changing the transmission and receiving angles. When the emission elevation angle was 30°, the bit-error rate increased from 10^{-6} to 10^{-1}. In 2011, Xu et al. [10] compared the path-loss and bit-error rate performance of links in different environments. In 2013, they proposed a configurable framework that combined the traditional line-of-sight turbulence theory with a Monte Carlo simulation framework for random photon scattering [11].

In 2015, Mohamed et al. [12] applied delay-compensation and spatial-diversity techniques to suppress detector noise in indirect UV optical communications. Experiments showed that under the same signaling conditions, the information-transmission rate of diversity technology was 50% higher than that of a single receiver.

In 2016, Ardakani et al. [13] analyzed the relationship between the signal-to-noise ratio and bit-error rate in three different modes: NLOS ultraviolet multiple-input multiple-output (MIMO), multiple-input single-output (MISO), and single-input multiple-output (SIMO).

In 2018, Refaai et al. [14] used decoding-and-forwarding relay technology to complete NLOS UV communication according to the channel-state information (CSI). The interruption probability of a multi-relay UV system was discussed, and the system performance at different elevation angles, atmospheric scattering parameters, and receiver fields of view were simulated and analyzed.

In 2019, Arya et al. [15] proposed a multi-hop ultraviolet indirect vision communication system based on amplification and forwarding and adopted subcarrier-intensity modulation to suppress the influence of turbulence. Simulation results showed that the system could effectively mitigate turbulence-induced fading without

sacrificing important performance criteria, such as the interrupt probability and average bit-error rate.

In 2020, Hasan et al. [16] derived a system model under MISO, SIMO, and MIMO modes by studying the spatial-diversity reception technology in NLOS ultraviolet optical communication. They analyzed the bit-error rate performance of the communication link in a single-input single-output (SISO) system model.

In 2021, Bhatia et al. [17] proposed an expression for the interrupt probability of a nonlinear ultraviolet communication system and proposed an equalizer based on the minimum bit-error rate criterion of the reproducing kernel Hilbert space (RKHS) to reduce the distortion generated by LED nonlinearity.

In 2022, Arslan et al. [18] proposed a steering optimization method based on a finite difference stochastic approximation (FDSA). It could optimize the pointing direction of both the transmitter (T_x) and receiver (R_x) without knowing the position or relative orientation of the two nodes.

Domestic Research Progress in Ultraviolet Optical Communication

Major domestic research institutions include the Beijing Institute of Technology, Xi'an University of Technology, Chinese Academy of Sciences, and other institutions. Most studies are still in the prototyping and feasibility testing stages, and some research on channel models is being explored.

In 1999, Ni et al. [19] achieved voice communication at a distance of 500 m using a low-pressure-gas ultraviolet mercury lamp with a 253-nm wavelength as the light source. In 2003, the team analyzed the influence of factors, such as elevation difference, visibility, weather, and transmission distance, on the atmospheric ultraviolet transmittance at the transmitter and receiver ends [20].

In 2005, Lan et al. [21] proposed to use frequency modulation for language coding in ultraviolet-light information transmission. A data-transmission rate of 2 kbit/s laid a good foundation for the solar-blind ultraviolet communication system.

In 2007, Xiao [22] used an ultraviolet LED to replace a low-pressure mercury lamp and adopted pulse-position modulation (PPM) technology to realize an experimental prototype with a 10-m communication distance.

In 2010, Ke [23] proposed to use the multi-hop feature of self-organizing networks to overcome the limited ultraviolet transmission distance, and added a reward-and-punishment mechanism to improve the original binary exponential-retreat algorithm. The competitiveness of the nodes is matched with their competitive windows, thereby achieving fair access to channels.

In 2011, considering the indirect UV optical communication characteristics, the coverage azimuth was characterized and the NLOS directional transmission node was improved. Moreover, a directional medium-access control (MAC) protocol for indirect UV optical communication based on angle perception was proposed and simulated [24]. The protocol not only shortened the average communication delay but also increased the network throughput. In 2012, a Monte Carlo (MC) multi-

scattering ultraviolet optical-channel model was continuously studied. Based on the single-scattered channel model, the node coverage of short-range communication was analyzed, and its mathematical expression was derived [25].

In 2013, Wu et al. [26] proposed a MAC-layer protocol suitable for ultraviolet optical communications. In the same year, Han et al. [27] adopted a low-density parity-check code algorithm to improve the system performance, and improved the communication distance without coding by 78% under the rated transmit power and a bit-error rate of 10^{-5}.

In 2015, Yang et al. [28] proposed a UV directional neighbor-discovery algorithm based on traditional time-division multiple access (TDMA), which can be applied to large-scale UV ad hoc networks with high-speed movement. Compared with the traditional algorithm, the probability of neighbor-node discovery was increased by 45%, and node collisions were reduced; however, the algorithm convergence speed was sacrificed.

In 2016, Song et al. [29] used the MC method to simulate and analyze the interference between links in space-division multiplexing and noted the pulse-broadening problem in non-coplanar conditions. In 2018, a UV mobile ad hoc communication node device was designed, and transmission and reception were integrated [30].

In 2019, Wang et al. [31] proposed the use of multi-decimal frequency-shift keying for modulation in view of the low modulation rate, and developed an ultraviolet optical communication system for experiments. Using quaternary frequency-shift keying (QFSK), the maximum transmission rate reached 30 kbit/s, which was double that of the binary FSK method.

In 2020, Zhang et al. [32] built a field-programmable gate array (FPGA)-based ultraviolet optical communication system, and analyzed its time delay. The results showed that using an FPGA to build the communication system effectively reduced the communication delay.

In 2021, Cao et al. [33] proposed a single-scattering loss model for an NLOS UV communication system based on an ultraviolet LED. Compared with the actual measurement results, the root-mean-square error of the proposed loss model was only about 1 dB.

In 2022, Cao et al. [34] established a reflection-assisted NLOS ultraviolet communication path-loss analysis model combined with a single collision-induced event (CIE), which worked well in both coplanar and non-coplanar geometries of reflection-assisted NLOS UV communication.

Channel Model

In short-range (usually less than 200 m) ultraviolet communications, the general single-scattering model is a good representation of the channel model. For medium- and long-range ultraviolet communications, the Monte Carlo method multiple-scattering model is more consistent with the experimental results [35].

Single-Scattering Model

As shown in Fig. 44.1, the emitter emits a beam with divergence and elevation angles. A receiver with an angle of view and elevation detects the scattered light from the atmosphere. The linear distance between the receiving and transmitting ends is r, and the common volume of the angle of view and beam angle is V.

In Fig. 44.1, F_1 and F_2 are the focus positions in the ellipsoidal coordinates. $2\Phi_t$ and $2\Phi_r$ represent the divergence angle at the beginning and the field angle at the end, respectively. The emitter elevation angle is relative to the horizontal plane; θ_r represents the angle of view of the receiver, and β_s is the scattering angle.

Feng [36] simulated the communication at different transmit and receive angles under different transmission distances. When the transmission distance increased from 1 m to 1 km and the bit-error rate increased from 10^{-10} to 10^{-1}, the simulation results are shown in Fig. 44.2. It can be observed that with an increase in distance, the overall transmission rate shows a downward trend.

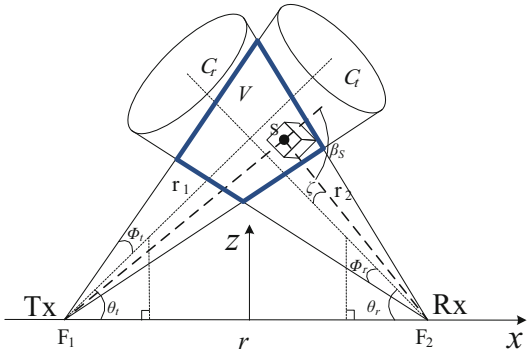

Fig. 44.1 Single-scattering model [1]

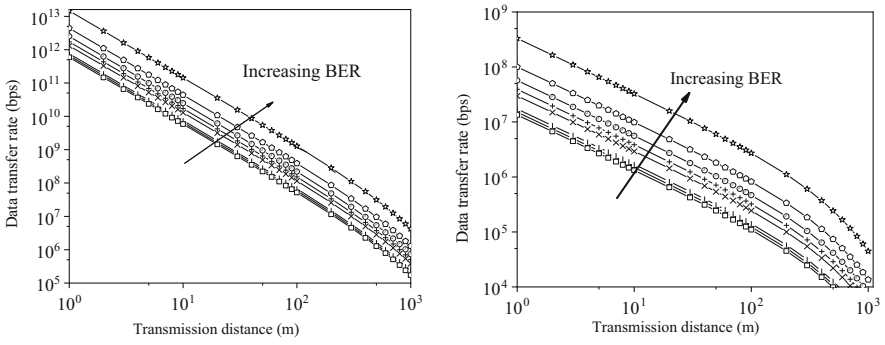

Fig. 44.2 Data-transfer rate comparison between LOS and NLOS systems [36]

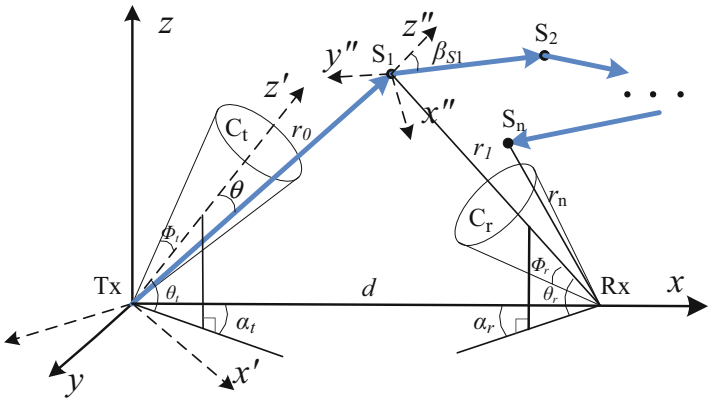

Fig. 44.3 Multiple-scattering propagation model [39]

Multiple-Scattering Model

As shown in Fig. 44.3, for the multiple-scattering model, to simplify subsequent coordinate calculations, T_x was placed at the origin (0, 0, 0) and R_x at the position of point (d, 0, 0) [38]. $2\Phi_t$ denotes the divergence angle of the beam at the emitting end, α_t denotes the offset angle of the emitting end, and α_r denotes the offset angle of the receiving end. $2\Phi_r$ denotes the angle of view of the detector at the receiving end; θ_t and θ_r denote the elevations of the starting and receiving ends, respectively; r_0 and r_1 denote the distance from T_x to the scattering point S_1 and from the scattering point S_1 to R_x, respectively.

Song [39] simulated the path loss of a UV NLOS communication system using the ergodic micro-element and pointing-probability methods. The simulation results are shown in Fig. 44.4. It can be seen from the graph that the path loss tends to increase and the common scatterers decrease as the offset angle α_r of the receiver increases.

UV NLOS Communication Link Model

Ultraviolet-light NLOS communication means that in the transmission process, the receiving and sending ends do not need to be aligned. It relies on ultraviolet-light scattering by atmospheric molecules to carry out barrier communication. The scattering occurs at the overlap of the transmitting and receiving fields of view, which is called the effective scatterer. According to the difference between the transmit and receive elevations, Ke [1] divided the scattering into three communication modes, as shown in Fig. 44.5a–c.

Different NLOS links can be used in different communication situations because of the different transceiver-elevation angles and communication distances. See Ref. [37] for a specific comparison. In Fig. 44.6, both ends are at the same level.

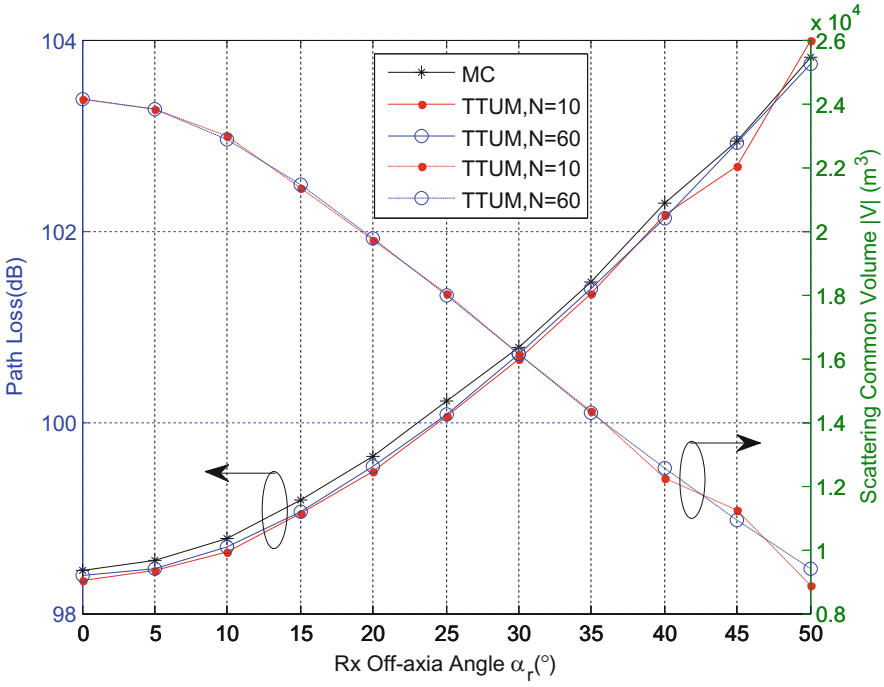

Fig. 44.4 Path loss at different receiver-offset angles [39]

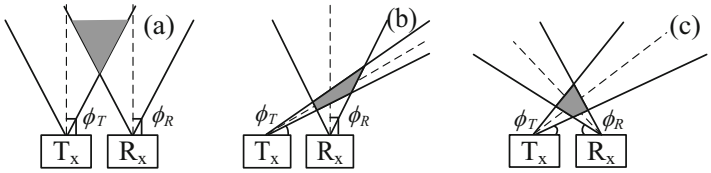

Fig. 44.5 Typical NLOS communication links [1]

The transmitting end emits a beam with divergence angle Φ_1 and elevation angle θ_1. The receiving end detects the scattered light from the atmosphere, with the field-of-view angle Φ_2 and elevation angle θ_2. The linear distance between the receiver and emitter is R, and the common volume of the angle of view and the angle of the beam is V.

When there is an elevation difference between the transmitting and receiving ends, as shown in Fig. 44.7, the line between T_x and R_x is not horizontal because of the height difference between them; at this point, the transmission and reception elevations become the same as θ_1' and θ_2' [41]. Thus, the received power calculation does not refer to R_x, but to a point on a circle centered on T_x, with a radius r and a height equal to T_x. In Fig. 44.7, P_r' is the received power at pointR_x'.

The receiver-power parameter P_r of the receiver R_x is the reference plane in the horizontal plane where the line between T_x and R_x is located. In Fig. 44.7, the

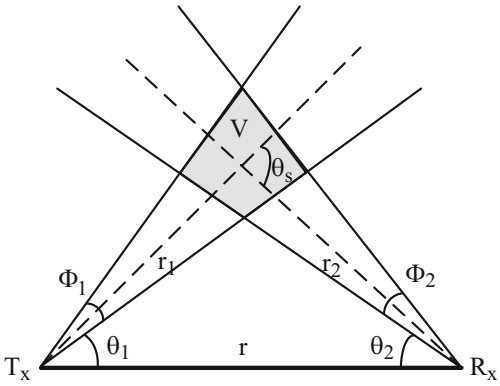

Fig. 44.6 NLOS link model [1]

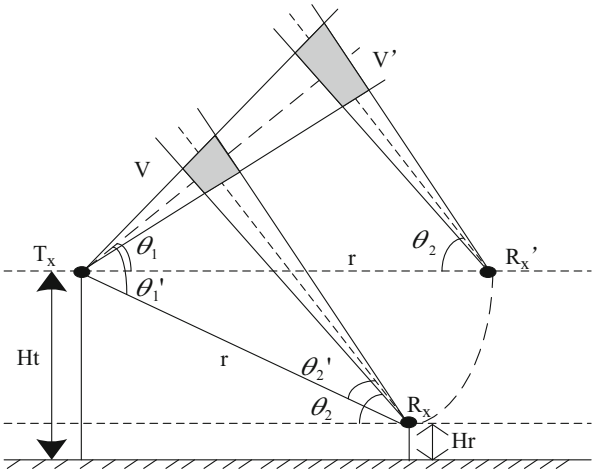

Fig. 44.7 Extremely poor UV NLOS communication [1]

transmit and receive elevations have become the same as θ_1' and θ_2', the changes are recorded as $\Delta\theta_1$ and $\Delta\theta_2$, and the other parameters are kept constant.

He [42] used a 250-nm solar-blind ultraviolet light as the light source in a simulation experiment. They obtained the receiving power after correction for certain heights: $H_t =$ 0.1 km andH_r = 0.04 km, H_t = 0.2 km and H_r = 0.05 km. The measured P_r' is compared with the calculated P_r and the results are shown in Figs. 44.8, 44.9, 44.10, and 44.11. The setting of the extinction coefficient can be found in [43].

As can be seen from the figures, P_r is generally better than P_r'. Therefore, when the ultraviolet communication equipment is networking, each node should look for a node with a small height difference to forward to in the routing process; if there is no available node with a small height difference, the transmission elevation angle should be reduced as much as possible, and the receiving elevation angle should be increased appropriately so that the receiving power is higher.

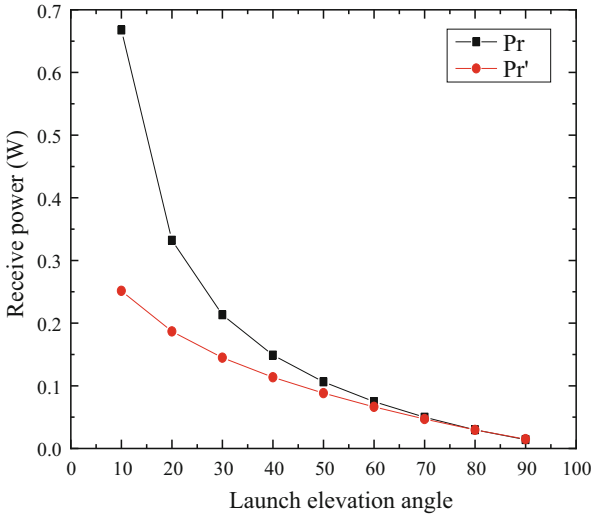

Fig. 44.8 $\theta_2 = 60°$ receiving power [43]. ($H_t = 0.1$ km, $H_r = 0.04$ km)

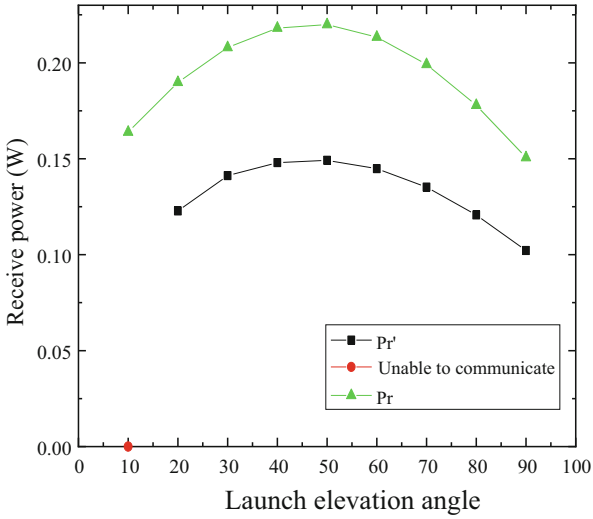

Fig. 44.9 $\theta_1 = 30°$ receiving power [43]. ($H_t = 0.1$ km, $H_r = 0.04$ km)

Pulse-Broadening Effect of NLOS Ultraviolet Communication

Owing to the different scattering points of different photons and different transmission paths after scattering by the common scatterer, the photons reach the receiving end at different times. In addition, multiple scattering may occur in practice, which eventually leads to pulse broadening of the received signal. Solving the pulse-broadening problem plays a key role in determining the decision-threshold level

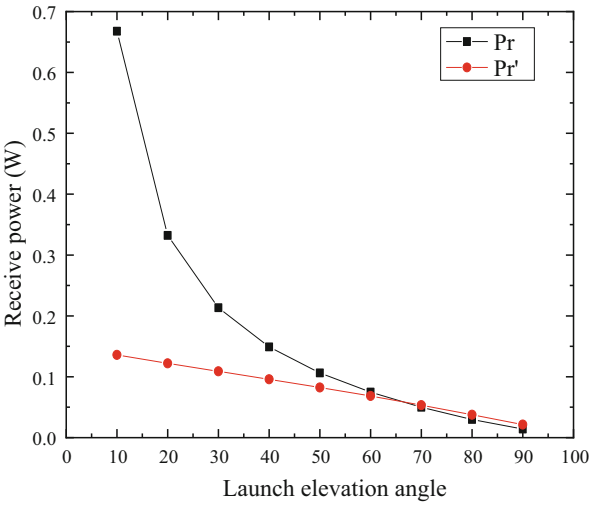

Fig. 44.10 $\theta_2 = 60°$ receiving power [43]. ($H_t = 0.2$ km, $H_r = 0.05$ km)

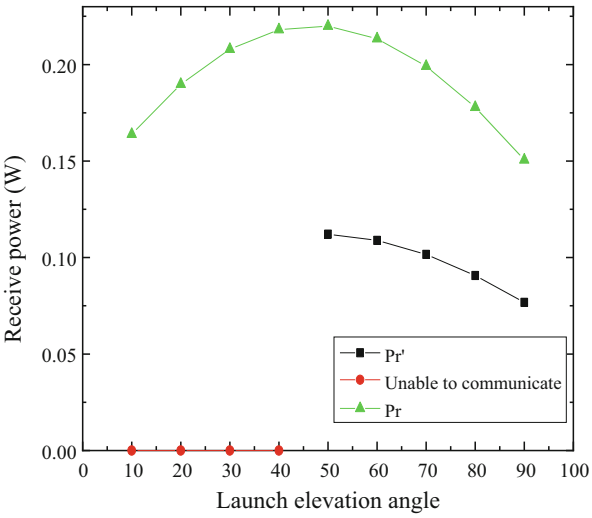

Fig. 44.11 $\theta_1 = 30°$ receiving power [43]. ($H_t = 0.2$ km, $H_r = 0.05$ km)

and decision time to reduce the intersymbol interference (ISI); this improves the system transmission rate and reduces the bit-error rate (BER) [44].

Song simulated the effect of multiple scattering on pulse broadening. The simulation parameters are presented in [40]. Figure 44.12 shows the simulation waveform of the pulse response at the receiving end when the receiving and transmitting elevation angles are the same. The figure shows the degree of pulse broadening after the pulse signal reaches the receiver through the channel. With an increase in

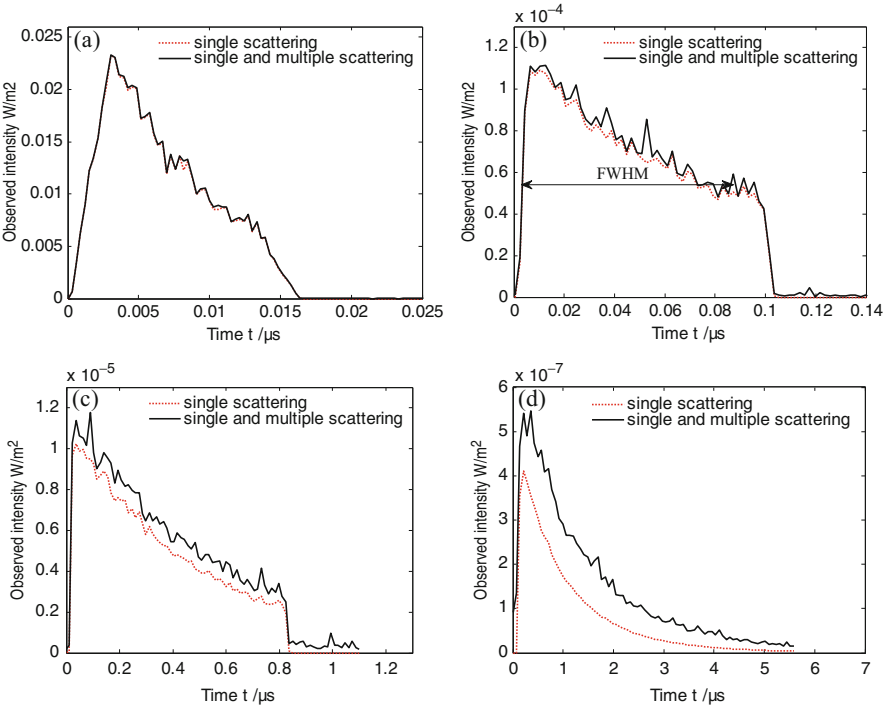

Fig. 44.12 Impulse responses for single and multiple scattering [40]. (**a**) $\theta_t = \theta_r = 10^{\circ}$; (**b**) $\theta_t = \theta_r = 40^{\circ}$; (**c**) $\theta_t = \theta_r = 70^{\circ}$; (**d**) $\theta_t = \theta_r = 90^{\circ}$

the elevation angle of the receiver, the pulse-broadening phenomenon becomes more obvious.

When considering the same transceiver elevation, we should also consider the different transceiver elevations and the pulse-broadening degree contrast. When simulating different elevation angles, the parameters were set the same as above, and the pulse broadening at different elevation angles was compared. The simulation results are shown in Fig. 44.13. A longitudinal comparison of Fig. 44.13a, c, e shows that when the elevation of the receiver is fixed, the larger the elevation of the transmitter, the more serious is the pulse-broadening phenomenon.

Influence of Atmospheric Turbulence on Ultraviolet NLOS Communication

The random fluctuation of local atmospheric physical properties (temperature, pressure, and air velocity) results in random changes in the atmospheric refractive index [45]. In addition, a light beam in the atmosphere will diverge, distort, and drift,

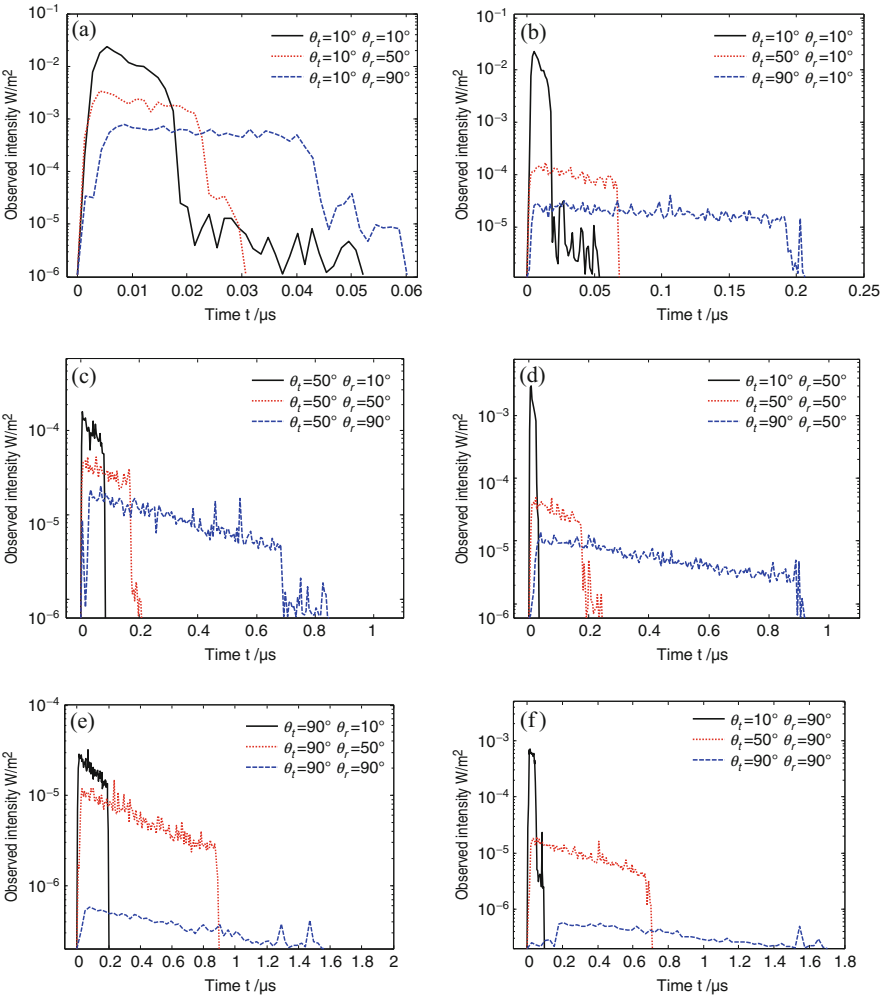

Fig. 44.13 Transmit–receive elevation and pulse broadening [40]. (**a**) $\theta_t = 10^\circ,\ \theta_r = 10^\circ,\ 50^\circ,\ 90^\circ$; (**b**) $\theta_t = 10^\circ,\ 50^\circ,\ 90^\circ,\ \theta_r = 10^\circ$; (**c**) $\theta_t = 50^\circ,\ \theta_r = 10^\circ,\ 50^\circ,\ 90^\circ$; (**d**) $\theta_t = 10^\circ,\ 50^\circ,\ 90^\circ,\ \theta_r = 50^\circ$; (**e**) $\theta_t = 90^\circ,\ \theta_r = 10^\circ,\ 50^\circ,\ 90^\circ$; (**f**) $\theta_t = 10^\circ,\ 50^\circ,\ 90^\circ,\ \theta_r = 90^\circ$

owing to the influence of turbulence, resulting in flickering and jittering in the received light intensity [46].

In weak turbulence, the Rytov solution of the wave equation describes scintillation according to the log-amplitude variance of the received wave. The variance of the log-amplitude fluctuation χ of a plane wave over a length-l channel is [47]

$$\sigma_x^2(L) = 0.56\left(\frac{2\pi}{\lambda}\right)^{7/6}\int_0^L C_n^2(x)(L-x)^{5/6}dx. \tag{44.1}$$

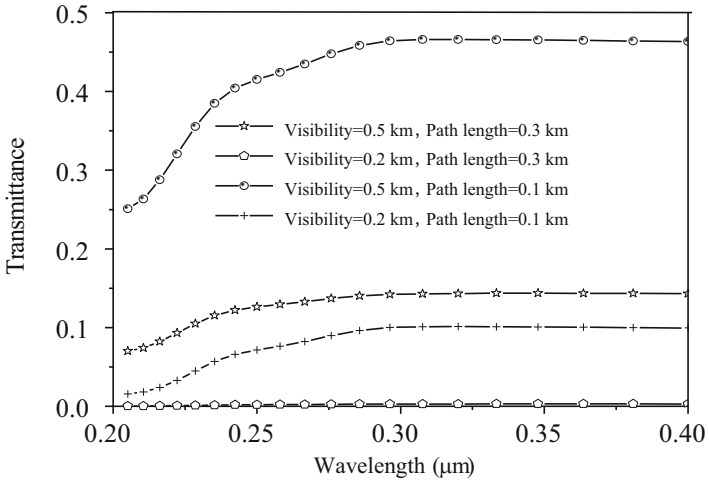

Fig. 44.14 Transmittance of different visibilities and transmission distances [48]

For spherical waves, the variance of the log-amplitude wave χ is [47]

$$\sigma_x^2(L) = 0.56\left(\frac{2\pi}{\lambda}\right)^{7/6}\int_0^L C_n^2(x)\left(\frac{x}{L}\right)^{5/6}(L-x)^{5/6}dx. \tag{44.2}$$

Feng [48] simulated the characteristics of atmospheric ultraviolet transmittance and analyzed it under different transmission distances, visibilities, climates, propagation directions, altitudes, etc.

Figure 44.14 shows the atmospheric transmittance for foggy days with visibilities of 0.2 km and 0.5 km and transmission distances of 0.1 km and 0.3 km. It can be seen that when the communication distance is fixed, the greater the visibility, the better the communication effect. When the visibility is fixed, the lower the transmission rate, the worse the communication quality.

Key Technologies of UV Self-Organizing Networks

An ad hoc network is a wireless mobile communication network composed of a group of mobile nodes; each node is equipped with a wireless transceiver and there is no preset infrastructure. Network communication is established temporarily. Because of its self-organization and distributed nature, it has wide application prospects in the military field. Mobile nodes in a network use their own wireless-transceiver devices for information exchange [1].

Node-Localization Algorithm of an Ultraviolet Optical Communication Network

Ke divided the UV communication network topologies into three types: ring, star, and mesh, as shown in Fig. 44.15a–c.

He discussed commonly used node-location algorithms [43]: trilateration and triangulation. The principle of trilateration is shown in Fig. 44.16. The node coordinates of three different regions are $A(x_1, y_1)$, $B(x_2, y_2)$, and $C(x_3, y_3)$. The distances from the unknown node $D(x, y)$ to the three anchor nodes A, B, and C are, respectively, d_1, d_2, and d_3, which can be obtained from the distance formula between the two points [48].

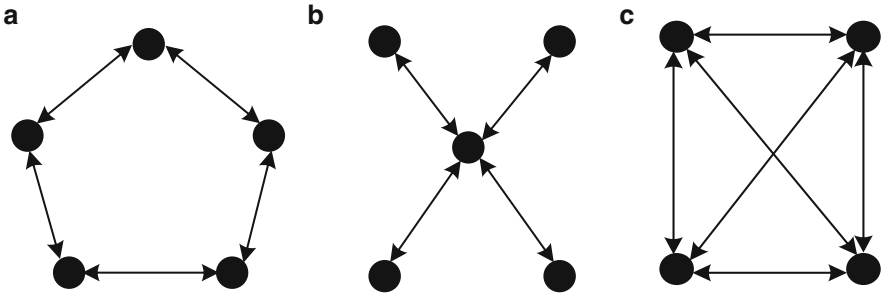

Fig. 44.15 UV network topologies [1]. (**a**) Ring network structure; (**b**) Star network structure; (**c**) Mesh network structure

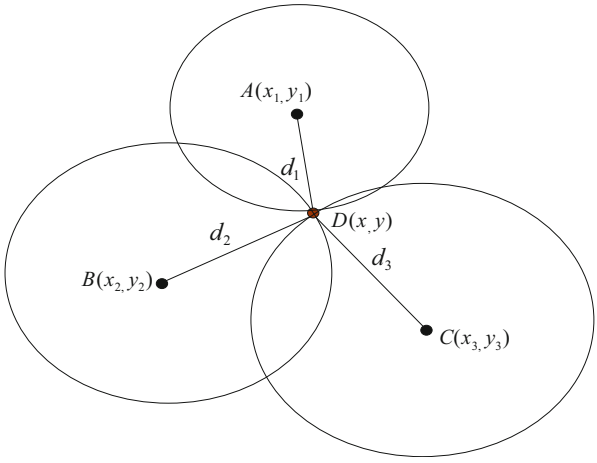

Fig. 44.16 Sketch of the trilateration location algorithm [48]

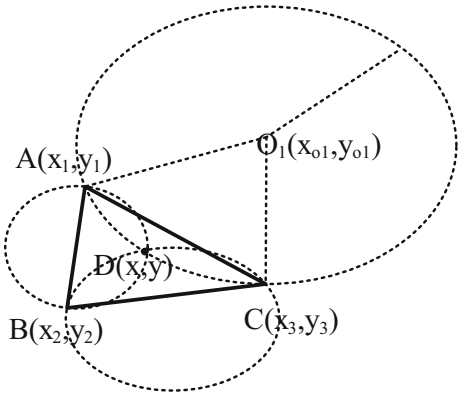

Fig. 44.17 Sketch of the triangulation location algorithm [48]

$$\begin{cases} d_1 = \sqrt{(x - x_1)^2 + (y - y_1)^2} \\ d_2 = \sqrt{(x - x_2)^2 + (y - y_2)^2} \\ d_3 = \sqrt{(x - x_3)^2 + (y - y_3)^2} \end{cases} \tag{44.3}$$

$$\begin{bmatrix} x \\ y \end{bmatrix} = \begin{bmatrix} 2(x_2 - x_1) & 2(y_2 - y_1) \\ 2(x_2 - x_3) & 2(y_2 - y_3) \end{bmatrix}^{-1} \begin{bmatrix} x_2^2 - x_1^2 + y_2^2 - y_1^2 + d_1^2 - d_2^2 \\ x_2^2 - x_3^2 + y_2^2 - y_3^2 + d_3^2 - d_2^2 \end{bmatrix} \tag{44.4}$$

The principle of triangulation is shown in Fig. 44.17. The coordinates of known nodes A, B, and C are $A(x_1, y_1)$, $B(x_2, y_2)$, and $C(x_3, y_3)$, and the coordinates of node D are assumed to be (x, y). The coordinates and radius of the center point of a circle are determined using Eq. 44.5.

$$\begin{cases} \sqrt{(x_{O1} - x_1) + (y_{O1} - y_1)} = r_1 \\ \sqrt{(x_{O1} - x_3) + (y_{O1} - y_3)} = r_1 \\ (x_1 - x_2)^2 + (y_1 - y_3)^2 = 2{r_1}^2 - 2{r_1}^2 \cos\alpha \end{cases} \tag{44.5}$$

Ultraviolet Self-Organizing-Network Multiuser Detection Technology

In [49], Liang analyzed the throughput of ad hoc networks based on multiuser detection technology and proposed the principles that should be followed in UV networks. Based on this, an adaptive recursive least-squares (RLS) algorithm was

introduced into optical code-division multiple access (OCDMA), and an improved variable forgetting-factor RLS algorithm was proposed [50].

The RLS adaptive algorithm differs from conventional least-squares in that it is an exponentially weighted least-squares algorithm. Using the weighted sum of squares of errors as the cost function and the exponential weighted sum instead of the constrained minimum output energy, $CMOE(\mathbf{c}_1) = E\left\{\left(\boldsymbol{c}_1^T\boldsymbol{r}\right)^2\right\}$, the following formula [50] is obtained:

$$\begin{cases} \min \sum_{i=1}^{n} \lambda^{n-i}\left[\mathbf{c}_1^T(n)\mathbf{r}(i)\right]^2 \\ \boldsymbol{s.t.}\ \ \boldsymbol{s}_1^T\boldsymbol{c}_1(n) = 1 \end{cases}, \tag{44.6}$$

where λ is the forgetting factor. By using the Lagrange multiplier method, the closed-form solution of the optimization problem can be obtained as follows:

$$\mathbf{c}_1(n) = \frac{\mathbf{R}^{-1}(n)\mathbf{s}_1}{\mathbf{s}_1^T\mathbf{R}^{-1}(n)\mathbf{s}_1}, \tag{44.7}$$

where $\mathbf{R}(n) = \sum_{i=1}^{n} \lambda^{n-1}\left[\mathbf{r}(i)\mathbf{r}^T(i)\right]^2$ represents the autocorrelation matrix of the observed signal.

Assuming the simulation condition of an additive white-Gaussian-noise synchronous OCDMA system, Liang simulated an adaptive multiuser detector using the RLS algorithm. The BER performance curves are shown in Figs. 44.18, 44.19, and

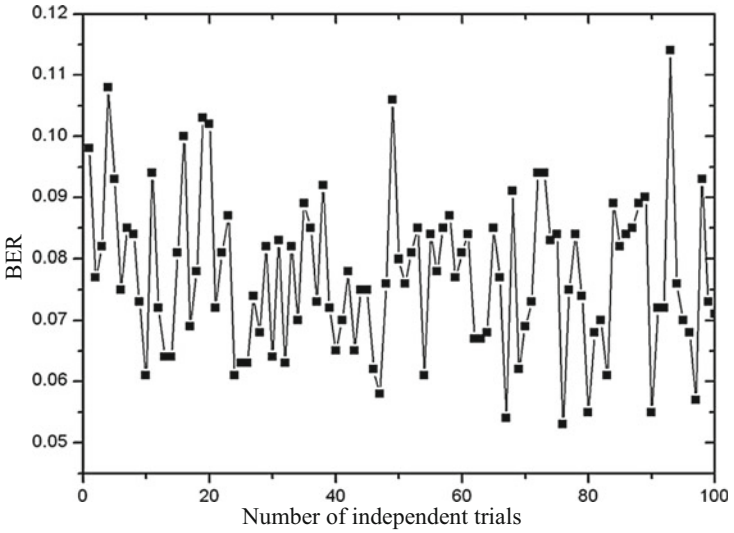

Fig. 44.18 $\lambda = 0.99$. RLS algorithm bit-error rate [49]

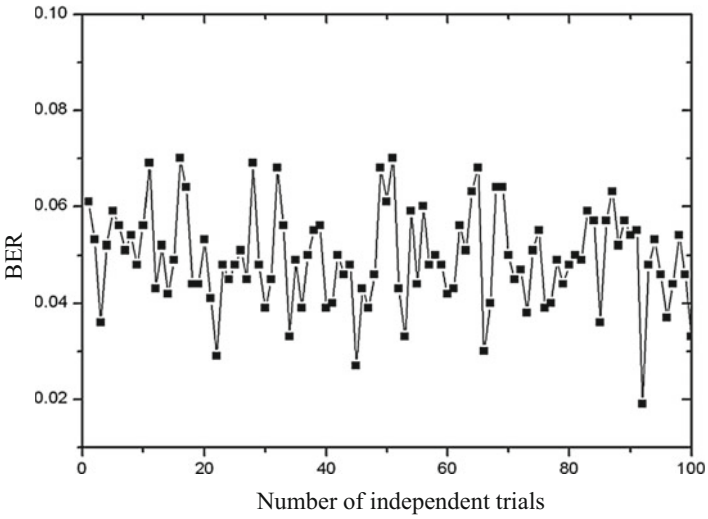

Fig. 44.19 $\lambda = 0.997$. RLS algorithm bit-error rate [49]

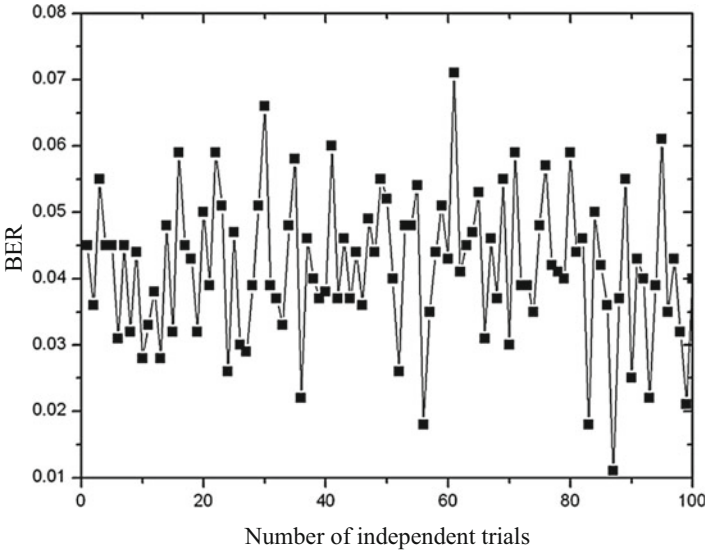

Fig. 44.20 $\lambda = 0.9997$. RLS algorithm bit-error rate [49]

44.20. The graph shows that when conducting blind multiuser OCDMA detection using the RLS algorithm, the expected user signal is tracked relatively well. The estimated bit-error rate of the information characters sent by the expected user is lower; the blind multiuser OCDMA detection can be completed very well.

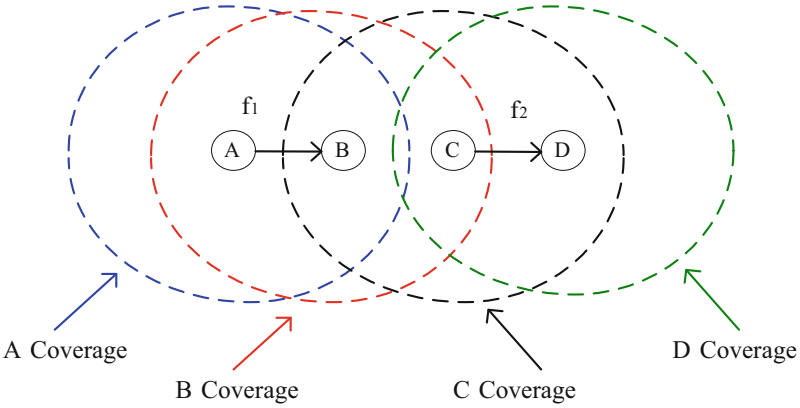

Fig. 44.21 Node-chain topology (exposed terminal) [51]

MAC-Layer Protocol

In the protocol stack of the wireless ad hoc network, the MAC protocol plays an important role. It is the manager that defines the medium in which the data are sent and received over a wireless channel. In [51], Chen analyzed the performance of ad hoc networks with MAC-layer saturation using the IEEE 802.11 distributed-coordination function (DCF) protocol by Markov modeling. In this chapter, history-based dynamic fair backoff (HDFB) and the new DCF (NDCF) improved backoff algorithms are proposed to solve different fairness problems.

For the above-mentioned improved algorithm, Chen et al. [51] carried out a simulation based on IEEE 802.11 DCF, in which the ultraviolet communication single-scattering link model was adopted to replace the default two-ray ground-reflection model in the NS2 network-simulation software. A typical four-node chain in the ad hoc network topology was selected for simulation, as shown in Fig. 44.21.

The simulation results are shown in Figs. 44.22 and 44.23 [52], which show that for the HDFB algorithm, the throughput difference between node *C* and node *A* is approximately 20 kbit/s, with the best fairness. For the NDCF algorithm, the throughput difference between nodes *C* and *A* was approximately 290 kbit/s, which is fair. For the binary exponential backoff (BEB) algorithm, the throughput difference between nodes *C* and *A* was up to 536 kbit/s, and the fairness is the worst.

UV Ad hoc: Network Routing Protocol

Ultraviolet (UV) communication is characterized by its small transmitter and receiver, low cost, indirect communication, high security, very low background noise, and potential for high-speed communication. This makes it an ideal complement to traditional communication. Requirements for ad hoc–network routing

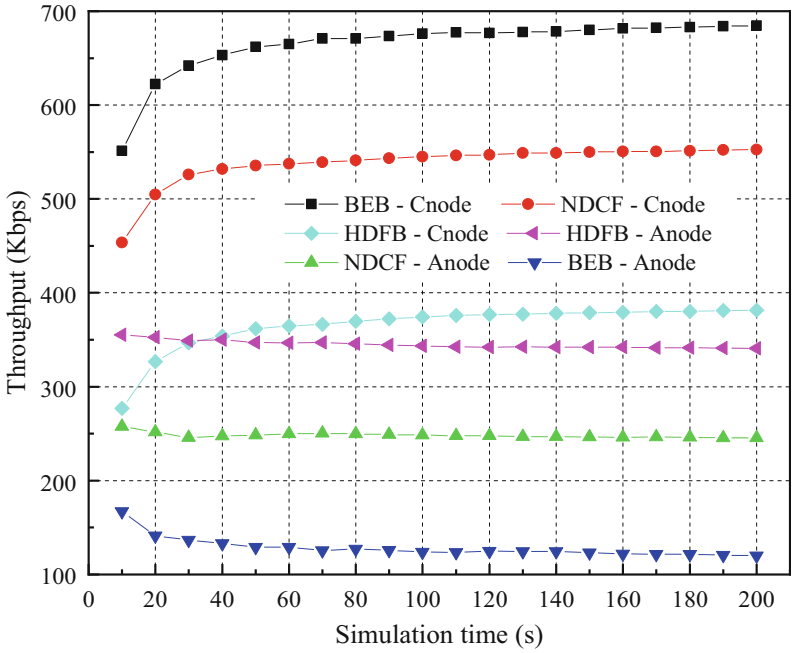

Fig. 44.22 Node-chain topology throughput [52]

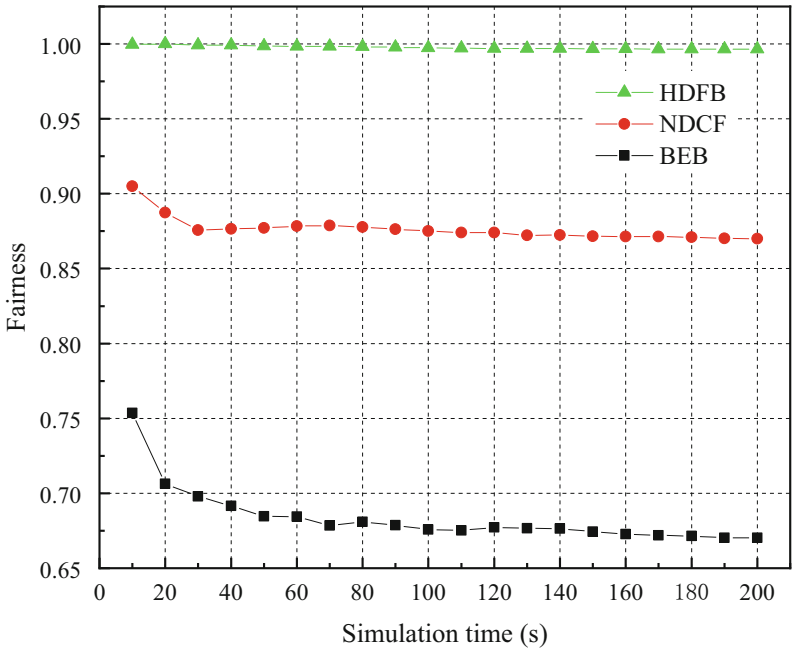

Fig. 44.23 Node-chain topology fairness index [52]

protocols, such as fast convergence, loop-free routing, infinite-computation avoidance, low overhead in control management, and support for one-way channels, have been presented [53].

Yang [53] proposed a position- and velocity-aided routing protocol (PVAR) using geographic-location information and nodes to maintain the effectiveness of the routing as long as possible, and effectively reduce the routing overhead in the network.

In the simulation, Yang set the number of nodes in the network to 50 and 100. The nodes in the network were limited to a 670 × 670 m square region. The velocities of the nodes were 1–10 ms, 10–20 ms, and 20–30 ms, and followed a Gaussian distribution. The PVAR and ad-hoc on-demand distance vector (AODV) protocols were then compared.

The simulation results for the packet arrival rate and routing overhead are shown in Figs. 44.24, 44.25, 44.26, and 44.27, respectively. From the figure, we can see that the performance of the PVAR protocol is better than that of the AODV protocol. At different speeds, the packet arrival rate of PVAR was approximately 90%, whereas the packet arrival rate of AODV was less than 90% when the node speed was between 20 and 30 m/s. The performance of PVAR was better than that of AODV, and PVAR maintained a low routing overhead. However, when the node speed in the network was between 20 and 30 m/s, the performances of PVAR and AODV degraded rapidly, and their jitter was very large.

To find the optimal path from the source node to the destination node, Wu used unidirectional-link routing based on an ant-colony algorithm for UV wireless mesh network (ULR-ACA-UVWMN); that is, in an ultraviolet wireless mesh-network topology using one-way and two-way link methods, the ant-colony algorithm and

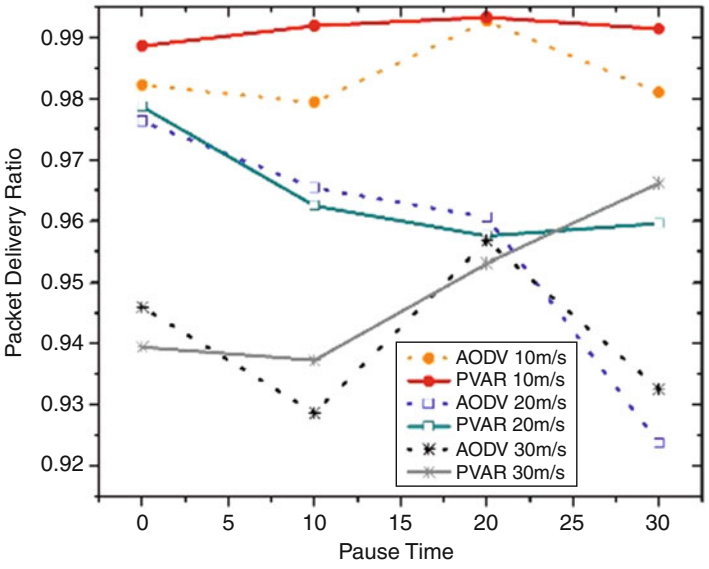

Fig. 44.24 50-node network packet arrival rate [53]

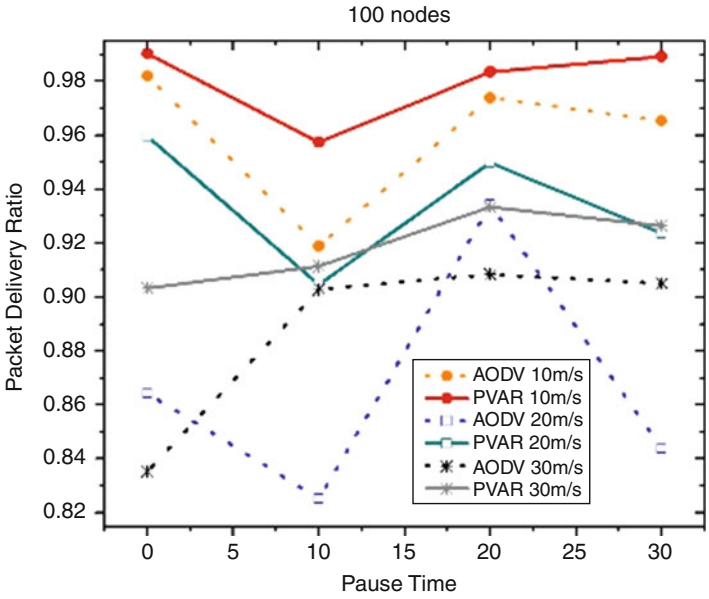

Fig. 44.25 100-node network packet arrival rate [53]

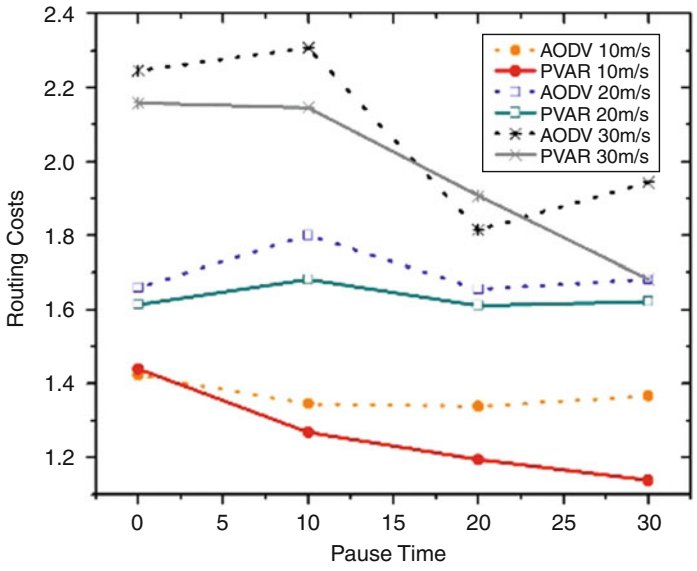

Fig. 44.26 50-node network routing overhead [53]

the ULR-ACA-UVWMN algorithm, which only supports two-way links, were simulated [54].

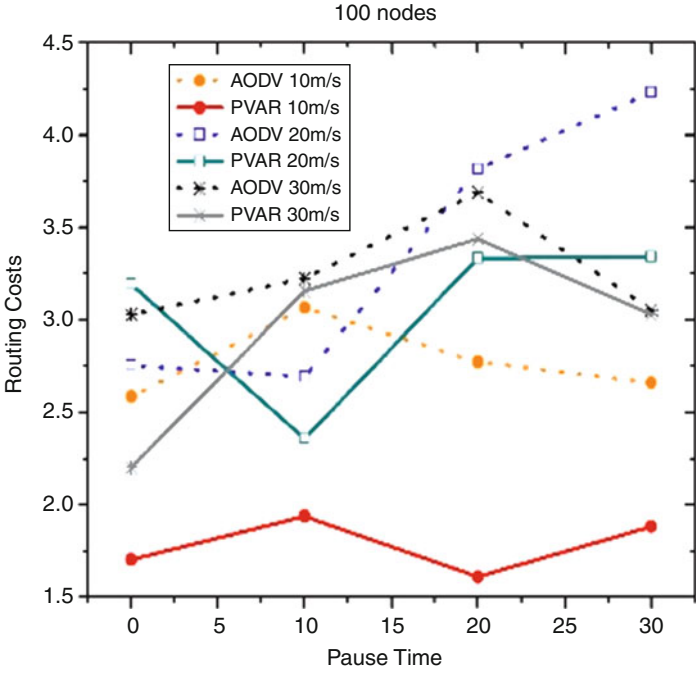

Fig. 44.27 100-node network routing overhead [53]

The simulation results are shown in Figs. 44.28 and 44.29. From the graph, it can be seen that the convergence speed of the ant-colony algorithm, which only supports bidirectional links, to reach the optimal path, is lower than that of the ULR-ACA-UVWMN algorithm.

Analysis of Energy Saving in UV Wireless Sensor Networks

Although multi-hop communication using ultraviolet light can save energy, the greater the number of hops, the more the routing load and MAC-layer load will increase, which is not conducive to energy saving; therefore, there must be an optimal hop number for multi-hop communication to optimize the network performance [55].

Using Fig. 44.30 as the simulation model, 11 nodes are configured in a 600 m × 600 m region, with an initial energy of 10 J for each node. Node 1 is the source node, and node 11 is the sink node. $d_{\max} = 550$ m and $d_{\min} = 55$ m, which means that data can be relayed from the source node to the sink node over a distance of up to 10 hops. The simulation compared and analyzed the energy consumption of the three communication modes, as shown in Fig. 44.31. As can be seen from the figure, five-hop communication is better than one-hop and nine-hop communication, in terms of

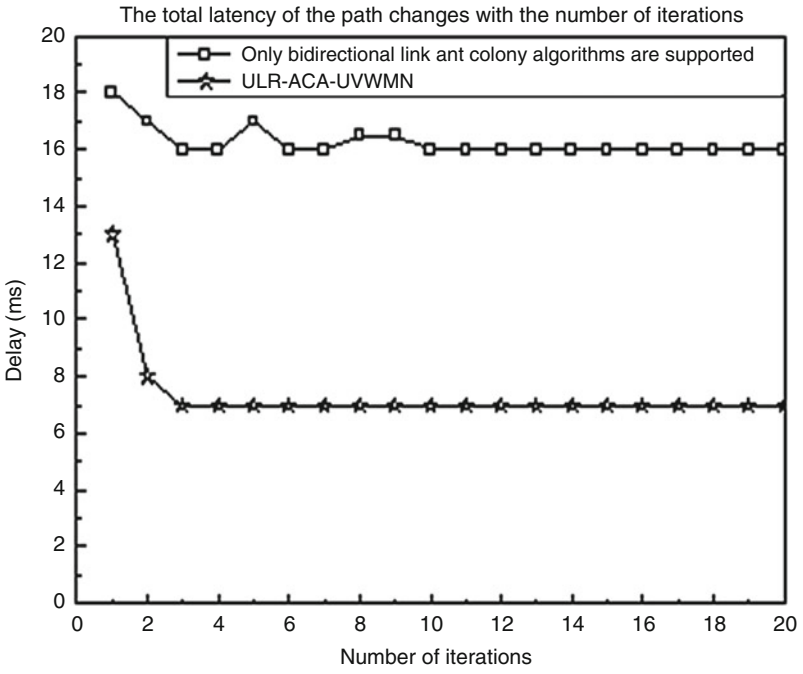

Fig. 44.28 Four-node network topology [54]

saving energy. The number of hops should also be combined with the actual application, not simply maximized.

Summary

Based on the development of ultraviolet communication at home and abroad, single- and multiple-scattering models for ultraviolet communication were introduced and the different links in ultraviolet communication were analyzed. The effects of pulse broadening and atmospheric turbulence on ultraviolet communication in NLOS links were discussed, and key technologies, such as node-localization algorithms, multi-user detection, MAC-protocol fairness, and routing protocols, were summarized. Currently, ultraviolet optical communication can be developed in the following ways.

1. The atmosphere strongly absorbs ultraviolet light, which attenuates to different degrees in the transmission channel, resulting in poor communication quality. Network relays can be used to solve this problem by increasing the number of appropriate nodes. In addition, full-duplex communication technology is necessary to realize practical ultraviolet communication. Because of UV's short wavelength and large bandwidth, the transmission rate of the optical signal can be

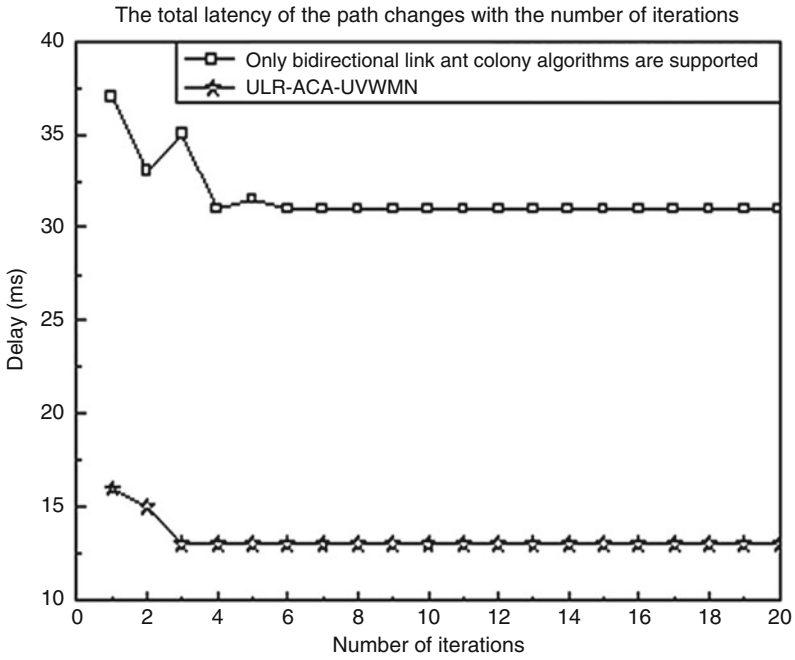

Fig. 44.29 Eight-node network topology [54]

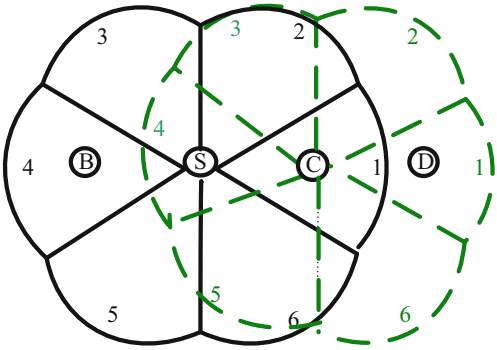

Fig. 44.30 UV sensor-node model [55]

effectively increased using space-division multiplexing; thus, long-distance coverage of UV communication can be achieved.

2. The key and difficult point of studying a UV sensor network is multiuser access in an uplink. Interference between adjacent nodes is consistently a major problem. At present, the interference between adjacent nodes can be reduced by space-division multiplexing.
3. UV NLOS positioning technology is the key direction for integrating UV NLOS communication and positioning in the future, which can be used to help stabilize

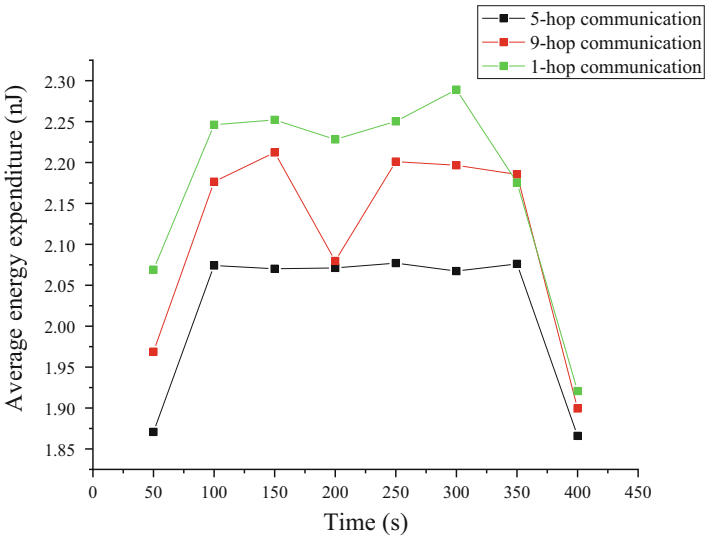

Fig. 44.31 Comparison of average energy consumption for 1-hop, 9-hop, and 5-hop communications [56]

the communication. In the future, the main challenge of UV NLOS positioning technology will be to deduce the distance and azimuth of the transmitter using the information in the receiving power.

Abstract

Ultraviolet (UV) wireless communication is a new method that uses 200 nm–280 nm "solar-blind"-band ultraviolet light as a carrier. It can realize nonline-of-sight (NLOS) communication in complex environments through the scattering of atmospheric molecules and aerosol particles. Under different weather conditions, the bit error rate and path loss of a UV optical communication system change with the particle concentration, particle size, and geometric parameters of the transmitter and receiver in the atmosphere. At different altitudes and times, the bit error rate and path loss of UV optical communication systems change with the concentration of atmospheric molecules and amount of background noise. In this study, the channel characteristics of the UV light scattering intensity distribution and path loss of different rainfall intensities, fog concentrations, and sand and dust types were studied using single-scattering and multiple-scattering UV communication link transmission models. The specific research contents are as follows:

1. To study the communication performance of NLOS ultraviolet optical communication in low-visibility environments, such as rain, fog, and dusty weather, a new empirical optical attenuation model was used for the ultraviolet atmospheric-channel attenuation analysis, the calculation of multiple-scattering transmission models, and the short distance of UV optical communication in low-visibility environments. Moreover, the asymmetric factors in the scattering phase function were simplified. The physical characteristics of aerosol particles under several weather conditions were analyzed; an empirical model of ultraviolet light attenuation in low-visibility weather was established, based on Mie scattering theory; and the ultraviolet light attenuation parameters of different aerosols at different concentrations were obtained.
2. Changes in ultraviolet background radiation at different times and seasons under sunny weather conditions were derived, and the effectiveness of the theoretical model was verified by comparing it with measurement data. The differences between the measured data and the theoretical models in cloudy and hazy weather were compared. Based on a theoretical model of the surface, the ultraviolet light noise distribution at high altitudes was measured, and the change in high-altitude noise was restored. The experimental results showed that with each 1000-m increase in altitude, the daily variation trend of ultraviolet noise remained unchanged, and the ultraviolet radiation value increased by approximately 20–23%. The establishment of this model lays a theoretical foundation and provides an experimental basis for space ultraviolet optical communication.

Ultraviolet optical communication · Atmospheric turbulence · Path loss model · High-altitude noise model

Introduction

Because of its strong scattering properties in the atmosphere, the ultraviolet (UV) band is ideal for nonline-of-sight (NLOS) optical communications. The optical transmission process is affected by Rayleigh and Mie scattering, and with an increase in transmission distance, the ultraviolet light intensity is rapidly attenuated; thus, the ultraviolet light signal can only be received within a certain range, which can prevent eavesdropping. This unique characteristic makes it highly valued by the military.

The ultraviolet band can be divided into multiple parts. The solar radiation in the 200-nm to 260-nm band is absorbed by the atmospheric ozone layer about 20 km above the earth's surface; therefore, the radiation in this band on the surface is much lower than the radiation of visible light and near-ultraviolet light. It is often called the ultraviolet "solar-blind region." If the solar-blind band with low

background noise is used as the communication spectrum, the system will be highly sensitive. The receiving end only needs to receive a small amount of ultraviolet light signal to be able to communicate, and a high signal-to-noise ratio can be obtained.

The main advantages of ultraviolet light communication are as follows:

1. Indirect vision: Conventional space laser communication uses direct visual transmissions. There can be no obstacles in the communication channel. Ultraviolet light signals are strongly scattered by atmospheric particles in the atmospheric channel; thus, an obstacle can be bypassed to complete the communication. Nonline-of-sight is a prominent advantage of UV optical communication over other atmospheric laser communications.
2. Low azimuth resolution: First, because ultraviolet light is invisible, it is difficult for the human eye to determine the orientation of the transmitter. Second, because the ultraviolet light signal is scattered in the air after the transmitter emits it and propagates in all directions, it is difficult to determine the specific orientation of the transmitter from the ultraviolet light signal.
3. Low eavesdropping rate: The ultraviolet light signal is strongly absorbed by the atmosphere during atmospheric propagation; therefore, the energy of the ultraviolet light signal is rapidly attenuated, and communication is only effective within a certain range. After exceeding the communication distance, the ultraviolet signal light energy is obliterated by atmospheric background noise. Even with highly sensitive detectors, it is difficult to detect, which ensures a low eavesdropping rate.
4. High interference resistance: The intensity of solar radiation on the near Earth's surface in the ultraviolet band of mountains is very small because it is scattered by the atmosphere. Ultraviolet solar radiation on the near Earth's surface is evenly distributed; this radiation is reflected in the detector side as DC signals; thus, low-pass filters can be easily used to filter out this background noise.
5. Nondirectional: The principle of ultraviolet communication mentioned above makes great use of the atmospheric scattering effect on ultraviolet light signals in ultraviolet communication.

Ultraviolet light signals are scattered in the atmosphere, and signals can be detected within the effective communication distance centered on the light source. It does not require strong directivity or beam calibration devices like conventional space laser optical communication does.

In an ultraviolet system, owing to the very weak received signal and low amplitude, noise can greatly interfere with the signal. If the noise characteristics are not analyzed, the level judgment will be affected, resulting in a serious decrease in the system bit error performance. To reduce the influence of background noise on communication quality and achieve more stable high-altitude ultraviolet communication and a wider communication bandwidth, it is necessary to study the background noise of ultraviolet light in the solar-blind zone.

In this study, the background noise of 220 nm ±10 nm in the boundary band of the solar-blind zone and 300 nm ±10 nm in the near-solar-blind zone is selected for theoretical modeling. The background noise of the band near the ground and at high altitudes is measured. The measurement results are compared with the theoretical model to verify its correctness and obtain a more complete background ultraviolet daily variation model.

When studying an ultraviolet optical communication system, the noise of the system was modeled, a theoretical model was established, and the parameters of the noise model were adjusted to make the noise model consistent with the measured model. The communication performance before and after modeling was compared to improve the communication quality of the ultraviolet optical communication system under rain, fog, snow, and dusty weather conditions.

Foreign and Domestic Research Progress

In recent years, with the rapid development of ultraviolet detection technology, ultraviolet optical communication has gradually become a research hotspot because of its inherent advantages, such as low solar background noise; indirect vision; strong confidentiality; no acquisition, pointing, and tracking (APT) tracking; and good concealment. Owing to its strong scattering properties in the atmosphere, the ultraviolet band is ideal for nonline-of-sight (NLOS) communication.

Foreign Research Status

As early as 1939, the United States discussed the technology and performance of ultraviolet light sources, detectors, and filters for naval communications but did not conduct actual research [1].

In 1968, Sunstein et al. [2] built the first ultraviolet optical communication link, discussed the selection and limitations of devices in detail, and provided experimental results for the system under different parameters. In 1976, under the American Standard Atmospheric Model, Reilly proposed and developed a theoretical model for describing single scattering based on ellipsoidal coordinate systems and evaluated various combinations of absorption and scattering coefficients, anisotropic phase functions, and transmitter/receiver distances [3].

In 1985, Geller et al. [4] used a mercury lamp as the ultraviolet light source and a photomultiplier tube and filter combination as the receiver to verify the feasibility of ultraviolet communication. In 1991, Luettgen et al. [5] proposed a single-scattering model describing uniform scattering and dielectric absorption. They analyzed the angular spectrum of single-scattered energy, as well as the pulse response time and path loss of short-range indirect communication systems.

In 2000, the General Telephone and Electronics (GTE) cooperated with the US military to develop ultraviolet optical communication systems. They achieved an

indirect communication distance of less than 2 km, an information transmission rate of 4.8 kbit/s, and a bit error rate of 10^{-6}, which met the requirements of video transmissions [6].

Early ultraviolet communication systems mostly used gas-discharge lamps as light sources, which had the disadvantages of a nonunique beam wavelength, small modulation bandwidth, and large size. To miniaturize this system, the Defense Advanced Research Projects Agency (DARPA) launched the Semiconductor UV Optical Source (SUVOS) program in 2002 and the Deep UV Avalanche Photodiode Program in 2007 [7].

In 2005, Shaw et al. [8] developed a modular solar-blind ultraviolet communication experiment bench and conducted field experiments in various environments, such as open areas and under a canopy. The measured data and supported single-scatter models showed that solar-blind UV light-emitting diodes (LEDs) could play an important role in short-range communication links with NLOS and LOS.

In 2008, Xu et al. [9] used commercial UV LEDs as a light source to build an ultraviolet communication test bench to evaluate the path loss and bit error rate of a communication system. When using on-off keying (OOK) modulation, the bit error rate of the communication system was obtained by changing the angles of the receiver (Rx) and transmitter (Tx), with different Rx elevation angles. When the Rx elevation angle was 30°, the bit error rate increased from 10^{-6} to 10^{-1}.

In 2009, Majumdar et al. [10] used the Monte Carlo simulation of photon tracking to establish a random indirect UV communication (UVC) channel model and compared multiple and single scattering. Indirect UV-scattering channels were studied from the aspects of impulse response, path loss, bandwidth, etc.

In 2011, Xu et al. [11] compared the path loss and bit error rate (BER) performance of links in different environments based on original commercial UV LEDs. By considering the unique UV physical layer characteristics, that is, changing the channel quality along different scattering directions, an efficient neighbor discovery protocol was developed. In 2013, the team proposed a configurable framework that combined the traditional line-of-sight turbulence theory with a Monte Carlo simulation framework for random photon scattering. The results showed that the model effectively characterized the irradiance probability density function (PDF) of the received signal of a UV channel under strong and weak turbulence [12].

In 2015, Mohamed et al. [13] proposed a spatial diversity technique for delay compensation and detector-noise suppression in indirect UV optical communication. The advantages of interunit receivers were compared and analyzed from the perspective of the information transmission rate. Experiments showed that, under the same signaling conditions, the use of diversity technology increased the information transmission rate of the single wire receiver by 50%.

In 2016, Ardakani et al. [14] conducted a simulation study on an NLOS multi-input–multi-output (MIMO) communication system and analyzed the relationship between the signal-to-noise ratio and bit error rate in three different modes: NLOS ultraviolet MIMO, multiple-input single-output, and single-input multiple-output.

In 2017, Maryam et al. [15] proposed a multihop UV system with decoding and forwarding relays, considering the turbulent influence of short-distance communication. The performance of the working link under lognormal turbulence was analyzed, including the probability density function of the interrupt probability, diversity gain, and power attenuation factor at different atmospheric refractive index structure constants and communication distances.

In 2018, Refaai et al. [16] analyzed the performance of multiple NLOS UV communication cooperative relays in turbulent channels. They used decoding and forwarding relay technology to complete the NLOS UV communication according to the channel state information (CSI). The interruption probability of a multirelay UV system was discussed according to the proposed model, and the system performance under different elevation angles, atmospheric-scattering parameters, and receiver field-of-view angles was simulated and analyzed. The experimental results showed that increasing the number of UV indirect coordinated relays did not necessarily improve the system performance; other factors, such as the elevation angle and the number of relays, must also be considered.

In 2019, Arya et al. [17] proposed a multihop ultraviolet NLOS communication system based on amplification and forwarding and adopted subcarrier intensity modulation to mitigate the impact of turbulence. Subsequent simulation results showed that the system could effectively mitigate turbulence-induced fading without sacrificing important performance criteria, such as the interrupt probability and average bit error rate.

In 2020, Hasan et al. [18] derived a system model under multiple-input single-output, single-input multiple-output, and MIMO modes by studying the spatial diversity reception technology in NLOS ultraviolet optical communication. They analyzed the bit error rate performance of the communication link in the single-input single-output system model and verified the accuracy of the model with Monte Carlo simulation.

In 2021, Bhatia et al. [19] characterized the expression for the interruption probability of a nonlinear UV communication system by analyzing the multiplicative distortion statistics caused by turbulence. Using the proposed multiplicative distortion model, the bit error rate of the nonlinear outdoor indirect UV channel was quantified, and an equalizer based on the minimum symbol error rate (MSER) criterion of the reproducing kernel Hilbert space was proposed, according to the derived bit error rate expression, to reduce the distortion caused by LED nonlinearity.

In 2022, Arslan et al. [20] proposed a novel steering optimization method based on a finite difference stochastic approximation (FDSA) to simultaneously optimize the pointing direction of the transmitter (Tx) and receiver (Rx) without knowing the position or relative orientation of the two nodes. Monte Carlo channel simulation was used for the parameter analysis to study and select the appropriate key algorithm parameters. Experiments with custom-designed UV Tx and Rx gimbal systems demonstrated the practicality and efficiency of the proposed steering optimization method, and the received photon count was significantly increased.

Domestic Research Status

Major domestic research institutions include the Beijing Institute of Technology, Xi'an University of Technology, Chinese Academy of Sciences, and other institutions. Most studies are still in the prototyping and feasibility testing stages, and some research on channel models is still being explored.

In 1999, Ni et al. [21] used a low-pressure gas ultraviolet mercury lamp with a 253-nm wavelength as the light source and a photomultiplier tube to build an ultraviolet communication experimental platform for the receiver. They completed voice communication at a distance of 500 m. In 2003, the team used a low-transmittance model to simulate the atmospheric transmission characteristics of the ultraviolet band and analyzed the influence of the elevation difference, visibility, weather, transmission distance, and other factors on the atmospheric ultraviolet transmittance at the transceiver end. The results showed that around the 250-nm band, weather, visibility, season, and other factors had little influence on the ultraviolet transmittance of the solar-blind zone [22].

In 2004, the half-duplex ultraviolet communication system built by Changsheng et al. [23] realized 9.6-kbit/s voice communication, laying the foundation for subsequent ultraviolet optical communication.

In 2005, Lan et al. [24] proposed the use of frequency modulation to realize language coding in ultraviolet light information transmission based on the ultraviolet communication system of the General Telephone and Electronics (GTE). In the experiment, an ultraviolet germicidal lamp was used as the light source, and a solar-blind photomultiplier tube was used as the photodetector. It realized a data transmission rate of 1.2 kbit/s, laying a good foundation for solar-blind ultraviolet communication systems.

In 2007, Xiao [26] used a low-voltage mercury lamp as the light source for an ultraviolet optical communication system and analyzed the shortcomings of the device, such as its small modulation bandwidth and high power consumption. Subsequently, ultraviolet LEDs replaced the low-voltage mercury lamps, and pulse-position modulation (PPM) technology was used to create an experimental prototype with a communication distance of 10 m [25]. In 2012, a field-programmable gate array (FPGA) was used for modulation and demodulation, realizing 9.6-kbit/s coded communication and 115-kbit/s noncoded communication.

In 2010, Ke [27] proposed to use the multihop feature of self-organizing networks to overcome the shortcomings of the limited ultraviolet transmission distance. He added a reward and punishment mechanism to improve the original binary exponential retreat algorithm. The competitiveness of the nodes matched their competitive windows, thereby achieving fair access to channels.

In 2011, based on the characteristics of NLOS ultraviolet communication, Ke et al. derived the coverage azimuth expression, improved the NLOS directional transmission node structure, and proposed and simulated an NLOS directional medium access control (MAC) protocol based on angle perception [28]. The results showed that the protocol greatly improved the network throughput and reduced the

average communication delay. In 2012, the Monte Carlo (MC) multiscattering ultraviolet optical channel model was further studied; based on the single-scattered channel model, the node coverage of short-range communication was analyzed, and its mathematical expression was derived [29].

In 2013, Wu et al. [30] designed and implemented a MAC layer power control mechanism suitable for ultraviolet optical communication. It was designed to reduce the energy consumption of nodes and mutual interference between nodes to extend the life cycle of the network and increase the system capacity. In the same year, Han et al. [31] adopted a low-density parity check code algorithm to improve the system performance. They improved the communication distance without coding by 78% under a rated transmit power and a bit error rate of 10^{-5}.

In 2015, Yang et al. [32] proposed a UV directional neighbor discovery algorithm, based on traditional time-division multiple access, that was applied to high-speed large-scale mobile UV ad hoc networks. Compared with the traditional algorithm, the probability of neighbor node discovery was increased by 45%, and node collisions were reduced; however, the convergence speed of the algorithm was sacrificed.

In 2015, Li et al. [33] proposed an anti-jamming relay link scheme and analyzed the corresponding power requirements considering that the ultraviolet optical communication distance was too short, owing to limited emission optical power and serious atmospheric attenuation. The scheme allocated different time slots to adjacent nodes through time-division multiplexing to prevent mutual interference between nodes.

In 2016, Song et al. [34] simulated and analyzed the interference between links in space-division multiplexing, based on a set of typical communication link models using the MC method. In addition, the pulse-broadening problem in the noncoplanar case was further analyzed. In 2018, a mobile self-organizing communication node device integrating transmission and reception was designed, and the relationship between capture time and speed was simulated and analyzed [35].

In 2017, Li et al. [36] established a high-altitude solar radiation distribution model to analyze high-altitude ultraviolet optical communication performance. They studied the high-altitude scattering and absorption coefficients of ultraviolet light of different wavelengths and simulated the loss and signal-to-noise ratio of direct and indirect UV links, considering the background light of solar radiation and shot particle noise at the receiving end.

In 2019, Wang et al. [37] proposed the use of multidecimal frequency-shift keying for modulation, in view of the low modulation rate, and developed an ultraviolet optical communication system for experiments. Using a quaternary frequency-shift keying modulation method, the maximum transmission rate reached 30 kbit/s, which was double that of the binary frequency-shift keying method.

In 2020, Zhang et al. [38] built an FPGA-based ultraviolet optical communication system and analyzed its time delay. The results showed that using an FPGA to build a communication system effectively reduced the communication delay.

In 2021, Cao Tong et al. [39] proposed a single-scattering loss model for an NLOS UVC system based on ultraviolet LEDs. They assumed that the LED

emission model followed a Lambertian distribution and derived the corresponding analytical expression. Monte Carlo simulations and experimental results verified the effectiveness of the proposed loss model. The experimental results demonstrated that the proposed model accurately predicted the loss of single scattering under actual conditions. Compared to the actual measurement results, the root-mean-square error of the proposed loss model was approximately 1 dB.

In 2021, Cheng et al. [40] proposed a UV lossless competition MAC protocol, considering the shortcomings of the UV MAC protocol. Based on the superposition logic of UV power, the MAC protocol effectively reduced the collision loss of multinode competing access. The basic working mechanism and protocol flow were provided in detail, and the network performance was mathematically simulated and analyzed, based on a four-node UV network. Simulation results showed that, compared with the time-slot ALOHA protocol, the protocol had a higher throughput and lower latency. Subsequently, the actual networking of the four communication terminals was designed and realized, and the effectiveness of the new UV-MAC protocol was fully verified.

In 2022, Cao et al. [41] established a reflection-assisted NLOS ultraviolet communication path loss analysis model combining a single collision-induced event (CIE) by treating both scattering and reflection events as CIEs, which referred to a single collision-induced (SCI) path loss model. Monte Carlo (MC) simulations and experimental results verified the correctness and validity of the proposed SCI path loss model. The results showed that the proposed SCI path loss model worked well for both coplanar and noncoplanar geometries of reflection-assisted NLOS UVC.

Theoretical Model of Ultraviolet Background Light

Because of the absorption of the ozone layer, the intensity of ultraviolet radiation in the 200-nm–280-nm band near the surface is very low; this is called the solar-blind zone [42]. Most current research focuses on the central band of the surface solar-blind zone, with low background noise. To reduce the influence of background noise on communication quality and achieve more stable high-altitude ultraviolet communication and a wider communication bandwidth, it is necessary to study the background noise of ultraviolet light in the solar-blind zone.

Theoretical Model of Solar Radiation to the Earth

Total solar radiation calculation models can be divided into three categories: physical, empirical, and machine learning [43]. Among them, the empirical model is one of the most widely used models because of its high computational accuracy and low computational complexity. Angstrom [44] first established a calculation model for total daily solar radiation, based on the correlation between the insolation percentage and total radiation/sunny day radiation. However, because of the complexity of the process of calculating sunny day radiation, Prescott [45] proposed the use of

astronomical radiation instead of sunny day radiation and established a model based on the Angstrom model, also known as the A-P model.

Photon Energy

The Sun transmits energy in the form of light throughout the solar system and beyond. The Sun's photons carry the Sun's energy; they are light quanta, the quanta of electromagnetic radiation, and the normative particles that transmit electromagnetic interactions. A photon's resting mass is zero, it has no charge, and its energy is the product of Planck's constant and the frequency of electromagnetic radiation, which can be expressed by the following equation [46]:

$$E = \frac{hc}{\lambda} = hf, \tag{45.1}$$

where h is Planck's constant, $h = 6.6260693 \times 10^{-34}$J. s, c is the speed of light, $c = 2.998 \times 10^{8}$m/s, and f is the frequency of light at different wavelengths. Light composed of high-energy photons has a shorter wavelength, while light composed of low-energy photons has a longer wavelength.

The amount of photon energy can be expressed as electron volts, in addition to joules. The electron volt represents the energy required to raise an electron by one volt; thus, a photon has the energy of $1\text{eV} = 1.602 \times 10^{-19}$J. The above constant hc can therefore be recharacterized in eV [47].

$$hc = \left(1.99 \times 10^{-25}\text{J.m}\right) \times \left(1\text{eV}/1.602 \times 10^{-19}\text{J}\right) = 1.24 \times 10^{-6}\text{eV.m} \tag{45.2}$$

The photon energy equation is transformed into eV and μm, and a common expression is obtained, which represents the relationship between photon energy and the wavelength, as shown below:

$$E(\text{eV}) = \frac{1.24}{\lambda(\mu\text{m})}. \tag{45.3}$$

The photon energy of different bands is different. Table 45.1 shows the frequency, wavelength, and photon energy of photons of different bands.

As can be seen from the table, as the wavelength decreases, the energy carried by the photon gradually increases, that is, the shorter the wavelength, the greater the

Table 45.1 Photon energies for different wavebands [48]

Band	Frequency f/Hz	Wavelength λ/μm	Photon energy hf/eV
Microwaves	3×10^{8}–3×10^{12}	10^{6}–10^{2}	1.2×10^{-6}–1.2×10^{-2}
Infrared light	8.8×10^{11}–4.3×10^{14}	3.4×10^{2}–7×10^{-1}	3.6×10^{-3}–1.7
Visible light	4×10^{14}–7.5×10^{14}	7.6×10^{-1}–4×10^{-1}	1.6–3
Ultraviolet light	7.5×10^{14}–3×10^{16}	4×10^{-1}–10^{-2}	3–120
X-rays	3×10^{16}–3×10^{20}	10^{-2}–10^{-6}	1.2×10^{2}–1.2×10^{6}
Gamma (γ) rays	$>3 \times 10^{19}$	$>10^{-5}$	$>1.2 \times 10^{5}$

energy of the photon. The minimum energy of a microwave is 1.2×10^{-6} eV–1.2×10^{-2} eV, and the maximum energy of a γ ray is more than 1.2×10^{5} eV.

Blackbody Radiation Model

Blackbody radiation is a thermal radiation phenomenon, that is, the law of change in the intensity and frequency of the radiation spectrum emitted by an object at different temperatures. The origin of this theory can be traced back to the early nineteenth century. The law of blackbody radiation was proposed by Planck and Wien and provided the basis for a large number of subsequent physics and astronomical studies [49].

Suppose that a black body is composed of many simple harmonic oscillators of different vibrational frequencies and energy level and that each harmonic oscillator can emit or absorb radiation of a certain frequency (energy). For a harmonic oscillator in an energy state whose energy is E, according to the Boltzmann distribution function, the number of simple harmonic oscillators for that energy state is [50]:

$$n(E) = \frac{g(E)}{\exp\left(\frac{E}{\kappa_B T}\right) - 1}, \tag{45.4}$$

where $g(E)$ is the number of harmonic oscillators in the blackbody at each energy level, κ_B is the Boltzmann constant, $\kappa_s = 1.380 \times 10^{-23}$J/K, and T is the blackbody temperature. At very high temperatures, the -1 term in the denominator can be ignored:

$$n(E) \approx \frac{g(E)}{\exp\left(\frac{E}{\kappa_B T}\right)}. \tag{45.5}$$

Within a certain frequency range, all harmonic oscillators located between energy E and $E + \Delta E$ can emit all the electromagnetic waves with energy of ΔE. Therefore, all electromagnetic waves at that frequency should also have the energy ΔE. Let this frequency range be v to $v + \triangle v$, so the energy flow through this band in a unit time (i.e., the radiation flux density) can be expressed as

$$I_v(v, T) = \frac{g(E)}{\exp\left(\frac{E}{\kappa_B T}\right) - 1} \cdot \frac{hv^2}{\lambda^3}. \tag{45.6}$$

According to electromagnetic wave theory, converting frequency v to wavelength λ yields

$$I_\lambda(\lambda, T) = \frac{hc^2}{\lambda^5 . \exp\left(\frac{hc}{\lambda \kappa_B T}\right) - 1}, \tag{45.7}$$

where λ is the wavelength of light, T is the blackbody temperature in K, h is Planck's constant, $h = 6.626 \times 10^{-34}$J. s, and c is the vacuum speed of light, 3×10^8 m/s.

This is a basic formula used in the fields of cosmology, astrophysics, and infrared technology.

Solar Radiation Model

Figure 45.1 shows a schematic representation of solar radiation from the Sun to the Earth's surface, where β is the ecliptic angle, the direction of the vernal equinox is 0° longitude, and α is called the yellow meridian of the Sun and is the angle between the current line of the Earth and the Sun to the line of the Earth and the vernal equinox. ν_0 is the meridian of perihelion. The axes (X, Y, Z) represent the coordinate system of the equator. It can be transformed by the zodiacal coordinate system (X', Y', Z') according to Eq. (45.8) [51]:

$$\begin{bmatrix} X \\ Y \\ Z \end{bmatrix} = \begin{bmatrix} 1 & 0 & 0 \\ 0 & \cos(\beta) & -\sin(\beta) \\ 0 & \sin(\beta) & \cos(\beta) \end{bmatrix} \begin{bmatrix} X' \\ Y' \\ Z' \end{bmatrix} \tag{45.8}$$

The position of the Sun can be expressed as P_s^y, a function of the day's longitude α: $P_s^y = [r\cos(\alpha) \;\; r\sin(\alpha) \;\; 0]^T$. r is the distance from the Sun to the Earth, which can be expressed as

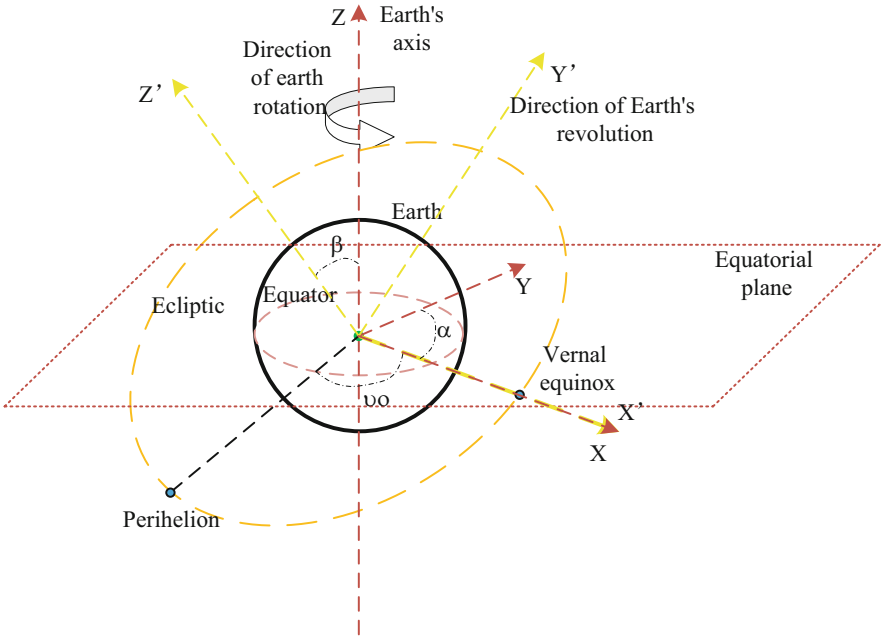

Fig. 45.1 Schematic diagram of solar radiation to the Earth

$$r = A\left(1 - \frac{e(\cos(\alpha + v_0))}{1 + e\cos(\alpha + v_0)}\right), \tag{45.9}$$

where A is the semimajor axis of the Earth's orbit, $A = 1.496 \times 10^{11}$ m, and e is the eccentricity of the solar orbit, $e = 0.016722$. The ecliptic α for a given date can be derived by the following formula:

$$\frac{\int_0^{\alpha} \frac{1}{2} r^2 d\alpha}{\pi A\sqrt{1 - e^2}} = \frac{n}{365}, \tag{45.10}$$

where n is the cumulative day, $\int_0^{\alpha} \frac{1}{2} r^2 d\alpha$, the number of days away from the vernal equinox, $\pi A\sqrt{1 - e^2}$ is the Earth–Sun line from the vernal equinox to the current date across the area, and A is the area of the ecliptic ellipse.

When there is an angle γ between the solar radiation and the surface horizontal normal vector, as shown in Fig. 45.2, the total surface solar radiation intensity can be expressed as [52]

$$E_0 = \frac{M_0}{4\pi r^2} \cos\gamma, \tag{45.11}$$

where M_0 is the external solar radiant power with a constant of 3.9×10^{26} W. $\cos\gamma$ can be given by the following equation:

$$\cos\gamma = \frac{P_s^r n_g^r}{\left\|P_s^r\right\|}, \tag{45.12}$$

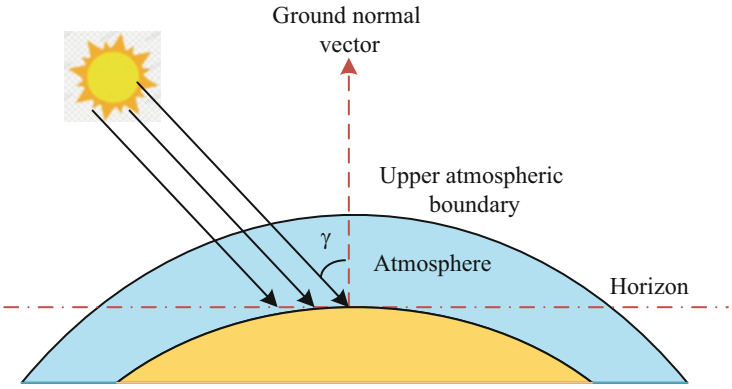

Fig. 45.2 Solar radiation on the ground

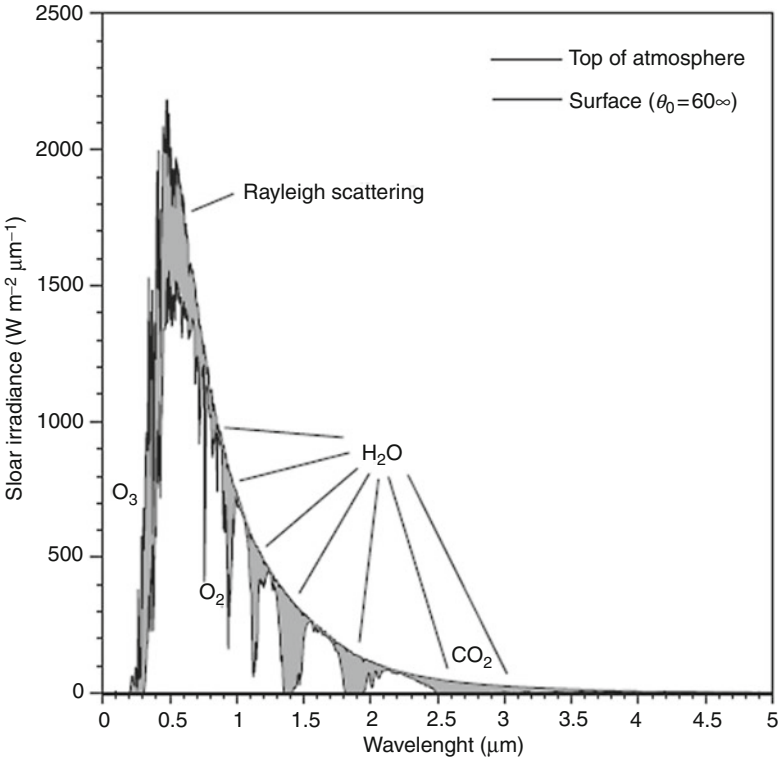

Fig. 45.3 Solar spectrum on a clear day [55]

where P_s^r is the position of the Sun in the equatorial system, which can be derived from the transformation matrix in (45.8); n_g^r is the surface normal vector expressed as $n_g^r = [\cos\theta\cos\phi \quad \sin\theta\sin\phi \quad \sin\phi]^T$, ϕ is the local latitude, and θ is the right ascension. Then, the solar radiation intensity can be expressed as [53, 54]:

$$E_0 = \frac{M_0}{4\pi r^2 \left\| P_s^r \right\|} P_s^r n_g^r. \tag{45.13}$$

Figure 45.3 shows the solar spectrum of the Earth's surface at a zenith angle of 60° in clear weather conditions [55].

Atmospheric Parameters

Atmospheric transparency is an important feature of the radiation climate and a decisive factor for direct ultraviolet radiation on the surface. It not only objectively reflects the atmospheric transparency and atmospheric physical state of optical radiation but is also an important parameter for characterizing the attenuation degree of ultraviolet radiation by the atmosphere [56].

For a certain solar altitude angle, changes in atmospheric transparency and clouds are the main factors that determine the intensity of ultraviolet radiation [57]. Direct radiation is weakened by the reflection and absorption of clouds. However, clouds influence ground long-wave effective radiation through two main aspects: First, the shielding effect of clouds on short-wave direct radiation reduces surface heating, thereby weakening long-wave ground radiation. Second, the presence of clouds increases atmospheric inverse radiation, such that the effective radiation on the ground is weakened to a greater extent [58].

According to the Bouguer–Lambert theorem, when solar radiation I with a wavelength A passes through an atmosphere dm thick, its radiative decay is reduced to [59]:

$$dI_\lambda = -\alpha_\lambda I_0.\lambda dm, \tag{45.14}$$

where α_λ is the extinction coefficient of the atmosphere.

For the solar-blind zone band in daylight, there should be a solution for the entire band from 200 nm to 280 nm:

$$S_m = \int_{0.2}^{0.28} S_0, \lambda P_\lambda^m d\lambda. \tag{45.15}$$

It can be simplified to

$$S_m = S_0 P_\lambda^m \tag{45.16}$$

$$P_\lambda = \sqrt[m]{S/S_0}, \tag{45.17}$$

where P_λ is the compound transparency coefficient, m is the atmospheric mass, and S_0 is the solar constant, $S_0 = 1381.6W.\, m^{-2}$. S_m indicates the solar radiation flux on the ground perpendicular to the surface of the Sun's rays when the atmospheric mass is m.

Equation (45.17) is an exact theoretical equation, not an empirical relationship. P_λ^m increases with m, a phenomenon known as the Forbes effect. The application of this effect greatly limits P_λ. To overcome the Forbes effect, atmospheric transparency must be adjusted to a given atmospheric quality. That is, $m = 2$ describes the calculated integral transparency. P can be divided into six grades: very turbid ($P < 0.625$), turbid ($P = 0.625$–0.675), low transparent ($P = 0.676$–0.725), normal transparent ($P = 0.726$–0.775), high transparent ($P = 0.776$–0.825), and very transparent ($P \geq 0.826$) [60].

According to the measurement data of meteorological stations in various places, China has established P_λ, an empirical check table that is corrected to P. The revised formula derived from the check table is

$$P = (1.91/S_0)^{1/2}(S_h/1.91)^{(\sin h+0.15)/1.3}, \tag{45.18}$$

where h is the solar altitude angle and S_h is the direct solar radiation perpendicular to the solar ray plane.

Solar-Blind Zone UV Background Light Radiation Model

The energy of solar radiation is primarily concentrated in the wavelength range of 0.15 μm–4 μm. This wavelength range can be divided into three main regions: the ultraviolet region with shorter wavelengths, the infrared region with longer wavelengths, and the visible region in between. Solar radiation is mainly distributed in the visible and infrared regions, with the former accounting for 50% of the total solar radiation and the latter accounting for 43%. The ultraviolet region accounts for only 7% of the energy. The capacity of solar radiation reaches its highest value at a wavelength of 0.475 microns.

The radiant capacity of the various wavelengths of the sun can be described by the blackbody radiation model, in which $w(\lambda)$ can be expressed as [61]

$$w(\lambda) = \frac{c^2 h}{\lambda^5}\left\{\frac{1}{\exp[hc/(k\lambda T)] - 1}\right\}, \tag{45.19}$$

where c is the vacuum speed of light, $c = 3 \times 10^8$ m/s; h is Planck's constant, $h = 6.626 \times 10^{-34}$ J s; T is the temperature in Kelvin; and k is Boltzmann's constant, $k = 1.380 \times 10^{-23}$J/K. Then, the percentage of the overall radiation capacity of a certain band of ultraviolet $F_{(\lambda_1-\lambda_2)}$ can be expressed as [62]

$$F_{(\lambda_1-\lambda_2)} = \frac{\int_{\lambda_2}^{\lambda_1} w(\lambda)d\lambda}{\int_0^{\infty} w(\lambda)d\lambda} = \frac{1}{\sigma T^4}\int_{\lambda_2}^{\lambda_1} w(\lambda)d\lambda = \frac{1}{\sigma T^4}\left[\int_0^{\lambda_1} w(\lambda)d\lambda - \int_0^{\lambda_2} w(\lambda)d\lambda\right]. \tag{45.20}$$

For solar-blind ultraviolet communication systems, the sensitive wavelength range of background noise is 200 nm–300 nm, and the main source is sunlight [63]. Figure 45.4 shows the blackbody radiation pattern when the surface temperature of the Sun is 5800 K. The gray area is the ultraviolet background light radiation spectrum, and its integral sum is the sum of the solar background noise in this band.

At latitude ϕ, longitude θ, receiver radius $D_r/2$, filter transmittance η_B, and receiving field of view $\theta_{r,\text{signal}}$, the receiving end of the UV background light power is [64]

$$P_B = F_{(\lambda_1-\lambda_2)} \cdot \eta_B \pi \left(\frac{D_r}{2}\right)^2 E_0 \cdot \left[P^m + \frac{1 - P^m}{2(1 - 1.4\ln P)}\right] \cdot \frac{\pi}{4}\theta_{r,\text{signal}}^2, \tag{45.21}$$

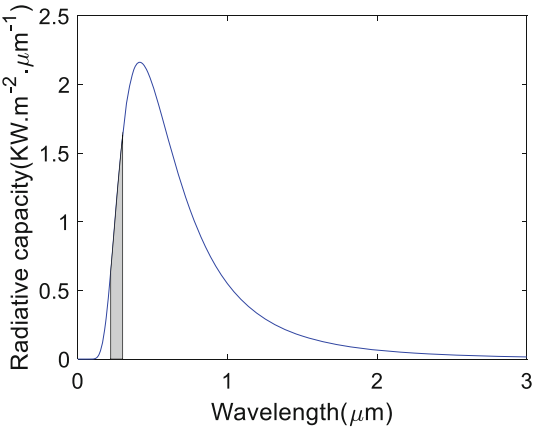

Fig. 45.4 Solar radiation capacity at each wavelength

where $F_{(\lambda_1-\lambda_2)}$ represents the percentage of a certain band to the overall radiation capacity, η_B is the filter transmittance, D_r is the receiver diameter, E_0 is the surface solar radiation intensity, P is the atmospheric transparency, and m is the air quality.

Assume that the measurement time is from 6 a.m. to 6 p.m. on a sunny day and the measurement location is Xi'an, China. The measurement wavelength is 300 nm, the receiver diameter is 10 mm, the receiving field of view is 20 mrad, the filter transmittance is 0.24, and the bandwidth is $\pm$10 nm. The winter solstice in Xi'an was simulated on December 22, 2022; the spring equinox on March 21, 2023; the summer solstice on June 21; and the autumn equinox on September 23.

A schematic diagram of the four solar terms, variation of ultraviolet background light, and days under sunny conditions with the seasons are shown in Fig. 45.5. It can be seen that the background light radiation value of the summer solstice is the largest, those of the autumn and spring equinoxes are similar, and the winter solstice is the smallest. With the change in seasons, the peak daily radiation time will also change. Figure 45.6 shows a comparison of the measured and theoretical values of the winter solstice, spring equinox, summer solstice, and autumn equinox. It can be seen that the winter solstice, spring equinox, summer solstice, and autumn equinox correspond to the theoretical changes in Japanese and Chinese times.

UV Optical Communication Path Loss Model

Single-Scattering Model and Theory

The single-scattering model, proposed by Luettgen et al. [65] in 1991, is an extension of the single-scattering transceiver axis collinear model proposed by Reilly and Warde [66] in 1979, which is essentially a single-scattering coplanar direct integration model, that is, the transceiver axis is coplanar. To facilitate the calculation, the ellipsoid coordinate system shown in Fig. 45.7 is established, and each point in the figure can be uniquely determined by the diameter ξ, corresponding angle η of the radial quantity, and azimuth φ.

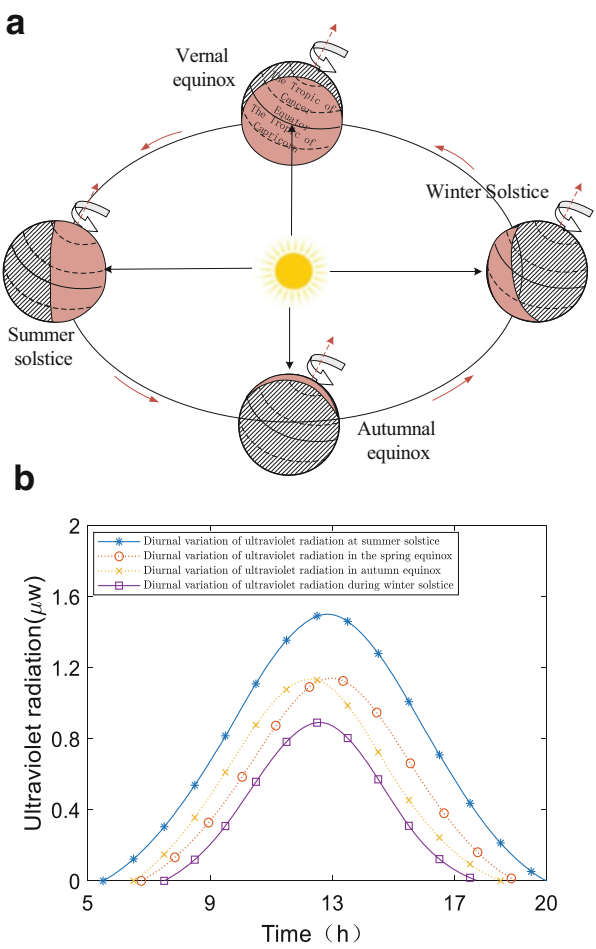

Fig. 45.5 Diurnal variation of four solar terms and ultraviolet background radiation. (**a**) Schematic of the four solar terms. (**b**) Theoretical values of the diurnal variation in ultraviolet radiation in different seasons

As shown in Fig. 45.7, F_1 and F_2 are the two focal points of the ellipsoid, r is the focal length of the ellipsoid, r_1 and r_2 are the two focal radii of the ellipsoid, and ψ_1 ψ_2 are the two focal angles of the ellipsoid.

The transformation relationship of any point under the Cartesian coordinate system (x, y, z) to the ellipsoid coordinate system (ξ, η, φ) is

$$\xi = (r_1 + r_2)/r \ \ (1 \le \xi \le \infty) \tag{45.22}$$

$$\eta = (r_1 - r_2)/r \ \ (\text{-}1 \le \eta \le 1) \tag{45.23}$$

$$\phi = \arctan(y, x) \ \ (\text{-}\pi \le \xi \le \pi) \tag{45.24}$$

$$\theta_s = \psi_1 + \psi_2. \tag{45.25}$$

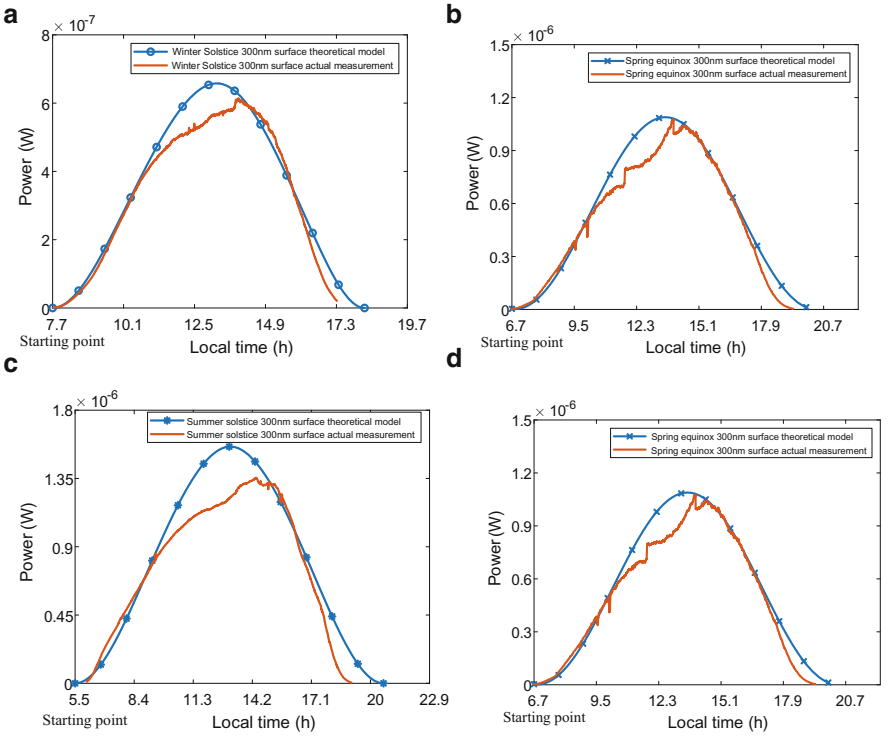

Fig. 45.6 Measured and theoretical values of the winter solstice, spring equinox, summer solstice, and autumn equinox. (**a**) Winter solstice. (**b**) Spring equinox. (**c**) Summer solstice. (**d**) Autumn equinox

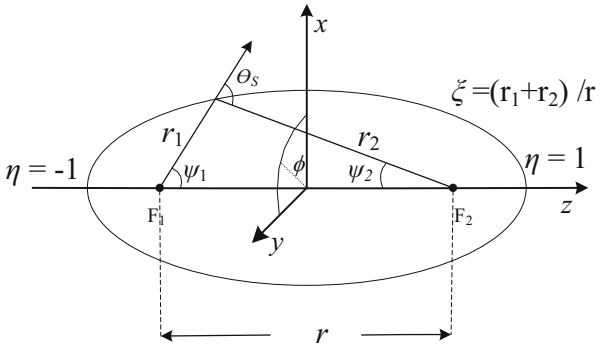

Fig. 45.7 Single-scattering ellipsoidal coordinate system

Equations 45.22 and 45.23 can be solved for r_1 and r_2:

$$r_1 = \frac{r(\xi + \eta)}{2} \tag{45.26}$$

$$r_2 = \frac{r(\xi - \eta)}{2}. \tag{45.27}$$

In an ellipsoidal coordinate system, the focal and scattering angles can be expressed as

$$\cos\psi_1 = (1 + \xi\eta)/(\xi + \eta) \tag{45.28}$$

$$\sin\psi_1 = \sqrt{(\xi^2 - 1)(1 - \eta^2)}/(\xi + \eta) \tag{45.29}$$

$$\cos\theta_s = \left(2 - \xi^2 - \eta^2\right)/\left(\xi^2 - \eta^2\right). \tag{45.30}$$

The single-scattering model is simplified by assuming that photons are emitted from the transmitting end and scattered only once before their arrival at the receiving end. The single-scattering coplanar model is shown in Fig. 45.8. The receiver and transmitter are located on the two focal points of the ellipsoid, F_1 and F_2, respectively; θ_R represents the receiving field-of-view half-angle; θ_T is the transmission field-of-view half-angle; β_R is the receiving elevation angle; β_T is the emission elevation angle; and θ_s is the scattering angle; $\theta_s = \beta_T + \beta_R$.$r$ is the distance between the transmitter and the receiver; r_1 is the distance from the transceiver to the effective scattering point; and r_2 is the distance from the effective scattering point to the receiver. The shaded part is the effective scattering volume V, that is, after one scattering, only the atmospheric light signal located in volume V can be received by the receiver.

It was assumed that the emission and receiving optical axes were in the same plane, and the influence of atmospheric turbulence was not considered. At moment

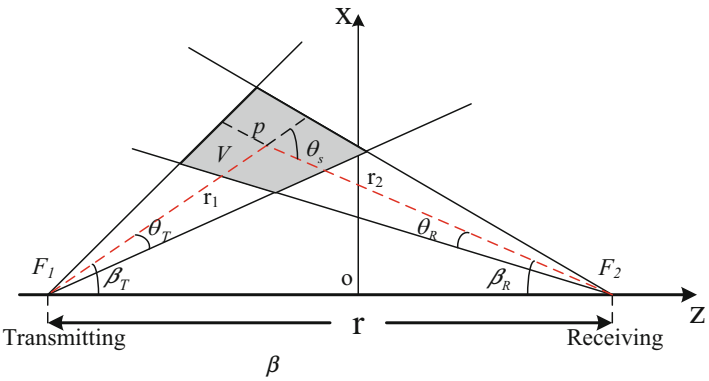

Fig. 45.8 Single-scattering NLOS model

$t = 0$, the emitter emits a pulse of ultraviolet light with an impulse response energy E_T and leaves the emitter at emission elevation angle β_T. After scattering and absorption by the atmosphere, it reaches point $p = (\xi, \eta, \varphi)$ at a distance r_1 from the emitter. $t = r_1/c$, where c is the vacuum speed of light. The energy at point p is

$$H_p = \frac{E_T \exp(-k_e r_1)}{\Omega_r \left(r_1^2\right)}, \tag{45.31}$$

where $\Omega_r = 2\pi(1 - \cos\theta_T)$ is the inherent cone angle of emission and k_e is the atmospheric extinction coefficient.

The differential volume element dV can be thought of as a secondary light source and can be seen as a spherical point light source that emits the following energy:

$$dR_p = k_s \frac{E_T \exp(-k_e r_1)}{\Omega_r \left(r_1^2\right)} \cdot \frac{P(\cos\theta_s)}{4\pi} dV. \tag{45.32}$$

The energy dR_p reaches the receiver after transmission distance r_2, and the energy received per unit area of the receiver is

$$\begin{aligned} dH_R &= dR_p \cdot \frac{\cos(\xi) \exp(-k_e r_2)}{r_2^2} \\ &= \frac{E_T k_s \cos(\xi) \exp(-k_e (r_1 + r_2))}{4\pi \Omega_r (r_1 r_2)} P(\cos\theta_s) dV, \end{aligned} \tag{45.33}$$

where k_s is the angle between the line of the scattering point s and ξ, the center of the receiving surface of the receiving end. $P(\cos\theta_s)$ is a scattering phase function, and $\cos(\xi)$ is the center axis of the cone of the receiving field of view:

$$\cos(\xi) = \sin\beta_R \sin\psi_1 \cos\phi + \cos\beta_R \cos\psi_1. \tag{45.34}$$

In ellipsoidal coordinates, dV can be expressed as

$$dV = \frac{r^3}{8} \left(\xi^2 - \eta^2\right) d\xi d\eta d\phi. \tag{45.35}$$

Substituting Eqs. (45.26), (45.27), and (45.35) into Eq. (45.32) yields

$$dH_R = \frac{E_T k_s \cos(\xi) \exp(-k_e r \xi)}{2\pi \Omega_r r \left(\xi^2 - \eta^2\right)} P(\cos\theta_s) d\xi d\eta d\phi. \tag{45.36}$$

The time for the ultraviolet light pulse to reach the receiver $t = (r_1 + r_2)/c$ and $\xi = (r_1 + r_2)/r$.

$$dE = \frac{E_T c k_s \cos(\xi) \exp(-k_e r \xi)}{2\pi \Omega_r r^2 \left(\xi^2 - \eta^2\right)} P(\cos\theta_s) d\eta d\phi \tag{45.37}$$

At moment $t = \xi r/c$, the integral of Eq. (45.36) provides an acceptable irradiance in W/m^2, which can be expressed as

$$E = \begin{cases} \dfrac{E_T c k_s \exp(-k_e r\xi)}{2\pi\Omega_r r^2} \displaystyle\int_{\eta_1(\xi)}^{\eta_2(\xi)} \int_{\phi_1(\xi,\eta)}^{\phi_2(\xi,\eta)} \dfrac{\cos(\xi) P(\cos\theta_s)}{\xi^2 - \eta^2} d\eta d\phi & (\xi_{\min} < \xi < \xi_{\max}) \\ 0 & (\text{otherwise}) \end{cases} \tag{45.38}$$

From the symmetry of ellipsoidal coordinates, $\phi_2(\xi, \eta) = -\phi_1(\xi, \eta)$; integrating with regard to φ, Eq. (45.37) can be reduced to

$$E = \begin{cases} \dfrac{E_T c k_s \exp(-k_e r\xi)}{2\pi\Omega_r r^2} \displaystyle\int_{\eta_1(\xi)}^{\eta_2(\xi)} \dfrac{2g[\phi_2(\xi,\eta)] P(\cos\theta_s)}{\xi^2 - \eta^2} d\eta & (\xi_{\min} < \xi < \xi_{\max}) \\ 0 & (\text{otherwise}) \end{cases} \tag{45.39}$$

where $g[\phi_2(\xi, \eta)] = \phi_2(\xi, \eta) \cos\beta_R \cos\psi_1 + \sin \sin\psi_1 \sin[\phi_2(\xi, \eta)]$; integrating the above equation yields the energy density at the receiving point in (J/m^2):

$$H_p = \int_{t_{\min}}^{t_{\max}} E(ct/r) dt. \tag{45.40}$$

The energy received by the receiver is

$$H = A_r . H_R, \tag{45.41}$$

where A_r is the receiving aperture area of the receiver; and then, the path loss is

$$L = 10\lg \frac{E_T}{H}, \tag{45.42}$$

where E_T is the pulse energy emitted by the transmitter.

Multiple-Scattering Model and Theory

The multiscattering propagation model of nonline-of-sight noncoplanar ultraviolet light is shown in Fig. 45.9. We set the transmitting end at the origin of the coordinate system (x, y, z) and the receiving end on the positive semiaxis of the x-axis, and the distance between Rx and Tx is d. Cones C_t and C_r represent the emitted beam and the receiving field of view, respectively. θ_t and ϕ_t represent the elevation and divergence angle half-angles of the transmitting end, respectively. θ_r and ϕ_r represent the receiving elevation and field-of-view angle half-angles, respectively.

α_t is the deflection angle of C_t and α_r is the deflection angle of C_r. S_n is the scattering point of the nth scatter. Here, r_0 is the distance from the transmitter to S_1, r_1 is the distance from the receiver to S_1, and r_n is the distance to S_n. ς_{sn} is the angle between the line of S_n and Rx on the central axis and is the angle between the

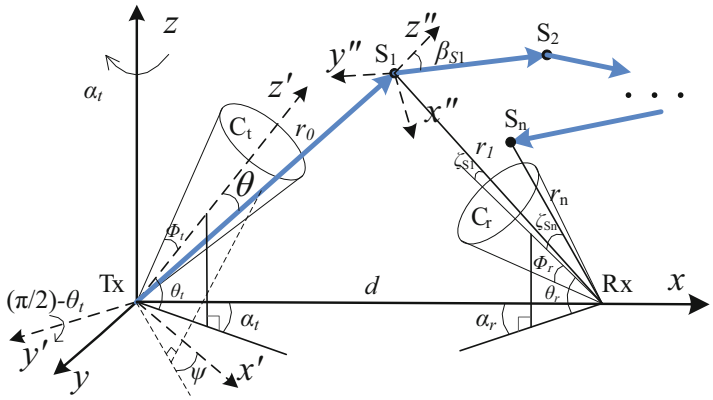

Fig. 45.9 Multiple-scattering propagation model of noncoplanar non-line-of-sight ultraviolet light

direction of photon incidence at the point and the direction of propagation after the photon scattering.

To conveniently describe the direction and distance of a photon transmission, coordinate system (x, y, z) needs to be transformed. The point coordinates based on coordinate system (x', y', z') and those based on coordinate system (x, y, z) are transformed according to Eq. (45.43):

$$\begin{bmatrix} x' \\ y' \\ z' \end{bmatrix} = R_{y'}\left(\frac{\pi}{2} - \theta_t\right) R_z(\alpha_t) \begin{bmatrix} x \\ y \\ z \end{bmatrix}, \tag{45.43}$$

where $R_{y'}\left(\frac{\pi}{2} - \theta_t\right) R_z(\alpha_t)$ is

$$R_{y'}\left(\frac{\pi}{2} - \theta_t\right) R_z(\alpha_t) = \begin{bmatrix} \cos\left(\frac{\pi}{2} - \theta_t\right)\cos\alpha_t & \cos\left(\frac{\pi}{2} - \theta_t\right)\sin\alpha_t & -\sin\left(\frac{\pi}{2} - \theta_t\right) \\ -\sin\alpha_t & \cos\alpha_t & 0 \\ \sin\left(\frac{\pi}{2} - \theta_t\right)\cos\alpha_t & \sin\left(\frac{\pi}{2} - \theta_t\right)\sin\alpha_t & \cos\left(\frac{\pi}{2} - \theta_t\right) \end{bmatrix}. \tag{45.44}$$

Suppose a photon is uniformly emitted in the emitting cone Tx, and any single photon is taken. In coordinate system (x', y', z'), the angle between the propagation direction of the photon and the forward direction of the coordinate axis z' is set to θ. The angle between the photon projection and the coordinate axis in the plane (x', y') is set to ϕ; (θ, ϕ) specifies the direction of the photon. θ is uniformly distributed among $(0, \phi_t)$ and can be found to be

$$\begin{aligned} \cos\theta &= 1 - \xi^{(\theta)}(1 - \cos\phi_t) \\ \phi &= 2\pi\xi^{(\phi)}, \end{aligned} \tag{45.45}$$

where $\xi^{(\theta)}$ and $\xi^{(\phi)}$ are random numbers that follow a uniform distribution in the [0, 1] interval. Thus, in coordinate system (x', y', z'), the directional cosine of the direction of the propagation of the emitted photons can be expressed as

$$\left(u_{x'},\ u_{y'},\ u_{z'}\right) = (\sin\theta\cos\phi,\ \sin\theta\sin\phi,\ \cos\theta). \tag{45.46}$$

From Eq. (45.43), the directional cosine of the photon propagation direction in coordinate system (x, y, z) can be expressed as

$$\begin{bmatrix} u_x \\ u_y \\ u_z \end{bmatrix} = \left[R_y\left(\frac{\pi}{2} - \theta_t\right)R_z(\alpha_t)\right]^{-1} \begin{bmatrix} u_{x'} \\ u_{y'} \\ u_{z'} \end{bmatrix}. \tag{45.47}$$

In the photon transmission process, both Rayleigh and Mie scattering occur; therefore, the scattering phase function can be expressed as the weighted sum of Rayleigh and Mie scattering:

$$P(\cos\beta_s) = \frac{k_s^R}{k_s}P^R(\cos\beta_s) + \frac{k_s^M}{k_s}P^M(\cos\beta_s). \tag{45.48}$$

In the photon propagation process, the angle between the directions of propagation and incidence, that is, the angle of scattering, is determined by the scattering phase function:

$$\xi^{(S)} = 2\pi\int_{-1}^{\mu_{S1}} P(\mu)\mathrm{d}\mu, \tag{45.49}$$

where $\mu_{s1} = \cos\beta_{s1}$ and $\xi^{(S)}$ is a random variable that is uniformly distributed between 0 and 1. $P(\mu)$ can be derived from Eq. (45.48).

The probability that a photon will reach the receiving surface is

$$P_{1n} = \frac{A\cos\zeta_{sn}}{4\pi {r_n}^2}P(\cos\beta_{sn}), \tag{45.50}$$

where A is the area of the receiving aperture and $P(\cos\beta_{sn})$ is the phase function of the n^{th} scattering. The probability that a photon will travel a distance r_n after scattering by point S_n is

$$P_{2n} = e^{-k_e r_n}. \tag{45.51}$$

Therefore, the probability that a photon will reach the receiving surface after the n^{th} scattering is

$$P_n = W_n P_{1n} P_{2n}, \tag{45.52}$$

where W_n is the probability of survival before the photon arrives. W_n can be expressed as

$$W_n = (1 - P_{n-1})\mathrm{e}^{-k_a|\mathrm{S}_n - \mathrm{S}_{n-1}|}W_{n-1}, \tag{45.53}$$

where $|\mathrm{S}_n\text{- }\mathrm{S}_{n\text{-}1}|$ is the distance from scattering point $\mathrm{S}_{n\text{-}1}$ to scattering point S_n.

The probability $P_0 = 0$ of photon scattering directly reaching the receiving end is 0. As the amount of photon scattering increases, the probability of photon survival is smaller, so the maximum photon scattering number is set to $N \leq 5$. During the photon motion, each scattering that occurs is independent of the others, and the probability of a photon arriving at S_n in the receiving plane is

$$P_N = \sum_{n=1}^{N} P_n. \tag{45.54}$$

Suppose that the emitter emits M photons. In this study, $M = 10^6$. The total probability that photon m can travel to the receiving surface of the receiver by a maximum of N scattering times is $(P_N)_m$. The average probability that a photon from the emitter will reach the receiving surface is

$$P = \frac{\sum_{m=1}^{M} (P_N)_m}{M}, \tag{45.55}$$

where $(P_N)_m$ can be obtained using (45.54). P reflects the average probability that a photon from the emitting end reaches the receiving end. The emitting end emits M independent photons. Then, the number of photons that can reach the receiving end is $M \times P$. The path loss of a nonline-of-sight ultraviolet communication system can be calculated as

$$PL = 10\log_{10}\left(\frac{M}{M \times P}\right) = 10\log_{10}\left(\frac{1}{P}\right). \tag{45.56}$$

Path Loss Analysis of Ultraviolet Optical Communications

As shown in Fig. 45.10, there are three NLOS communication modes [67]:

Mode 1: Vertical transceiver mode ($\beta_T = \beta_R = 90°$)
Mode 2: Vertical receive, oblique transmit or vertical transmit, oblique receive mode ($\beta_R = 90°, \beta_T < 90°$ OR $\beta_T = 90°, \beta_R < 90°$)
Mode 3: Oblique transmit–receive mode ($\beta_R < 90°, \beta_T < 90°$)

Assuming that the emitting and receiving optical axes are in the same plane and UV light is scattered once to the receiving plane, the three modes are simulated. The parameters are set as follows: The half-angle of the emitting side is $\theta_T = 45°$, the

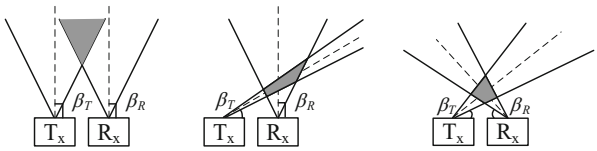

Fig. 45.10 Three modes of operation

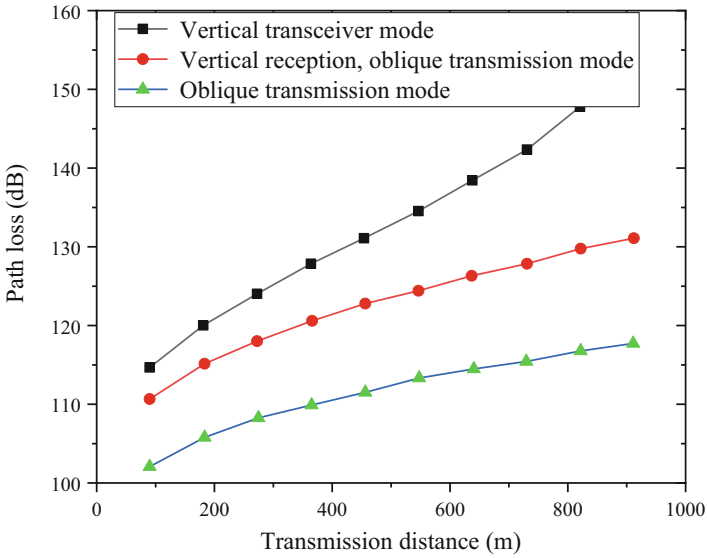

Fig. 45.11 Influence of the three working modes on the path loss

half-angle of the receiving side is $\theta_R = 30°$, wavelength $\lambda = 260$nm, Rayleigh scattering coefficient $\kappa_s^{\text{Ray}} = 0.24\text{km}^{-1}$, Mie scattering coefficient $\kappa_s^{\text{Mie}} = 0.25\text{km}^{-1}$, atmospheric absorption coefficient $\kappa_a = 0.9\text{km}^{-1}$, asymmetry factor $g = 0.72$, model parameter in the scattering phase function $r = 0.017$, and $f = 0.5$.

The simulation results are shown in Fig. 45.11. At the same transmission distance, the path loss of the vertical transceiver mode was the largest, followed by the vertical-receive and oblique-transmit mode, and the path loss of the oblique transmit and receive mode was the smallest. Therefore, when designing a transceiver system, the oblique transmit and receive mode should be chosen, which is more advantageous for ultraviolet communication under the same conditions.

In the third mode, the path loss differs for different receiving and transmitting elevation angles, and the parameter settings do not change. The divergence half-angle of the transmitter was set to $\theta_T = 10°$, and the field-of-view half-angle of the receiver was set to $\theta_R = 30°$. When the receiver angle was fixed at $\beta_R = 45°$, the elevation angle of the transmitter was changed to obtain the path loss. When the angle of the transmitter was fixed at $\beta_T = 45°$, the path loss was simulated by

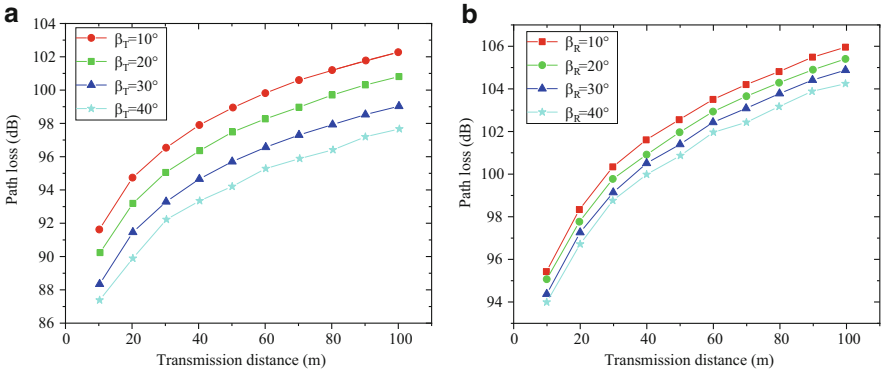

Fig. 45.12 Path loss for different transmit and receive elevation angles. (**a**) Different transmit elevations. (**b**) Different receive elevations

changing the elevation angle of the receiver. The simulation results are shown in Fig. 45.12.

The graph shows that the path loss increases with the increase of the transmit-receive angle, and the effect of changing the elevation angle of the transmitter is obviously greater than that of the receiver. The path loss increases with an increase in the elevation angle of the receiver, but the increase is small; therefore, the elevation angle of the receiver should be fixed and the elevation angle of the transmitter reduced to reduce the path loss.

In an ultraviolet communication system, the nonline-of-sight noncoplanar single-scattering model is more ideal than the NLOS noncoplanar multiple-scattering model. The path loss of the latter can be calculated using both the ergodic element method and the pointing probability method.

The receiving surface radius of the receiving end is 1.5×10^{-2} m, the distance between the receiving end and the sending end is $d = 100$ m, the angle of elevation of the sending end $\beta_T = 30°$, the angle of elevation of the receiving end $\beta_R = 60°$, and the angle of divergence of the sending end $\theta_T = 10°$. The angle of the field of view of the receiving end $\theta_R = 20°$, the angle of offset of the sending end $\alpha_t = 0°$, and the angles of offset of the receiving end are $\alpha_r = \{0°, 5°, 10°, 15°, 20°, 25°, 30°, 35°, 40°, 45°, 50°\}$.

In the pointing probability method, the number of photons sent is set to 10^6 and the parameters of the scattering phase function (γ, g, f) are set to (0.017, 0.72, 0.5). The atmospheric absorption coefficients are the Rayleigh scattering coefficient $k_S^{\text{Ray}} = 0.24 \times 10^{-3}\text{m}^{-1}$ and Mie scattering coefficient $k_S^{\text{Mie}} = 0.25 \times 10^{-3}\text{m}^{-1}$. The simulation results are shown in Fig. 45.13.

Figure 45.13 shows that the path loss increases and the volume of the common scatterer decreases with an increase in the offset angle at the end. The path loss calculated using the pointing probability method and the path loss energy calculated using the ergodic-microelement method both fit well.

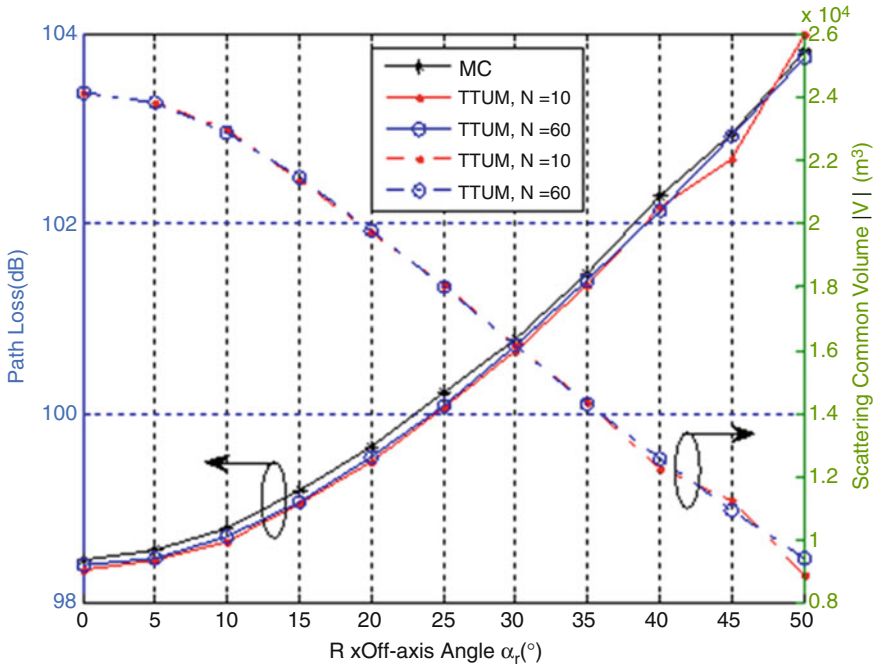

Fig. 45.13 Relationship between path loss and volume of the common scatterer and offset angle of the receiver [68]

UV Light Scattering Channel Characteristics Under Different Weather Conditions

UV Light Scattering Channel Characteristics on Rainy Days

When the ultraviolet light signal and raindrop particles are scattered in a rainy environment, the received ultraviolet light signal will be attenuated to varying degrees. In severe cases, it will interrupt the ultraviolet optical communication link. Therefore, to ensure the normal operation of the communication link, it is necessary to study the attenuation effect of raindrops of different sizes on ultraviolet light. At present, the main models used to describe the shape of raindrop particles are the approximate ellipsoid model, the Beard–Chuang raindrop-shape model, and the Pruppacher–Pitter shape model [69].

When the radii of the raindrop particles are greater than 0.5 mm, the Pruppacher–Pitter approximate raindrop-shape model should be used. The model uses the ratio of the major and minor axis radii a_r/b_r, which can approximate the degree of deformation of raindrop particles. A schematic diagram of the ellipsoid shape is shown in Fig. 45.14. The ellipsoid is formed by the rotation of its major axis a_r and minor axis b_r, and the corresponding ellipsoid shape is described as follows [70]:

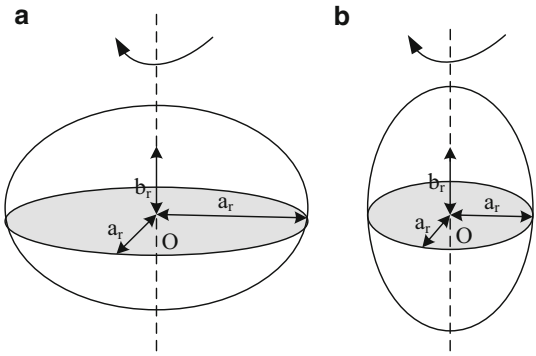

Fig. 45.14 Rotationally symmetric ellipsoids. (**a**) Oblate ellipsoid. (**b**) Long ellipsoid

$$r(\theta_p) = a_r\left(\sin^2\theta_p + \frac{a_r^2}{b_r^2}\cos^2\theta_p\right)^{-1/2}, \tag{45.57}$$

where θ_p represents the angle between the rotation angle and the longitudinal axis.

For deformed raindrop particles, the following mathematical expression [70] applies the Beard–Chuang (BC) model to the generic Chebyshev particle to describe the shape of the particle:

$$r(\theta_p) = r_0\left[1 + \sum_{n_p=0}^{10} c_n \cos(\theta_p n_p)\right], \tag{45.58}$$

where $r(\theta_p)$ is the particle radius corresponding to different orientation angles θ_p; r_0 is the radius of an equal area sphere. c_n is a constant, and $\cos(\theta_p n_p) = T_n(\cos\theta_p)$, which represent Chebyshev polynomials of the n_p order.

The BC model for calculating the shape of raindrops can be approximated as an ellipsoid, based on the deformation of raindrop particles while falling; this is called the approximate ellipsoid model. By considering the symmetry of the cross-section of the raindrop model, the area of the cross-section of the BC model was approximated by volume equality. Suppose the major axis of the approximate ellipsoid model section is a_{pr}; the minor axis is c_{pr}. Since the ellipsoid section is symmetrical along the abscissa axis and the ordinate axis, the short-axis c_{pr} of the approximate ellipsoid is solved by taking half the length of the corresponding longitudinal axis in the BC model, which can be expressed as [70]

$$c_{pr} = \frac{1}{2}\left[r(0^\circ) + r(180^\circ)\right] = r_v(1 + c_0 + c_2 + c_4 + c_6 + c_8 + c_{10}). \tag{45.59}$$

As the area of the section of the ellipsoid model is approximately equal to that of the BC model, the area of the vertical section of the BC model is expressed as

$$\begin{aligned} A &= r_v^2 \int_0^{\pi} \left[1 + \sum_{n_p}^{10} c_n \cos\left(n_p \theta_p\right) \right]^2 \\ &= \pi r_v^2 \left[1 + 2c_0 + c_0^2 + \sum_{n_p=1}^{10} \frac{c_n^2}{2} \right]. \end{aligned} \tag{45.60}$$

a_{pr} approximates the long axis of an ellipsoid model, which can be expressed as

$$a_{pr} = (1.05 - 0.131 r_v)^{-\frac{1}{3}} r_v. \tag{45.61}$$

Because raindrop particles in rainy environments have different scales, it is necessary to consider raindrop particles of different sizes in combination with the particle size distribution. A large amount of measured data shows that the size distribution of raindrop particles can be based on a negative exponential Marshall–Palmer (M-P) raindrop spectral distribution model. Its expression is

$$N(D) = 8 \times 10^3 \exp\left(-4.1 R^{-0.21} D\right), \tag{45.62}$$

where $N(D)$ represents the unit volume, that is, the number of raindrop particles in the unit radius interval, R represents the rainfall rate (mm/h), and D represents the radius of the raindrop particles.

The simulation results are shown in Fig. 45.15. It can be seen from the figure that for the same raindrop particle radius, the larger the rainfall rate, the more raindrop particles. The number of raindrops is distributed negatively exponentially with the increase of raindrop particle size.

In practical applications, raindrop particles of different sizes and number densities are randomly distributed in the atmosphere; therefore, the scattering effect of raindrop particles should be considered. The M–P spectral distribution can be used to calculate the attenuation caused by the raindrop particle swarm.

According to the relationship between the droplet size distribution and particle number density in Fig. 45.15, it can be concluded that the raindrop particle radius is mainly concentrated in the range of 0.1 mm–3 mm. The number of particles per unit volume can be determined based on the rainfall intensity. Using the above experimental conditions, a UV light path with a 260 nm wavelength under different rainfall conditions was simulated and analyzed.

The experimental wavelength $\lambda = 260$nm, elevation angles $\beta_R = \beta_T = 10°$, divergence angle $\theta_T = 30°$, receiving field angle $\theta_R = 60°$, receiving aperture $A = 1.66\ \text{cm}^3$, and a 1-mW emitting light power were assumed. The precipitation particle sizes, scattering coefficients, and absorption coefficients under different rainfall conditions are listed in Table 45.2.

Mie scattering is the main consideration in the scattering of UV light by raindrops. The results of the receiver power simulation are shown in Fig. 45.16.

Figure 45.16 shows that under different rainfall conditions, the power of the receiving end decreases with an increase in the communication distance, showing a

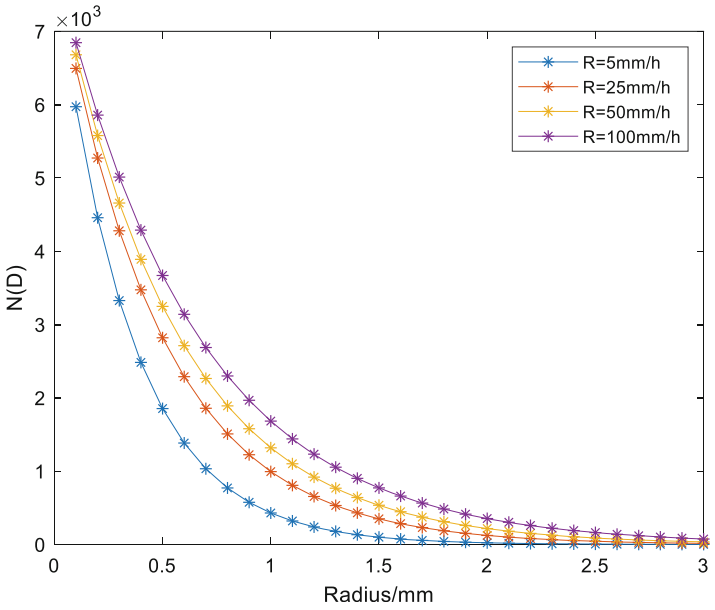

Fig. 45.15 Size distribution of raindrop particles

Table 45.2 Attenuation coefficients at different rainfall rates

Type of rainfall	Particle size (mm)	Scattering coefficient (m^{-1})	Absorption coefficient (m^{-1})
Drizzle	$0.1 < D < 1.5$	1.2×10^{-3}	0.906×10^{-3}
Widespread	$0.5 < D < 2$	3.4×10^{-3}	2.3×10^{-3}
Thunderstorm	$1 < D < 3$	9.3×10^{-3}	6.03×10^{-3}

negative index reduction trend. For the same communication distance, the transmission attenuation of ultraviolet light by thunderstorms is the largest, followed by widespread rain, and a drizzle has the least impact on it. This is mainly because the raindrop particles in a thunderstorm have a strong attenuation effect on ultraviolet light, so the received optical power is small.

UV Light Scattering Channel Characteristics on Foggy Days

According to the standards of the World Meteorological Organization, weather with a visibility of less than 1 km is attributed to foggy days; when the visibility is between 1 km and 10 km, it is considered light fog or haze. Weather with a horizontal visibility of less than 10 km is usually called haze. Haze is different from fog; its water vapor content is small, and the relative humidity is low, while the water vapor content in fog is basically saturated. The differences between foggy and hazy days are presented in Table 45.3.

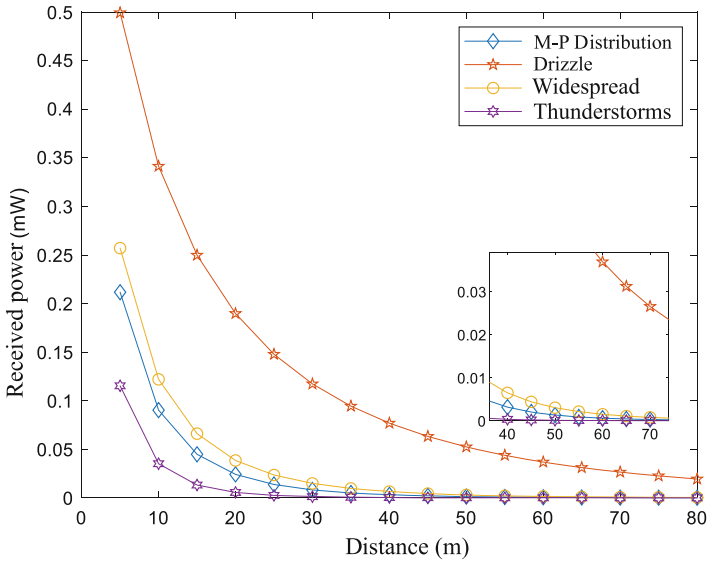

Fig. 45.16 Received power loss under different rainfall conditions

Table 45.3 Foggy and hazy weather characteristics [71]

Weather phenomenon	Composition	Relative humidity	Particle size	Visibility	Color	Concentration distribution
Foggy days	Tiny water droplets, ice crystals	$\geq 90\%$	1 μm–10 μm	< 1 km	Sky is milky white or cyan	Uneven
Hazy days	Fine, dry dust particles, carbon-containing particles, and soluble salts	$\leq 80\%$	0.001 μm–1 μm	< 10 km	Sky appears yellow or orange	Homogeneous and stable

The scale of rainfall and fog particles influences the scattering characteristics of ultraviolet light, and the scale parameters depend on the particle shape, particle size, and concentration distribution. Table 45.4 shows the radii and number densities of atmospheric particles.

Two models are commonly used for the distribution of fog particles: the modified gamma (Γ) function and the generalized gamma distribution. The parameters of the modified Γ function need to be determined by experimental data, so they have fitting errors. The generalized gamma distribution has wide applications, not only for fog particles over continents and oceans but also for aerosols in the stratosphere. The gamma-spectrum model is expressed as follows [72]:

Table 45.4 Radii and concentrations of atmospheric particles [71]

Type	Radius (μm)	Concentration (A/cm^3)
Air molecules	10^{-4}	10^{19}
Aitken	10^{-3}–10^{-2}	10^{-4}–10^{2}
Smog particles	10^{-2}–1	10–10^{3}
Fog particles	1–10	10–10^{2}
Rain particles	10^{2}–10^{4}	10^{-5}–10^{-2}

$$n(r_p) = a_d r_p^{\alpha_d} \exp\left(-b_d r_p^{\beta_d}\right), \tag{45.63}$$

where r_p is the radius of the fog particle, α_d and β_d are the gamma distribution index and are expressed as $a_d = (9.781/(V^6.\ W^5)) \times 10^{15}$, $b_d = (1.304/(V.\ W)) \times 10^4$, and V W are the visibility and liquid water content, respectively. Based on this spectral distribution model, the droplets are divided into advection droplets and radiation droplets, according to the empirical relationship between the water content and visibility [72]:

$$n(r) = 1.059 \times 10^7 V^{1.15} r^2.\exp\left(-0.8359 V^{0.43} r\right) \tag{45.64}$$

$$n(r) = 3.104 \times 10^{10} V^{1.7} r^2.\exp\left(-4.122 V^{0.54} r\right), \tag{45.65}$$

where V is the visibility in km, r is the radius of fog particles in μm, and $n(r)$ is in $\mathrm{m}^{-1}\mu\mathrm{m}^{-1}$.

Thick fog ($V = 0.05$ km), medium fog ($V = 0.2$ km), and mist ($V = 2$ km) were analyzed. From Eqs. (45.64) and (45.65), the size distributions of the advection and radiation droplets were obtained, as shown in Fig. 45.17.

As shown in Fig. 45.17, at the same visibility, the diameter of advection droplets is larger than that of radiation droplets at the highest droplet concentration: the concentration of advection droplets is two orders of magnitude lower than that of radiation droplets. The lower the visibility, the larger the radius of the droplet under the highest droplet concentration. With a decrease in visibility, the maximum droplet concentration gradually decreases.

When analyzing the performance of direct ultraviolet optical communication systems, the attenuation of optical signals in the atmospheric channel has an important impact on communication performance, and accurately and easily analyzing ultraviolet light attenuation is key. In foggy weather, light attenuation caused by fog is often analyzed using empirical attenuation models, such as the Kim, Kruse, and Nabousi models [72].

The empirical formula used by the Kim and Kruse models is [73]

$$\alpha = \frac{3.912}{V}\left(\frac{0.55}{\lambda}\right)^q, \tag{45.66}$$

where V is the visibility in km, λ is the wavelength of the incident light in μm, q is a constant related to V, and the q values of the Kim and Kruse models are different, as follows:

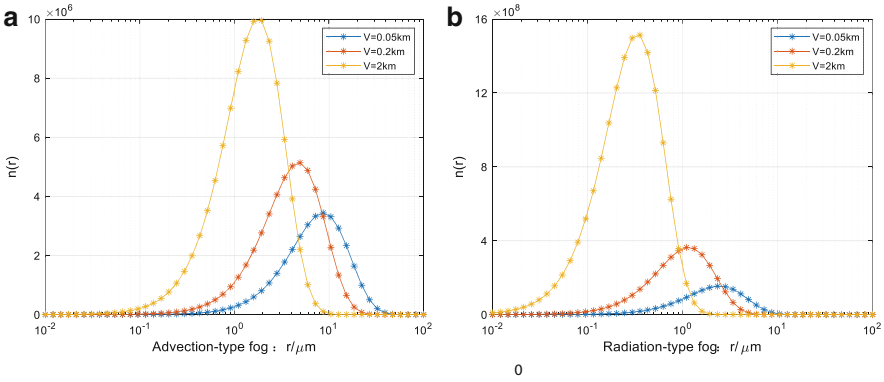

Fig. 45.17 Size distribution of different types of fog particles. (**a**) Advection-type fog particles. (**b**) Radiation-type fog particles

$$q_{\text{Kim}} = \begin{cases} 1.6 & \text{V} > 50\text{km} \\ 1.3 & 6\text{km} < \text{V} < 50\text{km} \\ 1.6V + 0.34 & \text{V} < 6\text{km} \\ V - 0.5 & 0.5\text{km} < \text{V} < 1\text{km} \\ 0 & \text{V} < 0.5\text{km} \end{cases} \tag{45.67}$$

$$q_{\text{Kruse}} = \begin{cases} 1.6 & V > 50\text{km} \\ 1.3 & 6\text{km} < V 50\text{km} \\ 0.585V^{\frac{1}{3}} & V < 6\text{km} \end{cases} \tag{45.68}$$

The Nabousi model divides fog into advection and radiation fogs, and its attenuation models are [74] the following:

$$\alpha_{\text{adv}} = \frac{0.11478\lambda + 3.8367}{V} \tag{45.69}$$

$$\alpha_{\text{rad}} = \frac{0.18126\lambda^2 + 0.13709\lambda + 3.7502}{V}, \tag{45.70}$$

where V is the visibility in km and λ is the wavelength of the incident light in μm. A simulation of the decay coefficients of the three empirical equations at an incident wavelength of 260 nm is shown in Fig. 45.18.

Overall, all three models exhibited a gradual decrease in attenuation with increasing visibility. As shown in Fig. 45.18, the attenuation curves of the Kim and Kruse models are almost identical at a 2-km visibility, while the magnitudes of the attenuation coefficients of the Nabousi model and the first two are quite different. However, as the visibility increased, the difference between the two models gradually decreased.

UV Light Scattering Channel Characteristics on Dusty Days

Sandy and dusty weather is caused by strong winds that carry sand, soot particles, etc., into the atmosphere. They are suspended in the atmosphere to form stable forms

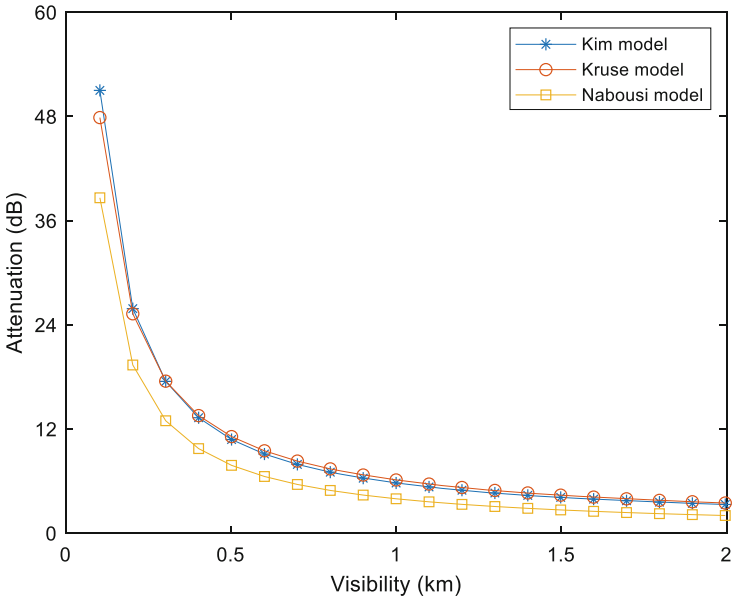

Fig. 45.18 Comparison of three empirical decay models

of dust particles, soot particles, aerosols, etc., resulting in low atmospheric visibility and decreased air quality. The scale spectrum distribution of dusty aerosol particles in the air differs in different grades of dusty weather. Aerosol particles in dusty weather include particles that are difficult to dissolve in water, such as sand, dust, and soot. The size distribution of aerosol particles in dusty weather follows a lognormal distribution, and the scale spectral distribution function is [75]

$$n(r) = \frac{N_0}{r\sqrt{2\pi}\lg\sigma} \exp\left\{-\frac{1}{2}\left[\frac{\lg r - \lg r_m}{\lg\sigma}\right]^2\right\}, \tag{45.71}$$

where r is the radius of the aerosol particle, r_m is the average radius of the particle, σ is the standard deviation, and N_0 is the particle number density. The scale spectral distribution probability density function of aerosols in this weather is expressed as

$$p(r) = \frac{1}{r\sqrt{2\pi}\lg\sigma} \exp\left\{-\frac{1}{2}\left[\frac{\lg r - \lg r_m}{\lg\sigma}\right]^2\right\}. \tag{45.72}$$

Table 45.5 shows the parameters of different types of aerosol commonly found in dusty weather [76].

Because N_0 is a very difficult physical quantity to measure, the concentration of dust aerosols is often described using the visibility, V, when studying the attenuation of UV light transmission during dusty weather:

Table 45.5 Scale distribution model parameters of different types of aerosol

	Dust type	Soot type
r_m	0.5	0.0118
σ	2.99	2.00

$$N_0 = \frac{15}{8.686 \times 10^3 \pi V \int_{r_1}^{r_2} r^2 p(r) dr}. \tag{45.73}$$

According to the parameters of different types of aerosol, combined with the lognormal distribution of the aerosol scale spectrum distribution function, the scale spectrum distribution of aerosol particles in different visibility and dusty weather conditions was obtained.

As shown in Fig. 45.19, the particle radii of different aerosol types differ in dusty weather. The particle radius of dust-type aerosols is mostly around 10^{-2} μm–1 μm while that of soot-type aerosols is mostly around 10^{-3} μm–10^{-1} μm.

Table 45.6 shows the particle number densities of dust-type and soot-type particles at different visibilities. As shown in the table, the higher the visibility, the lower the number density of the aerosol particles. Equation (45.72) shows that the probability density function of the same aerosol particle's scale spectrum distribution is the same. Under the same distribution probability density function, visibility is the only variable that affects the number and density of aerosol particles; therefore, visibility is inversely proportional to the number and density of aerosol particles.

In dusty weather, visibility affects the particle number concentration of aerosol particles and thus the light attenuation coefficient; therefore, this study considers visibility as the independent variable of the empirical attenuation model in dusty weather. From the Mie scattering theory, it can be seen that the attenuation ability of ultraviolet light through a unit distance is

$$A = 4.343 \times 10^3 \int_{r_1}^{r_2} N_0 C_{\text{ext}}(m, x) P(r) dr, \tag{45.74}$$

where $x = 2\pi r/\lambda$ is the aerosol particle scale parameter and the unit of A is dB/km. The above equation can be simplified to

$$\begin{aligned} A &= 4.343 \times 10^3 \int_{r_1}^{r_2} N_0 C_{\text{ext}}(m, x) P(r) dr \\ &= \frac{15 \int_{r_1}^{r_2} C_{\text{ext}}(r) p(r) dr}{2\pi V \int_{r_1}^{r_2} r^2 p(r) dr}. \end{aligned} \tag{45.75}$$

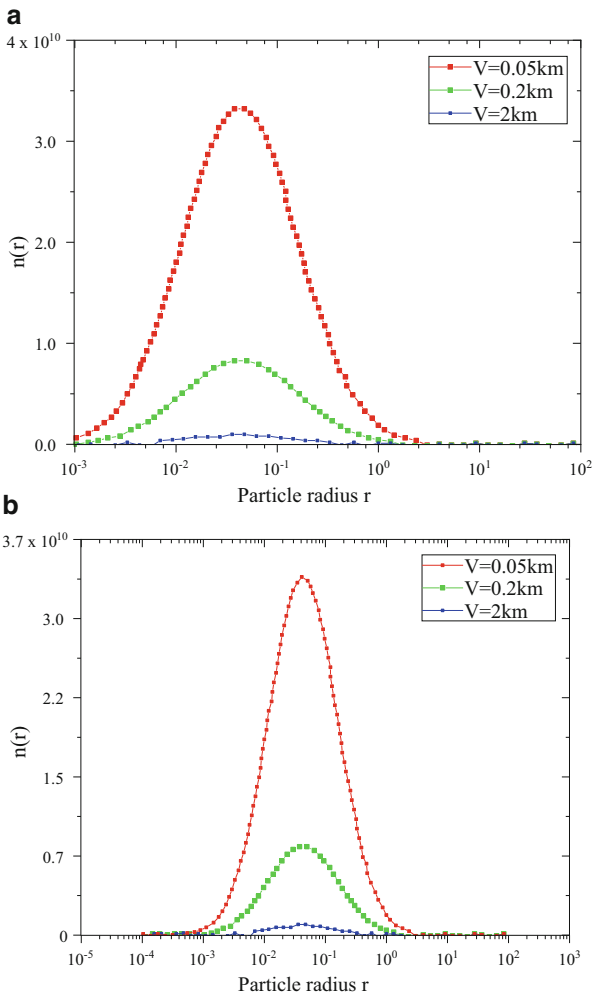

Fig. 45.19 Distribution of different particle scale spectra in dusty weather. (**a**) Dust-type particles. (**b**) Soot-type particles

Table 45.6 Number density of aerosol particles in different visibilities

		Particle number density	
Visibility/km	0.05	0.2	2
Dust-type particles	1.1×10^7	2.75×10^6	2.64×10^5
Soot-type particles	1.1×10^{10}	2.75×10^9	2.67×10^8

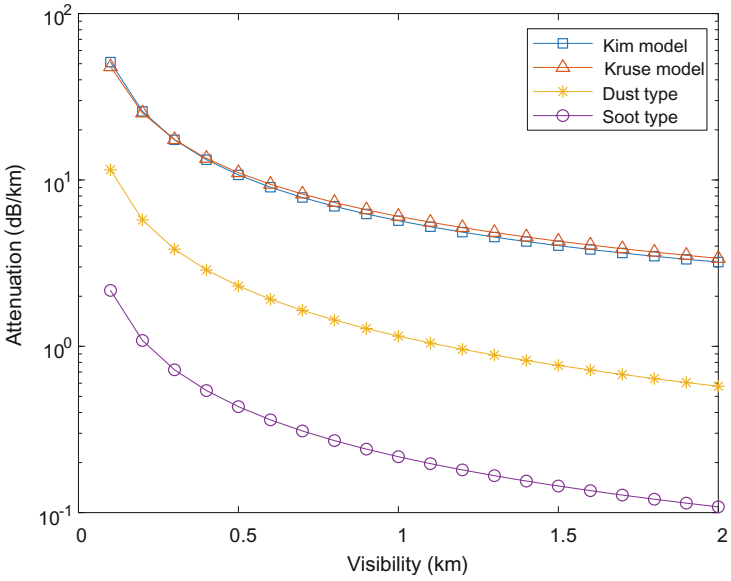

Fig. 45.20 Attenuation coefficients for four attenuation models

For a 260-nm incident wavelength, the results of simulating the attenuation coefficient using the above formula in dusty weather and the attenuation coefficient in foggy weather are shown in Fig. 45.20.

As shown in Fig. 45.20, in the ultraviolet light band, light attenuation in the two types of aerosol environment on foggy days is much greater than that in the two types of aerosol environments in dusty weather; both show exponential attenuation. Among the three aerosol types, the attenuation capacity of ultraviolet light from highest to lowest is fog, sand and dust, and soot.

Experimental Study of the Noise Model Under Different Weather Conditions

Experimental Setup

The experimental device shown in Fig. 45.21 was built to measure the ultraviolet background noise from sunrise to sunset on sunny days during the spring equinox and winter solstice seasons in Xi'an. In the figure, sunlight is transmitted through the atmospheric channel, reaching the surface of detector B (model OPHIR-PD 300-UV) through filter A (220 nm and 300 nm) on the detector surface. The detector then converts the optical signal into an electrical signal and transmits it to the computer. The StarLab 3.62 software was used to store and analyze the data. The

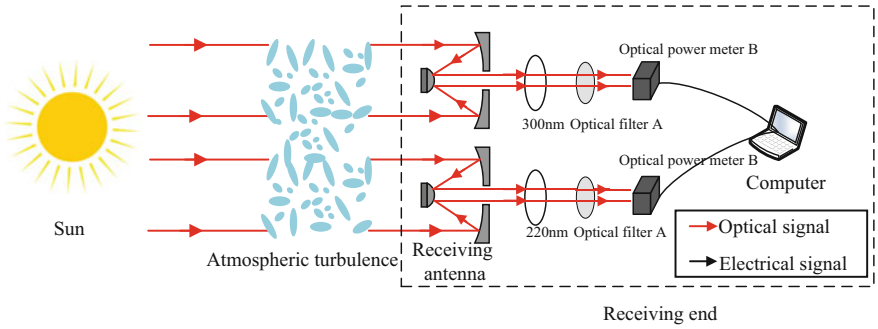

Fig. 45.21 Schematic diagram of experimental measurements

detector sampling frequency was 15 Hz, and the response wavelength was set to the 220-nm and 300-nm bands. The accuracy of the theoretical model was verified by comparison with measured data.

Near Earth Background Light Noise Model

When sunlight passes through the atmosphere, it is scattered by scattering elements, such as atmospheric molecules and aerosol particles, forming a background light in the sky. The complexity of the atmospheric channel constantly changes the radiant intensity of the sky background light, which increases the difficulty of theoretical calculations. The measured and theoretical values vary depending on the weather conditions.

Measured Data Analysis on Sunny Days

To intuitively observe the peak changes on different dates, the accuracy of the verification theoretical model (21) was compared, and the measured and theoretical values of the background noise of ultraviolet light during different periods of sunny days in January and February 2023 in Xi'an were compared. The measurement conditions matched the above simulation conditions, and the ultraviolet background noise in the 220-nm ±10-nm and 300-nm ±10-nm bands were measured simultaneously.

The results are shown in Fig. 45.22. The peak ultraviolet radiation on January 7 is small and the peak is about 12:41; with the passage of time, the daylight time becomes longer, the ultraviolet background radiation increases, the peak gradually increases, and the time of appearance is closer to 13:00. The peak offset reaches the maximum on February 27, and the peak size continues to increase. In sunny weather, the overall ultraviolet radiation trend was consistent with that of the theoretical model.

As shown in Fig. 45.22, the intensity of the UV radiation varies with different dates and bands. On January 7, the daily maximum radiation value at 300 nm was

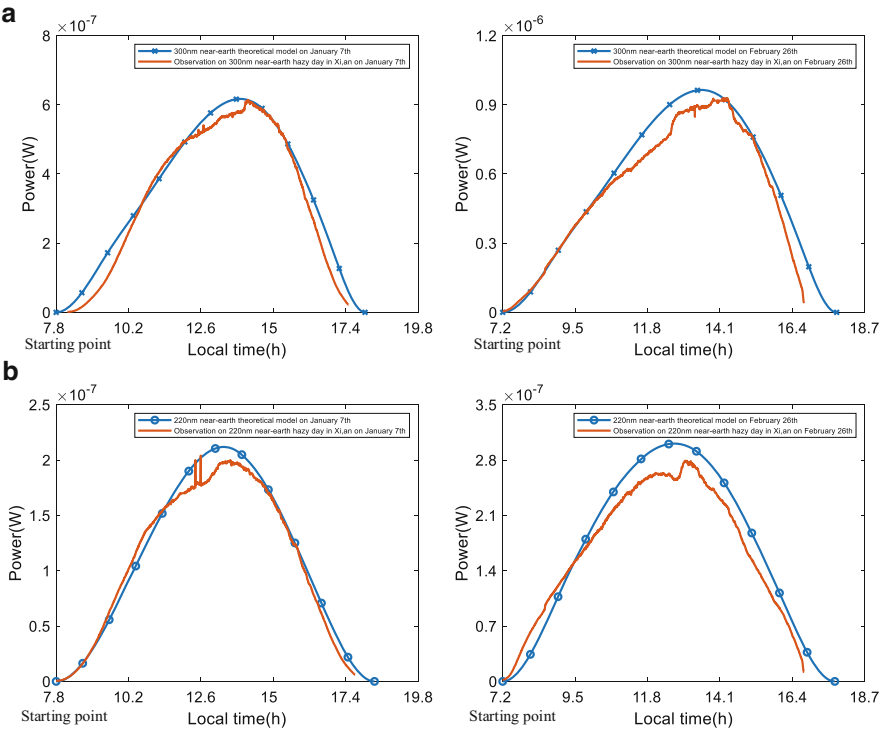

Fig. 45.22 Comparison between theoretical and measured results on a sunny day. (**a**) Results measured at different times on sunny days at a 300-nm wavelength. (**b**) Results measured at different times on sunny days at a 220-nm wavelength

6.14×10^{-7} W and the daily average UV radiation value was 3.46×10^{-7} W. On February 26, the daily maximum radiation at 300 nm was 1.03×10^{-6} W and the daily average ultraviolet radiation was 5.95×10^{-7} W. The maximum measured on February 26 in the 300-nm band was 1.68 times higher than the maximum on January 7.

On January 7, the daily maximum radiation at 220 nm was 2.04×10^{-7} W and the daily average ultraviolet radiation was 1.13×10^{-7} W. On February 26, the daily maximum radiation at 220 nm was 33.10×10^{-7} W and the daily mean UV radiation was 1.87×10^{-7} W. The maximum measured at 220 nm on February 26 was 1.52 times greater than the maximum on January 7.

Measured Data Analysis on Cloudy Days

The theoretical and measured values in sunny weather are basically the same; however, in cloudy weather, owing to the increase in cloud cover, the intensity of ultraviolet radiation is seriously attenuated. Moreover, owing to the influence of atmospheric turbulence and the movement of clouds, the fluctuation of ultraviolet radiation is large and the change trend is irregular.

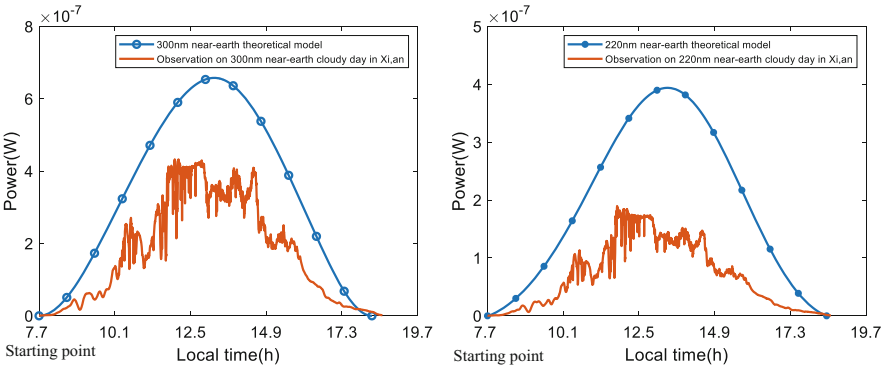

Fig. 45.23 Comparison between theoretical and measured data on cloudy days

As shown in Fig. 45.23, the actual measured values are generally in line with the theoretical trend; however, their values fluctuate greatly and exhibit obvious attenuation. Under cloudy weather, the daily maximum radiation value at the 300-nm band is 4.18×10^{-7} W and the daily average ultraviolet radiation value is 2.48×10^{-7} W. The daily maximum radiation value at the 220-nm band is 1.90×10^{-7} W and the average daily UV radiation value is 6.84×10^{-8} W. This differs from the theoretical value and cannot be used to describe the changing trend of UV radiation in cloudy weather.

Measured Data Analysis on Rainy Days

On rainy days, clouds become denser, the scattering and absorption of water vapor make the attenuation more severe, and the UV radiation amplitude is smaller. Compared with the severe waveband on overcast days, the fluctuation range is gentler and concentrated on rainy days, and the influence of atmospheric turbulence on the cloud layer is not significant.

As shown in Fig. 45.24, the actual measurement is similar to the theoretical trend, reaching a maximum at noon; however, its magnitude varies greatly. In cloudy weather, the maximum daily radiation value of the measured 300-nm band is 1.55×10^{-7} W, and the daily average ultraviolet radiation value is 5.44×10^{-8} W. The maximum daily radiation value of the 220-nm band is 7.00×10^{-8} W, and the daily average ultraviolet radiation value is 2.56×10^{-8} W. The difference between the two is large, compared with the theoretical value, and cannot well characterize the ultraviolet radiation trend in cloudy weather.

Analysis of Measured Data on Hazy Days

The influence of the cloud layer and surface-suspended particles in hazy weather makes the change in the UV background radiation more drastic. The change in the UV background radiation is not correlated with the change in the solar altitude angle but is related to the degree of air turbidity. In the morning, the air is clearer and the UV radiation is higher. As the turbidity of the air increases, the UV radiation

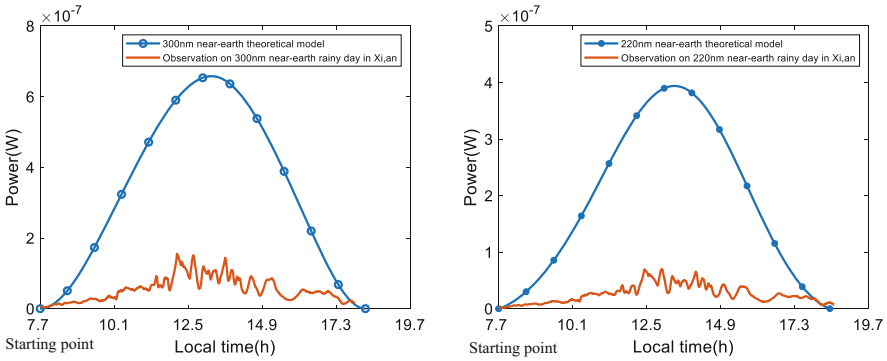

Fig. 45.24 Comparison between theoretical and measured data on rainy days

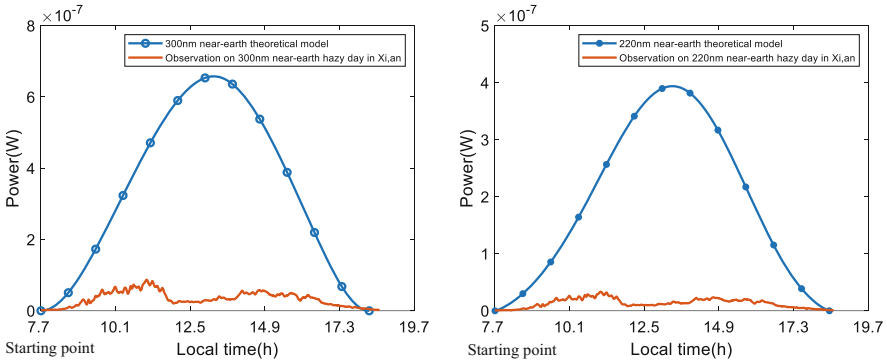

Fig. 45.25 Comparison between theoretical and measured data on hazy days

decreases continuously until the afternoon, when the UV radiation begins to rise; however, by this time, the Sun's altitude angle has begun to decrease. When the air turbidity recovers, there is a brief rise, and then the ultraviolet radiation begins to slowly decrease.

As shown in Fig. 45.25, the actual measured values do not conform to the theoretical trend, and the amplitude difference is large. Under hazy weather, the daily maximum radiation at 300 nm is 1.35×10^{-7} W and the daily average ultraviolet radiation is 4.44×10^{-8} W. The daily maximum radiation at 220 nm is 4.00×10^{-8} W and the daily mean UV radiation is 2.56×10^{-8} W. This is different from the theoretical value and cannot be used to describe the changing trend of UV radiation in hazy weather.

High-Altitude Background Light Noise Model

Based on an existing near-ground noise model, this study measured the ultraviolet background noise during part of a high-altitude period to restore the high-altitude

noise model. To ensure the accuracy of the high-altitude model, high-altitude ultraviolet background noise at 10 km in Urumqi, 8 km in Beijing, 8 km in Nanjing, and 7 km in Yantai were measured from Xi'an.

By comparing the measured data in the high-altitude time period with the near-ground noise model in this period, the expectation of an increased multiple of the high-altitude background noise was obtained, and the wave peak of the high-altitude noise model was determined. Cubic spline interpolation was used to select the correct data on both sides of the wave peak, according to the measured data and other time intervals, and the model was restored.

The principle is to divide the interval $[a, b]$ into n intervals $[((x_o, x_1), \ldots., (x_1, x_2))]$ and (x_{n-1}, x_n) with $n + 1$ points, two of which have two $x_o = a$, $x_n = b$ endpoints. Cubic spline interpolation uses the curve of each interval as a cubic equation. The cubic equation satisfies the condition that for each interval, $[x_i, x_{i+1}]$, $S(x) = S_i(x)$ is a cubic equation satisfying $S_i(x) = y_i$ $(i = 0, 1, \ldots, n)$ and $S(x)$, $S'(x)$ where $S''(x)$ is continuous. Then, these three conditions can be used to construct an equation $S_i(x) = a_i + b_i x + c_i x^2 + d_i x^3$ to obtain a_i, b_i, c_i, and d_i in a complete interpolation function by solving.

Xi'an–Urumqi 10-km Altitude

Figure 45.26 shows the noise model of the restoration of the 10-km high-altitude route between Xi'an and Urumqi. The roundtrip flights to Urumqi were HU7898 and GS7525 at 12:25–16:10 on March 11 and 7:45–11:15 on March 12, respectively.

As shown in the figure, the high-altitude noise model also conforms to the diurnal variation law of the solar altitude angle, in which the maximum value of the 300-nm high-altitude ultraviolet background noise model in Xi'an–Urumqi is 3.416 μW, and the peak appears at about 13:48, which is 3.322 times that of the same time near Earth. The 220-nm band is more seriously absorbed by ozone and the attenuation is more obvious. Its background noise maximum is 1.152 μW and the peak moment occurs at 12:48, which is 3.152 times that of the same time near Earth.

Xi'an–Beijing 8-km Altitude

Figure 45.27 shows the noise model of the 8-km high-altitude route between Xi'an and Beijing. The roundtrip flights to Beijing were HU7238 and HU7237 at 15:30–18:00 on March 6 and 7:50–10:15 on March 7, respectively.

As the figure shows, with a decrease in altitude, the propagation path of sunlight increases and the UV radiation decreases. The maximum value is 2.631 μW and the peak appears at about 13:36, which is 2.623 times of that at the same time on the surface. At 220 nm, the absorption of ozone is more serious and the attenuation is more obvious. The maximum value of background noise is 0.967 μW and the peak time is 12:36, which is 2.696 times that at the same time on the surface.

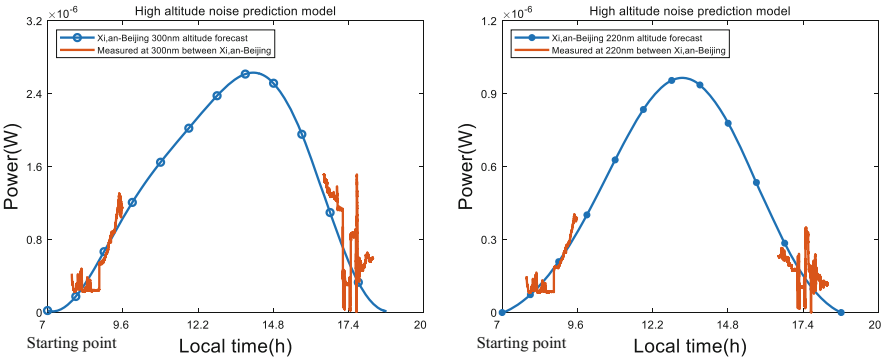

Fig. 45.27 Xi'an–Beijing 8-km altitude on March 7: (left) 300 nm and (right) 220 nm

Xi'an–Nanjing 8-Km Altitude

Figure 45.28 shows the noise model of the restoration of the 8-km high-altitude route between Xi'an and Nanjing. The roundtrip flights to Nanjing were 3 U3259 and MU2200 at 7:00–9:05 on April 15 and 15:55–17:50 on April 16, respectively.

As shown in the figure, the maximum of 300-nm UV background noise in Xi'an–Nanjing is 2.551 μW, which is close to the UV radiation at an 8-km altitude in Xi'an–Beijing, and the peak appears at about 13:42, 2.552 times as large as that of the surface at the same time. The 220-nm band is close to the Beijing route and the maximum background noise is 0.951 μW. The peak time appears at approximately 13:00, which is 2.58 times that at the same time on the surface.

Xi'an–Yantai 7-km Altitude

As shown in Fig. 45.29, the noise model of the Xi'an–Yantai 7-km high-altitude flight route was restored. Flights 9H8397 and HU7506 to Yantai ran from 15:50 to 17:50 on March 31 and from 9:40 to 12:00 on April 3, respectively.

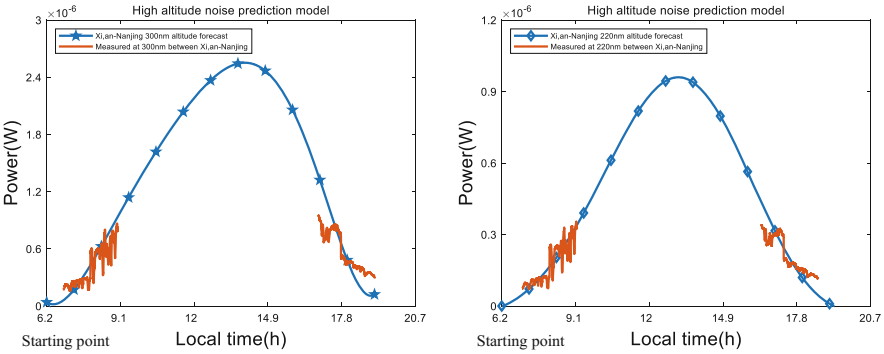

Fig. 45.28 Xi'an–Nanjing at an altitude of 8 km on April 15: (left) 300 nm and (right) 220 nm

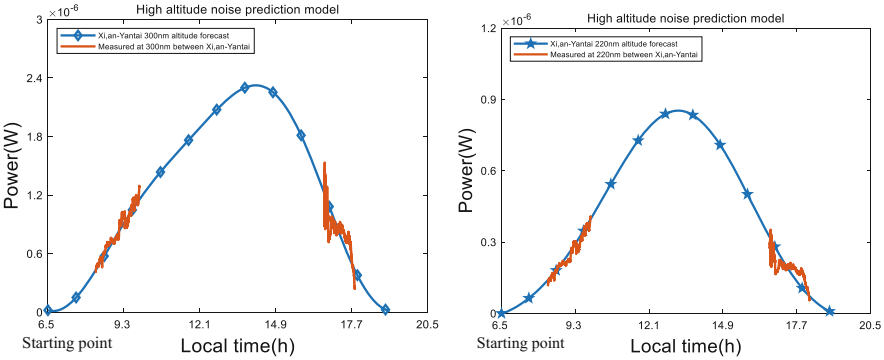

Fig. 45.29 Xi'an–Yantai at an altitude of 7 km on March 31. (left) 300 nm and (right) 220 nm

As shown in the figure, the background noise of 300-nm ultraviolet light at a high altitude from Xi'an to Yantai increases with a decrease in altitude; the propagation path of sunlight increases and the ultraviolet radiation decreases. The maximum value is 2.324 μW and the wave peak appears at about 14:00, 2.260 times that of the surface at the same time. The maximum value of UV background noise at 220 nm is 0.853 μW, and the peak time appears at about 13:00, which is 2.33 times of that at the same time on the surface.

Table 45.7 lists the peak moment, maximum peak, and multiple of the intensity of the UV background radiation compared to the near Earth UV background radiation under different high-altitude conditions.

The experimental results show that the UV background noise at 220 nm is consistent with the variation in the solar altitude angle and reaches its maximum near 13:00. However, the peak of the UV background noise at 300 nm is slightly shifted, and the peak appears at approximately 14:00. The maximum ultraviolet background noise values at 300 nm at 7-km, 8-km, and 10-km altitudes were 2.324 μW, 2.631 μW, and 3.416 μW, respectively, which were 2.26 times, 2.623

Table 45.7 Model parameters of high-altitude background noise in different cities

Region/wavelength	Altitude (km)	Peak time (h)	Peak amplitude (μW)	Multiple
Urumqi/300 nm	10	13.8	3.416	3.322
Urumqi/220 nm	10	12.8	1.152	3.152
Beijing/300 nm	8	13.6	2.631	2.623
Beijing/220 nm	8	12.6	0.967	2.696
Nanjing/300 nm	8	13.7	2.551	2.552
Nanjing/220 nm	8	13	0.951	2.58
Yantai/300 nm	7	14	2.324	2.26
Yantai/220 nm	7	13	0.853	2.33

times, and 3.322 times the surface noise, respectively. UV background noise values at 220 nm were 0.853 μW, 0.967 μW, and 1.152 μW, which were 2.33 times, 2.696 times, and 3.15 times that of the surface noise, respectively.

Above the clouds, UV radiation increases by 20–23% for every 1000-m increase in altitude. For an all-weather ultraviolet communication system, the threshold of the filter can be flexibly adjusted to filter the background noise according to the time change in clear weather to improve the stability of the UV communication system.

Data Correlation Function Analysis

As shown in Fig. 45.30, the correlation function of the 300-nm and 220-nm bands at high altitudes in each city shows that the similarity between the two bands is relatively high. This indicates that the measurement environment of the two bands is the same, the change trend is similar, and the measurement results are not affected by other factors. The similarity between the two bands is the strongest at the same time, and as the delay increases, the correlation coefficient decreases exponentially, indicating an uncorrelated nature.

Analysis of Light Intensity Distribution Characteristics of Ultraviolet Optical Communication

Ultraviolet Indirect Turbulence Model

Figure 45.31 shows a geometric sketch of an NLOS UV single-scattering transmission when there is atmospheric turbulence in the UV communication link. The NLOS transmission path is divided into two LOS links: the first from the Tx to the common volume V (link length l) and the other from the scattering volume V to the Rx (link length L). It is assumed that the Tx emission plane is C_t and the Tx beam angle is small, so that the flicker caused by turbulence in the scattering volume V is constant. To facilitate processing, the received optical power is calculated using the single-scattering principle.

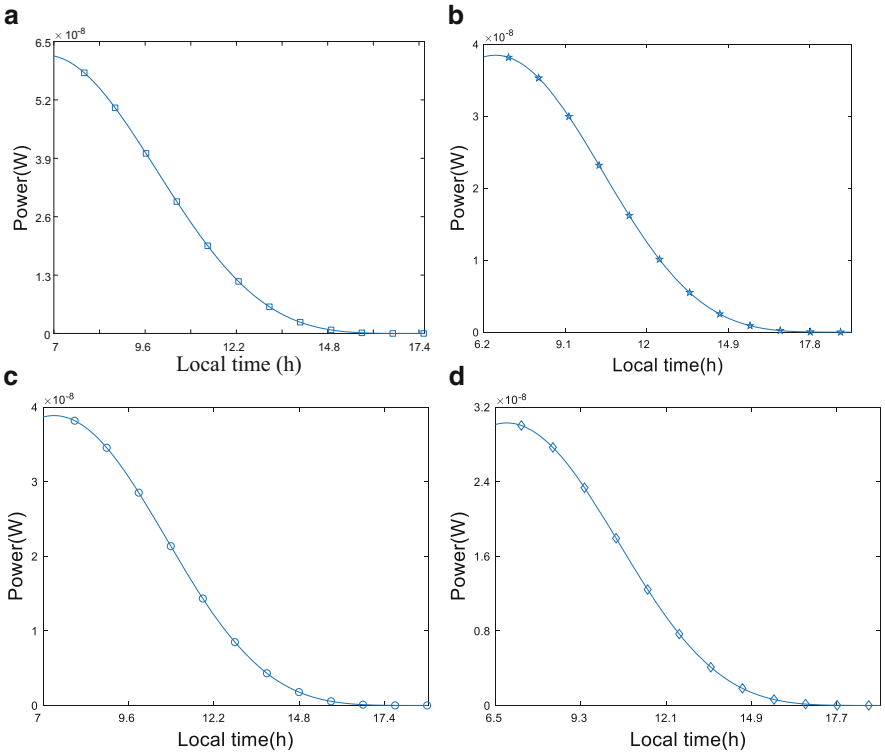

Fig. 45.30 High-altitude 300-nm and 220-nm-band correlation functions. (**a**) Correlation function for Xi'an–Urumqi. (**b**) Correlation function for Xi'an–Beijing. (**c**) Correlation function in Xi'an–Nanjing. (**d**) Correlation function in Xi'an–Yantai

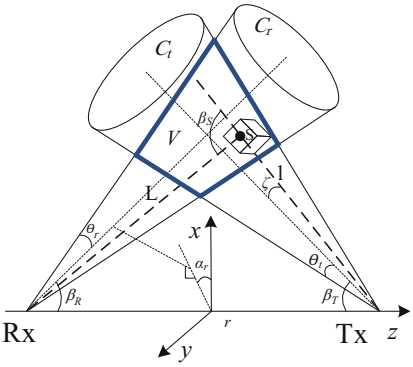

Fig. 45.31 Ultraviolet optical communication link in a turbulent atmosphere

When considering UV attenuation, both the optical power attenuation caused by scattering and absorption and the flicker attenuation caused by turbulence are considered to obtain a more accurate optical power PDF. The flickering attenuations of the two LOS links are

$$\alpha_{\text{turb_}l} = 2.\sqrt{23.17.C_n^2.(2\pi)^{7/6}.l^{11/6}} \tag{45.76}$$

$$\alpha_{\text{turb_}L} = 2.\sqrt{23.17.C_n^2.(2\pi)^{7/6}.L^{11/6}}. \tag{45.77}$$

The flicker attenuation caused by turbulence was simulated using Eq. (45.76), as shown in Fig. 45.32. It can be seen that as the communication distance or turbulence intensity increases, the flicker attenuation increases. In addition, it can be seen from the above equation that as the wavelength of the light wave decreases, the flicker attenuation increases and the flicker becomes more intense. This implies that UV light is more affected by turbulence than traditional free space optical communication, owing to its smaller wavelength.

The ultraviolet optical communication link is composed of links from the transmitting end to the scattering point and the scattering point to the receiving end. Then, the flicker attenuation of the entire indirect UV optical communication link is

$$\alpha_{\text{turb}} = \alpha_{\text{turb_}l} + \alpha_{\text{turb_}L}. \tag{45.78}$$

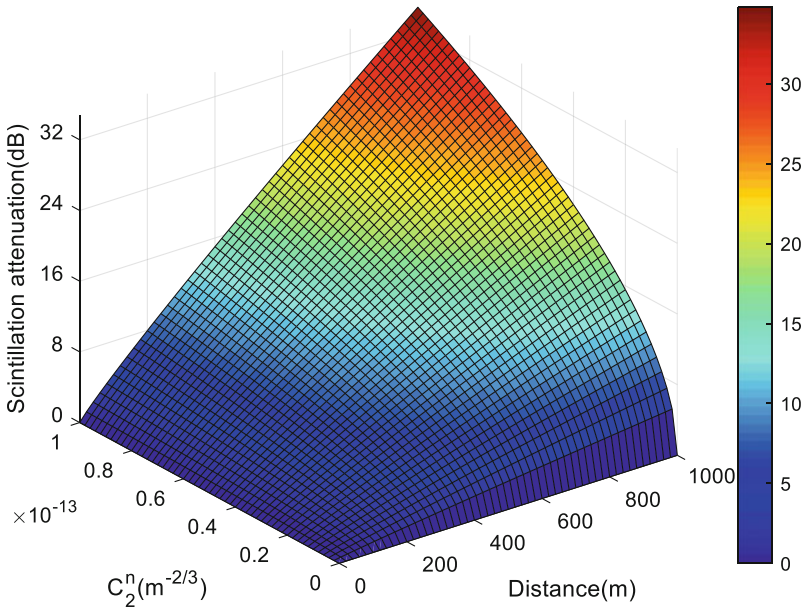

Fig. 45.32 Scintillation attenuation as a function of turbulence intensity and distance

For the link before scattering, the log normal distribution of the optical power reaching the scattering volume V PDF is

$$p(P_i) = \frac{1}{\sqrt{2\pi}\sigma_l P_l} \exp\left\{ -\frac{\left[\ln(P_l/P_{l0}) - \langle \ln(P_l/P_{l0})\rangle\right]^2}{2\sigma_l^2} \right\}, \tag{45.79}$$

where P_i is the power at scattering volume $V$and σ_l^2 is determined by a plane wave or spherical wave. The average optical power when the turbulence is not considered is $P_{l0} = P_T k_s V \exp(-k_s l)/(\Omega_T l^2)$, where P_T is the emitted optical power. $\langle P_l/P_{l0}\rangle$ can be expressed as

$$\langle P_l/P_{l0}\rangle = \exp\left[\left\langle \ln(P_l/P_{l0}) + \sigma_l^2/2\right\rangle\right]. \tag{45.80}$$

Defining α_{PL_l} as the path loss due to absorption and scattering,

$$\alpha_{PL_l} = 10\lg(P_T/P_{l0}). \tag{45.81}$$

When accounting for attenuation due to turbulent flickering, the total path loss is

$$\alpha_{\text{turb}_l} + \alpha_{\text{turb}_L} = 10\lg(P_T/\langle P_l\rangle). \tag{45.82}$$

A geometric transformation of the above equation can be obtained:

$$\langle \ln(P_l/P_{l0})\rangle = -\sigma_l^2/2 - \left(\alpha_{\text{turb}_l}.\ln 10\right)/10. \tag{45.83}$$

Substituting Eq. (45.82) into Eq. (45.79) yields

$$p(P_l) = \frac{\exp\left\{ -\frac{\left[\ln(P_l/P_{l0}) + \sigma_L^2/2 + \left(\alpha_{\text{turb}_l}\cdot \ln 10\right)/10\right]^2}{2\sigma_L^2} \right\}}{\sqrt{2\pi}\sigma_l P_l}. \tag{45.84}$$

Similarly, for the scattered link, the conditional PDF for the optical power received by Rx is

$$p(P_R, P_l) = \frac{\exp\left\{ -\frac{\left[\ln(P_R/P_{L0}) + \sigma_L^2/2 + \left(\alpha_{\text{turb}_L}\cdot \ln 10\right)/10\right]^2}{2\sigma_L^2} \right\}}{\sqrt{2\pi}\sigma_L P_R}, \tag{45.85}$$

where P_R is the received optical power and the variance σ_L^2 is calculated from the turbulence intensity. The average received optical power without considering turbulence is $P_{L0} = P_l P(\theta_s) A_R \cos(\xi) \exp(k_e L)/(4\pi L^2)$. Thus, the P_R edge of the PDF is

$$p(P_R) = \int p(P_l, P_R) dP_l = \int p(P_R|P_l) p(P_l) dP_l. \tag{45.86}$$

Ultraviolet Indirect Vision PDF Experimental Measurements

The probability density function was measured in sunny, rainy, and hazy weather conditions, in which the distance between the receiving and transmitting ends was 4 m and the transmission power was 20 mW. Figure 45.33 shows the probability density function of the measured ultraviolet light intensity under different transmission and reception elevation angle conditions.

As shown in Fig. 45.33, the probability density function of the received optical power is basically in line with the Gaussian model for different weather conditions. After normalizing the received power value, the variance of the probability density function differs under different weather conditions and transmission and reception elevation angles; however, the change trend is basically the same.

After the signal emitted by the transmitting end passes through the atmospheric channel, different transmission and reception elevation angles have different effects on the attenuation, and the magnitude of the path loss also differs. When the elevation angle of the signal is increased from $\beta_R = \beta_T = 20^\circ$ to $\beta_R = \beta_T = 40^\circ$, the energy of the signal decreases gradually, and the variance of the probability density function of the signal strength changes little. However, when the elevation angle of the signal increases to $\beta_R = \beta_T = 60^\circ$, the attenuation of the signal energy is more serious, that is, with the synchronous increase of β_R and β_T, the variance of the signal strength probability density function increases, and the energy attenuation gradually increases.

To reflect the distribution of light intensity under different receiving angles, the light intensity of different receiving elevation angles was measured, and the results are shown in Fig. 45.34. The probability density function of the ultraviolet light intensity was measured by changing the elevation angle of the receiving end. The distance between the receiving and transmitting ends was 4 m, the transmission power was 20 mW, and the elevation angle of the transmitting end was fixed at $\beta_T = 80^\circ$.

It can be seen from Fig. 45.34 that the probability density function of the received optical power conforms to the Gaussian model, and after normalizing the received power value, the variance of the probability density function differs under different transmission and reception elevation angles. After the signal emitted by the transmitting end passes through the atmospheric channel, different transmission and reception elevation angles have different effects on its attenuation, and the size of the path loss is also different.

With the increase of the receiving elevation angle β_R, the signal energy attenuation is very small, and the variance of the signal strength probability density function changes very little, indicating that the influence of the β_T/β_R ratio on the energy attenuation of the communication signal is greater. Therefore, when designing an ultraviolet optical transceiver system, the receiving elevation angle should be fixed as much as possible, and the emission elevation angle should be reduced to reduce the path loss.

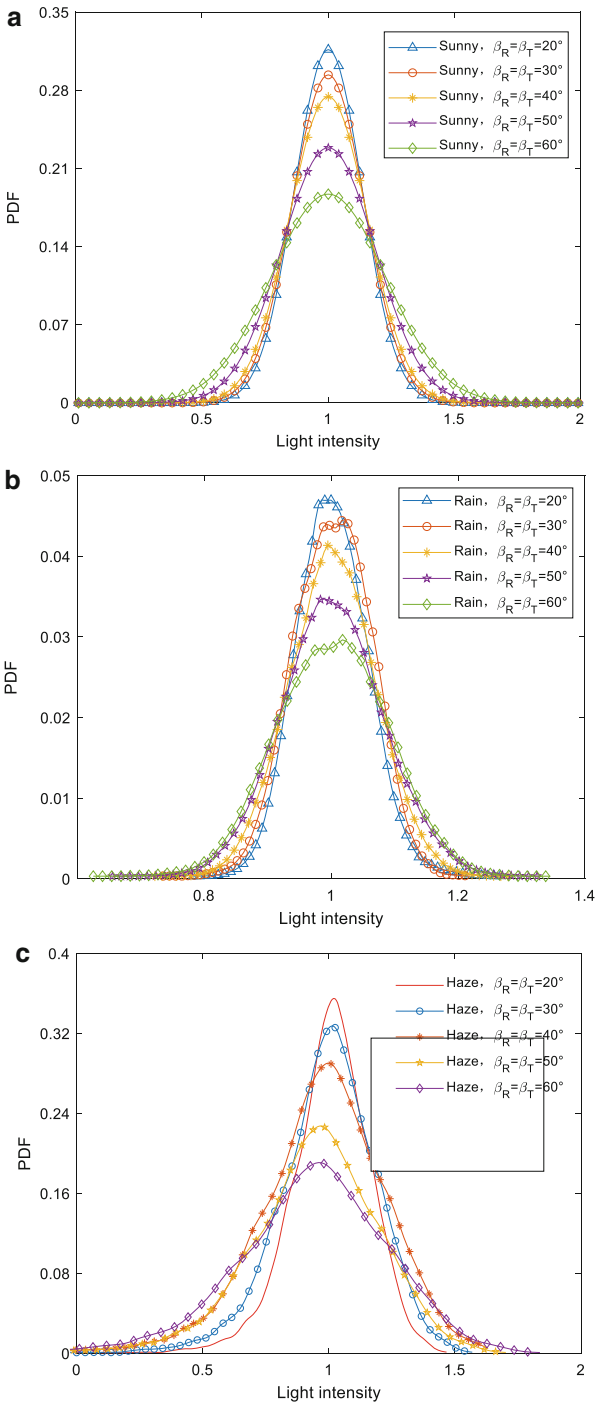

Fig. 45.33 Probability density function of light intensity at different elevation angles for different weather conditions. (**a**) Probability density function of light intensity on sunny days. (**b**) Light intensity probability density function on rainy days. (**c**) Light intensity probability density function on hazy days

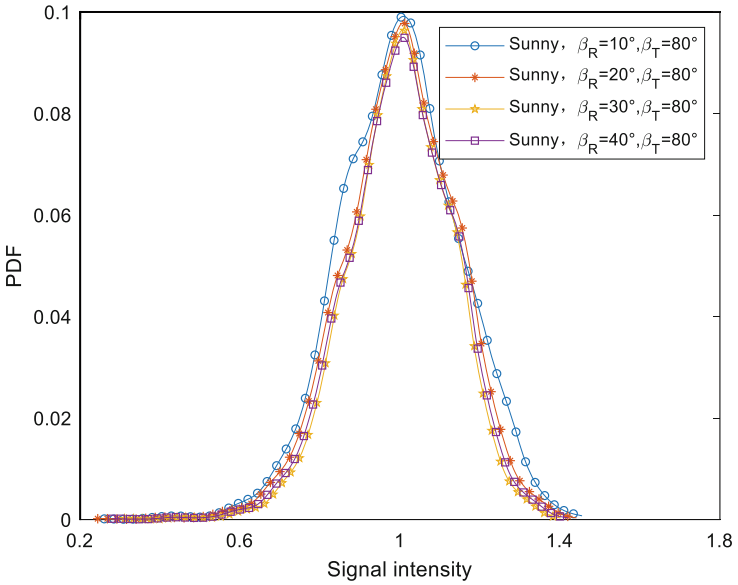

Fig. 45.34 Light intensity probability density function at different receiving elevation angles

Summary

In this study, an experimental measurement method was deduced, changes in ultraviolet background radiation at different times and seasons under sunny weather conditions were derived, and the effectiveness of the theoretical model was verified by comparison with the measured data. In addition, this study compared and analyzed the differences between the measured data and theoretical models in cloudy and hazy weather conditions.

Based on a theoretical model at the surface, the ultraviolet light noise distribution at high altitudes was measured, and the change in high-altitude noise was restored. The physical characteristics of aerosol particles in low-visibility environments, such as rainy days, foggy days, and dusty weather, were analyzed separately.

Moreover, a new empirical attenuation model was used to simplify the asymmetric factors in the scattering phase function for the common empirical model of optical attenuation for the analysis of ultraviolet atmospheric channel attenuation, complex calculation of the multiscattering transmission model, and short ultraviolet communication distance in low-visibility environments. Finally, the light intensity distribution characteristics of ultraviolet optical communication under different weather conditions and transmission and reception elevation angles were analyzed.

Optical wireless/radio frequency hybrid communication · Atmospheric turbulence · Switching mechanism · Relay protocol

Introduction

Hybrid optical wireless communication/radio frequency (OWC/RF) systems make up for the limitations of a single communication system. They maximize the advantages of optical wireless communication while making up for the shortcomings of radio frequency communication. They significantly improve link availability and reliability and provide a unique solution for future high-speed and high-capacity information transmission.

Optical wireless communication (OWC) [1] uses light as a carrier wave for transmissions in space. It has high speed, high capacity, and high confidentiality, does not need for spectrum licensing, and has received considerable attention in recent years. However, OWC is affected by atmospheric turbulence, weather conditions (fog, snow, etc.), and pointing errors but is not sensitive to rain and multipath fading [2].

Radio frequency (RF) communication is mainly affected by rain and multipath fading but is insensitive to turbulence, pointing errors, snow, and fog [3]. It is precisely complementary to OWC, and OWC/RF hybrid communication has emerged. The OWC/RF hybrid communication system combines the advantages of OWC and RF communication and provides higher reliability and availability than a single communication system under highly variable channel conditions. It meets the requirements for future information transmissions with high capacity, high speed, long distance, safety, and reliability. It is an important development direction for optical wireless communication.

Foreign and Domestic Research Progress

The OWC/RF hybrid communication system is a new scheme to address the impact of severe weather on wireless communication systems. Because of the effects of different weather on OWC and RF communication, they are combined to form an

OWC/RF hybrid communication system that improves the system reliability and realizes high-quality end-to-end communication.

Foreign Research Progress

In 2009, Schober et al. [4] proposed a new OWC/RF hybrid system architecture to enable the acquisition of channel state information. Bit-interleaved coded modulation (BICM) was used on the bit stream transmitted by the RF and OWC subchannels to improve the robustness of the hybrid system.

In 2009, Nadeem et al. [5] considered the high dependence of OWC links on weather conditions and formed a hybrid network using GHz RF links as backup for OWC links. They investigated the effect of fog, rain, and snow on the hybrid OWC/GHz RF network to select the GHz-RF links with the best complementary characteristics. The simulation results showed that a 40-GHz RF link significantly improved the availability of the hybrid system link.

In 2010, Abdulhussein et al. [6] proposed an automatic repeat request (ARQ) scheme using rate-free coding in an OWC/RF hybrid system. Regardless of changes in the OWC or RF channel conditions, this scheme fully utilized the available OWC and RF channel resources without requiring a priori rate selection at the transmitter. The simulation results showed that using rate-free coding was more advantageous than using fixed rate coding under strong atmospheric turbulence conditions.

In 2011, Lee et al. [7] investigated the performance of an asymmetric dual-hop relay OWC/RF hybrid system, in which the RF channel followed Rayleigh fading and the OWC channel followed gamma–gamma fading. The relay node converted the received RF signal into an optical signal using subcarrier intensity modulation. Simulation results showed that the interrupt performance of this hybrid OWC/RF link was extremely close to that of an RF/RF link as the signal-to-noise ratio increased.

In 2013, Ansari et al. [8] analyzed a hybrid OWC/RF communication system with pointing errors and derived the cumulative distribution, probability density, and moment-generating functions for the system, which led to an expression for the average bit error rate (BER) of the hybrid system. Monte Carlo simulation results showed that the system BER performance gradually deteriorated as the pointing errors increased.

In 2014, Usman et al. [9] studied a hybrid OWC/RF communication system based on hard-switching technology and compared the performance of the hybrid communication system under both single and dual OWC threshold conditions. Numerical simulations showed that using OWC/RF hybrid communication effectively improved the system performance, and the dual OWC threshold switching scheme achieved performance similar to a single OWC threshold. It avoided frequent link switching and extended the OWC link lifetime.

In 2016, Touati et al. [10] investigated the effect of joint fading on hybrid OWC/RF links. The experimental results showed that the hybrid OWC/RF system

performed significantly better than OWC alone, in the cases of strong turbulence or a low signal-to-noise ratio, which effectively overcame the drawbacks of OWC links.

In 2017, Hasna et al. [11] proposed an adaptive and efficient OWC/RF hybrid communication system considering the actual communication environment. It could multiplex multiple RF users into a single high-speed OWC link and thus achieved a higher system capacity. However, the application of multiuser diversity only slightly improved the system performance under low signal-to-noise ratio conditions.

In 2019, Amirabadi et al. [12] proposed a novel OWC/RF hybrid system model using a receive-diversity technique in a parallel single-hop OWC/RF hybrid system. Simulation results showed that the proposed OWC/RF hybrid system had a lower outage probability than normal OWC and RF systems with receive diversity under different average signal-to-noise ratio conditions. However, its reduction in power consumption came at the cost of increased receiver complexity.

In 2019, Esmail et al. [13] experimentally evaluated all-optical OWC/RF hybrid communication links for 5G applications under harsh sandy and dusty conditions. The experimental results showed that the RF link had good communication performance in a dense sandy environment, while the OWC link experienced communication interruptions, proving that an OWC/RF parallel link was a feasible solution to overcome the dust effect.

In 2020, Ashrafzadeh et al. [14] constructed a new hybrid three-hop-relay RF-OWC system to solve the problems of congestion and nonline-of-sight transmission in urban environments and mitigate the fading effects caused by turbulence. However, the system relay node had to be equipped with partial or complete OWC transceivers, significantly increasing the system complexity.

In 2021, Khan et al. [15] analyzed an adaptive OWC/RF hybrid system under different weather conditions. Using adaptive modulation and power allocation, the adaptive OWC/RF hybrid system achieved more than 1 dB performance gain at a minimum power level and adapted to changing weather conditions.

In 2022, Vishwakarma et al. [16] investigated the ergodic capacity performance of a hybrid OWC/RF system based on an adaptive combining switching scheme. Closed expressions for the ergodic capacity were derived using a generalized binary Meijer G-function and binary Fox H-function under high signal-to-noise ratio conditions. The optimal switching threshold signal-to-noise ratio and beamwidth values were determined to obtain the optimal ergodic capacity of the adaptive merged system. The numerical results showed that the ergodic capacity of the adaptive combining-based OWC/RF hybrid system was greater than that of the maximal ratio combining (MRC) and hard-switching-based OWC/RF hybrid communication system.

In 2022, Magidi et al. [17] analyzed the performance of a hybrid OWC/RF communication system under the combined effects of atmospheric fading and pointing errors. In this case, a 16-way quadrature amplitude modulation (16QAM) was used for the RF link, and multipulse position modulation (MPPM) was used for the OWC link. The experimental results showed that the smaller the normalized jitter standard deviation, the better the outage probability performance, regardless of the atmospheric turbulence severity. Using an OWC/RF hybrid link reduced the outage probability from the 10^{-2} order of magnitude for the OWC link alone to the 10^{-5} order of magnitude.

Domestic Research Progress

In 2008, Shu et al. [18] studied the theory of automatic link switching for OWC/RF hybrid communication systems. The system signal-to-noise ratio was first improved by reducing the communication rate when the weather conditions deteriorated; and then the system switched to RF channels if the performance of the low-speed OWC communication system was still below a set threshold. This method made full use of the complementary advantages of OWC and RF links to reduce the amount of channel switching while improving the system reliability.

In 2009, Meng [19] demonstrated that the received power strength could reflect the channel quality. They improved the rapid spanning tree protocol (RSTP) used in switches to handle redundant network links, as a switching method for OWC/RF hybrid systems, effectively improving the system communication quality.

In 2010, Su et al. [20] studied the switching technique of an OWC/RF hybrid communication system based on the network packet loss rate. The switching judgment mechanism more accurately responded to the current link conditions, so that the hybrid link was switched in a timely and effective manner to ensure that the data could be transmitted without interruption.

In 2015, to alleviate the influence of multipath fading and atmospheric turbulence on an OWC/RF hybrid system, Gao et al. [21] adopted diversity transmission at the source, selective combination at the sink and only one RF receiving antenna and relay aperture for information forwarding at the relay node. This provided a theoretical reference for the design of an OWC/RF hybrid communication system.

In 2016, Wang et al. [22] extended multiuser diversity to OWC/RF hybrid links and proposed a point-to-multipoint system consisting of a hybrid access point, multiple OWC users, and multiple RF users. For each transmission module, the user with the best link quality was selected to communicate with the hybrid access point through a user scheduling policy.

In 2017, Zhao et al. [23] established an OWC/RF hybrid communication system model with aperture smoothing using subcarrier multiband phase-shift keying modulation. They compared and analyzed the outage probability and bit error rate performance of the hybrid system under different turbulence intensities. The simulation results showed that the aperture-smoothing effect significantly improved the communication performance of the hybrid system and the OWC channel played a major role in the hybrid system performance.

In the same year, Zhao et al. [24] studied hybrid systems with RF and OWC links subject to the Nakagami-m and exponential Weibull distributions, respectively. Based on end-to-end statistical characteristics, a new outage probability expression was derived to evaluate the performance of fixed-gain relay systems and channel state information-assisted relay systems. It was found that the latter was very sensitive to atmospheric turbulence.

In 2017, Shao et al. [25] investigated the system performance, using low-density parity-check (LDPC) hybrid coding and pulse-position modulation for the OWC link and quadrature amplitude modulation for the RF link. They used a soft-switching

mechanism for the reliable transmission of physical layer data in OWC/RF hybrid communication link networking. Simulation results showed that the performance of the proposed soft-switching hybrid coding-modulation scheme improved from 1.3 dB to 8.0 dB, which significantly improved the data transmission reliability of the OWC/RF hybrid parallel system.

In 2019, Yi et al. [26] studied the performance of a decode-and-forward-based dual-hop OWC/RF hybrid communication system in a 5G cloud radio access network (C-RAN). The user transmitted data to a remote RF unit via an RF link, and the RF unit acted as a relay system to forward the received data to the baseband unit. Owing to the presence of small-scale fading and line-of-sight components, the RF link obeyed a κ-μ shadow distribution.

In 2020, Liu et al. [27] introduced a dual-hop OWC/RF hybrid system into deep space communication. The signal arrived at the relay system through the RF link, was amplified and forwarded by the relay system, and then was transmitted by the OWC link to reach the receiver. Compared with traditional OWC systems, this OWC/RF hybrid system can achieve a lower BER in deep space communication. The system performance can be further improved when the hybrid system adopts hybrid modulation.

In 2020, Liu et al. [28] studied the performance of an RF/OWC hybrid aviation communication system based on selective combined diversity technology. The system transmitter did not require feedback links to obtain the channel state information, simplifying system design. Under a high signal-to-noise ratio, the RF/OWC hybrid parallel communication scheme with reception diversity had better performance than that with low-order modulation.

In 2021, Wu et al. [29] investigated the advantages of subcarrier modulation technology in atmospheric turbulence channels. The BER performance of the following OWC/RF hybrid system subcarrier modulation techniques was investigated: differential binary phase-shift keying (DBPSK), noncoherent binary frequency-shift keying (NBFSK), coherent binary phase-shift keying (CBPSK), and coherent binary frequency-shift keying (CBFSK). The simulation results showed that the performance of the OWC/RF hybrid communication system using CBPSK subcarrier modulation technology was obviously better than that of the other three modulation technologies.

In 2022, Liu et al. [30] proposed a millimeter-wave RF/multiple-input multiple-output (MIMO) OWC relay system based on the RF/OWC hybrid relay system. It used a fixed-gain scheme at the relay and an equal-gain merging method at the receiver to combine multiple signals. Numerical simulations demonstrated that the MIMO technique effectively mitigated the performance degradation of the hybrid relay system due to the enhanced atmospheric turbulence intensity. The performance of the hybrid relay system was gradually enhanced as the number of transceiver apertures of the OWC link increased; however, the system complexity also increased. Considering the system complexity and cost, the hybrid system performance was optimized with two transmitting and two receiving apertures.

System Model

OWC/RF Hybrid Parallel System Model

OWC/RF hybrid parallel systems are critical to improving the reliability of hybrid systems by selecting the appropriate channel according to the current communication conditions. Channel selection requires an efficient link-switching mechanism [31], which currently includes hard- and soft-switching types.

Hard Switching

An OWC/RF hybrid parallel system based on a hard-switching mechanism [32] means that either the OWC link or the RF link can be selected for data transmission at a given moment. Typically, the OWC link is used as the primary link, and the RF link is used as the backup link. The working principle is shown in Fig. 46.1.

The OWC link is used by default when the system starts up, and the link is automatically switched for information transmission, according to the threshold information detected by the receiving end of the OWC link. The switching threshold of the hard-switching mechanism can be set according to the system signal-to-noise ratio, bit error rate, and power [32–35]. Most current studies are based on the signal-to-noise ratio threshold. Taking the signal-to-noise ratio threshold as an example, the working principles of single and dual-threshold handovers for OWC links in hybrid systems are described below.

Single Threshold Switching

The signal-to-noise ratio thresholds for the OWC link and RF link are set to $\gamma_{\text{th}}^{\text{OWC}}$ and $\gamma_{\text{th}}^{\text{RF}}$, respectively, and the operating region of the single-threshold hybrid system is shown in Fig. 46.2. If the instantaneous signal-to-noise ratio of the OWC link is higher than the threshold $\gamma_{\text{th}}^{\text{OWC}}$ (in region 1), the OWC link is used to transmit information. If the instantaneous signal-to-noise ratio of the OWC link is lower than $\gamma_{\text{th}}^{\text{OWC}}$, the system will check the communication quality of the RF link. If the instantaneous signal-to-noise ratio of the RF link is higher than the threshold $\gamma_{\text{th}}^{\text{RF}}$ (within region 2), it switches to the RF link to transmit the information.

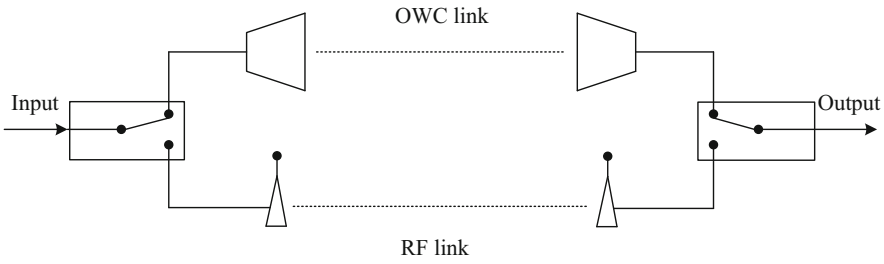

Fig. 46.1 Hard-switching schematic [16]

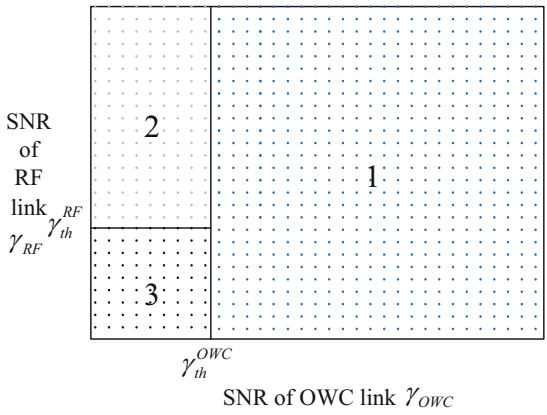

Fig. 46.2 Working area of a hybrid system under single-threshold hard switching [9]

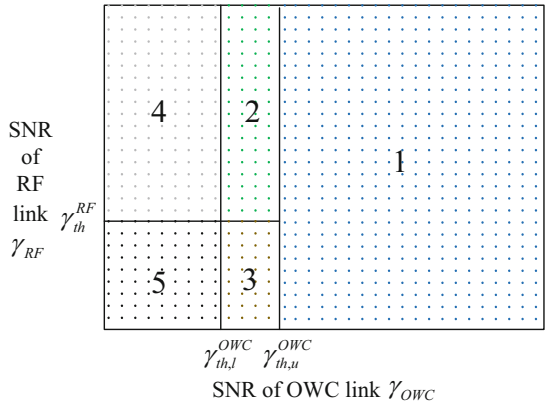

Fig. 46.3 Working area of the hybrid system under dual-threshold hard switching [9]

If the instantaneous signal-to-noise ratios of both links are below both thresholds (in region 3), the communication is interrupted. The single-threshold switching scheme has the problem of frequent link switching. To reduce the frequency of link switching and extend the link life, the double-threshold switching scheme can be used.

Dual-Threshold Switching

Dual-threshold switching refers to setting two signal-to-noise ratio thresholds on the OWC link, namely, the upper limit $\gamma_{\mathrm{th},u}^{\mathrm{OWC}}$ and the lower limit $\gamma_{\mathrm{th},l}^{\mathrm{OWC}}$ ($\gamma_{\mathrm{th},l}^{\mathrm{OWC}} < \gamma_{\mathrm{th},u}^{\mathrm{OWC}}$). Another signal-to-noise ratio threshold $\gamma_{\mathrm{th}}^{\mathrm{RF}}$ is set on the RF link, dividing the plane formed by the signal-to-noise ratio values of the OWC/RF hybrid system into five regions, as shown in Fig. 46.3.

If the instantaneous signal-to-noise ratio of the OWC link is higher than $\gamma_{\text{th},u}^{\text{OWC}}$ (in region 1), the OWC link is used to transmit the information. If the instantaneous signal-to-noise ratio of the OWC link is between $\gamma_{\text{th},l}^{\text{OWC}}$ and $\gamma_{\text{th},u}^{\text{OWC}}$, and the instantaneous signal-to-noise ratio of the RF link is higher than $\gamma_{\text{th}}^{\text{RF}}$ (in region 2), either the RF link or the OWC link may be used, depending on the previous state of the OWC link. If the instantaneous signal-to-noise ratio of the OWC link is higher than $\gamma_{\text{th},u}^{\text{OWC}}$ at the previous moment, the information is transmitted by the OWC link and vice versa.

If the instantaneous signal-to-noise ratio of the OWC link is between $\gamma_{\text{th},l}^{\text{OWC}}$ and $\gamma_{\text{th},u}^{\text{OWC}}$, and the instantaneous signal-to-noise ratio of the RF link is lower than $\gamma_{\text{th}}^{\text{RF}}$ (in region 3), the probability of the OWC link switching is the same as in region 2; however, the RF link always remains off in this region, so either the information is transmitted using the OWC link in region 3, or the communication is interrupted.

If the instantaneous signal-to-noise ratio of the OWC link is lower than $\gamma_{\text{th},l}^{\text{OWC}}$ and the instantaneous signal-to-noise ratio of the RF link is higher than $\gamma_{\text{th}}^{\text{RF}}$ (in region 4), the RF link is used for transmission. If the instantaneous signal-to-noise ratios of the OWC link and the RF link are lower than $\gamma_{\text{th},l}^{\text{OWC}}$ and γ_{th}^{RF} (in region 5), respectively, both links are off and communication is interrupted.

The dual-threshold switching hybrid system sets two switching thresholds in the OWC link. The size of the gap between these two switching thresholds directly determines the frequency of link switching: the larger the gap between $\gamma_{\text{th},l}^{\text{OWC}}$ and $\gamma_{\text{th},u}^{\text{OWC}}$, the lower the link-switching frequency [9]. Hence, the gap between $\gamma_{\text{th},l}^{\text{OWC}}$ and $\gamma_{\text{th},u}^{\text{OWC}}$ should be increased as much as possible to ensure the performance of the hybrid system. This effectively reduces the amount of switching between the OWC and RF links and expands the life cycle of the link.

Soft Switching

The hard-switching-based OWC/RF hybrid parallel system allows only one channel to transmit at a time. The other channel is idle, leading to wasted resources and low bandwidth utilization. To overcome these drawbacks, a hybrid OWC/RF parallel system based on a soft-switching mechanism is proposed [36]. Its working principle is shown in Fig. 46.4.

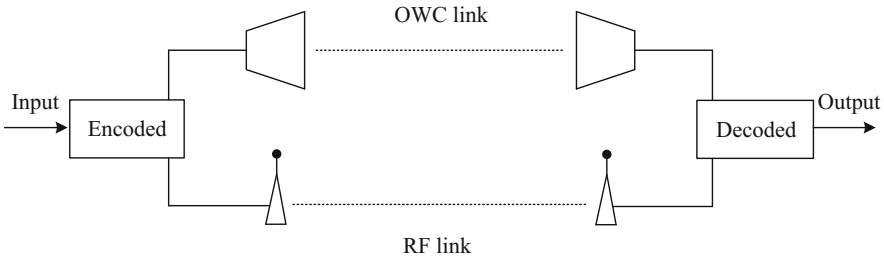

Fig. 46.4 Soft-switching schematic [16]

It uses a pair of coders and decoders to divide the data according to the real-time channel state information and assigns them to the two channels at different data rates. Hence, the data are transmitted on both OWC links and RF links [37], which improves the channel resource utilization and increases the channel capacity.

OWC/RF Hybrid Relay System Model

OWC/RF hybrid relay systems [38] provide wider coverage by relaying information from RF links to OWC links through relay nodes. Current research on hybrid OWC/RF relay systems mainly focuses on two-hop hybrid relay systems [23], where one hop uses an RF link transmission and the other hop uses an OWC link. The structure of a typical two-hop hybrid relay system is shown in Fig. 46.5.

At the source node S transmitter, the source data is modulated into an electrical signal, which is transmitted to the relay node R through an RF link. The relay node R modulates the received RF signal to an optical signal, and the optical signal is transmitted through the atmospheric channel to reach the destination node D.

Depending on the relaying protocols, they can be classified into amplify-and-forward (AF) and decode-and-forward (DF) relay systems [39, 40]. In the amplify-and-forward relay system, the relay node R directly amplifies the signal received from the source node S with a certain gain and forwards it to the destination node D. In the decode-and-forward relay system, the relay node R first decodes the signal received from the source node S and then recodes the processed signal and forwards it to the destination node D.

Because the decode-and-forward relay system requires the signal to be decoded and recoded, it is more costly and complex compared to the amplify-and-forward

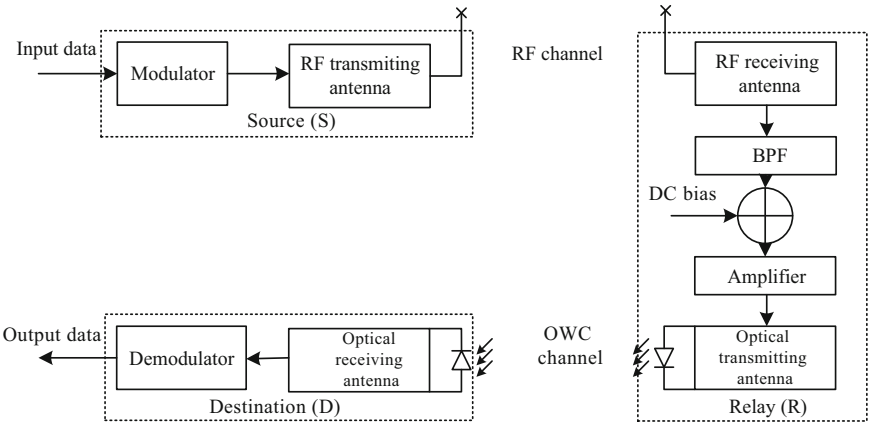

Fig. 46.5 Typical dual-hop OWC/RF hybrid relay system structure [41]

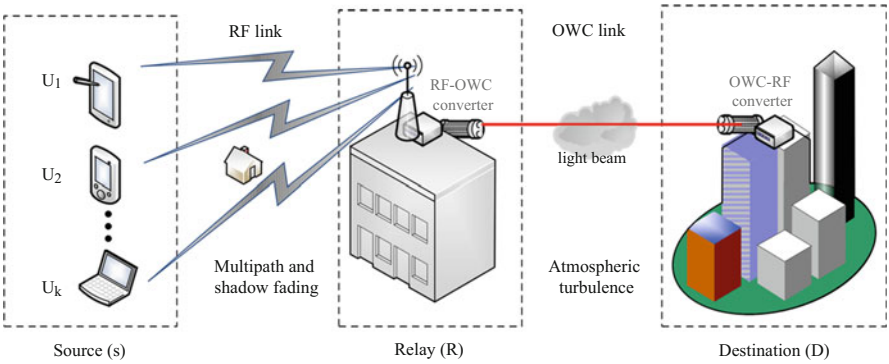

Fig. 46.6 Multiuser dual-hop hybrid relay system diagram [42]

relay system. However, the amplify-and-forward relay system amplifies the noise in the channel along with the signal, which leads to poor communication performance [41].

Multiuser Hybrid Relay System

The multiuser hybrid relay system [42] is shown schematically in Fig. 46.6. The source node S contains K mobile users, each equipped with a single antenna. There is no direct communication link between the user and the destination; the user can only send data to the destination through the relay node.

The model contains two types of communication links: a source-to-relay (S-R) RF link and a relay-to-destination (R-D) free-space optical link. In the RF link, the RF signal is affected by multipath and shadowing effects. In the free-space optical link, the optical signal is mainly affected by atmospheric turbulence and pointing errors. To provide a more accurate line-of-sight connection for OWC links, optical transmitters and receivers are generally placed on top of buildings.

Multiuser hybrid relay systems can simulate a number of practical applications [43], including the following;

1. Cellular communications, where mobile nodes send their data to a relay station, which forwards the data to a base station
2. Small cell networks, where mobile nodes on the floor of a building send their data to an access point, which forwards the information to a macro base station

Intelligent Reflecting Surface-Assisted Hybrid Relay System

An intelligent reflecting surface (IRS) [44] is a new type of device composed of a large number of low-cost passive components. By changing the amplitude or phase

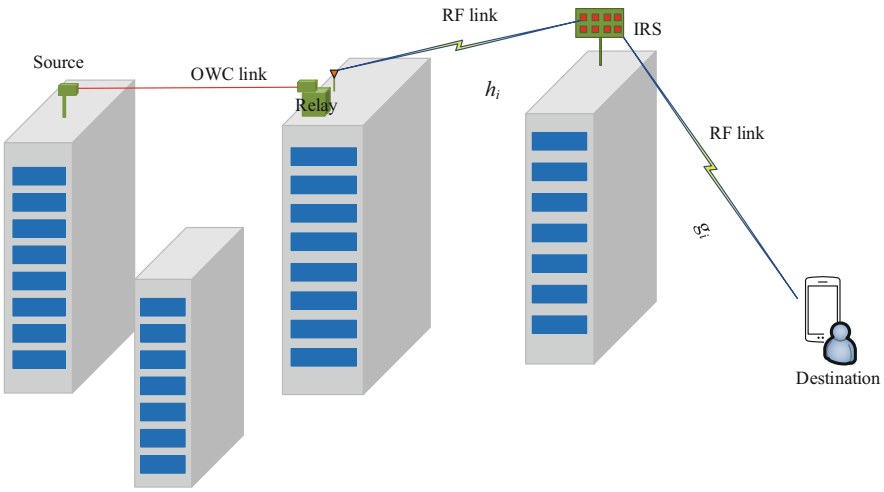

Fig. 46.7 Intelligent reflecting surface-assisted hybrid relay system diagram [45]

of the incident signal, it controls the phase distribution of the wavefront, allowing the incident beam to be reflected in any desired direction.

Owing to the small signal coverage of the intelligent reflecting surfaces, and the lack of a power supply and complex encoding and decoding algorithms, there is no mutual interference between the components of the intelligent reflecting surface. Thus, it can easily be integrated into wireless communication systems. The intelligent reflecting surface-assisted hybrid relay system model [45] is shown in Fig. 46.7.

An intelligent reflecting surface is installed on the top floor of a building. It utilizes RF links to reflect signals from the relay station to a predetermined receiver, solving the obstruction problem and ensuring reliable and high-speed data transmissions.

Application Scenarios for OWC/RF Hybrid Communication

Hybrid System for Space Communication

The US Air Force Research Laboratory conducted the Integrated RF/Optical Networked Tactical Targeting Networking Technologies (IRON-T2) program [46] to demonstrate the effectiveness of airborne hybrid OWC/RF communication. The project adapts terminals by adding high-speed routers and optical inputs, which allow interactive operations with supporting OWC link terminals. The router is designed to accommodate brief interruptions caused by flicker, and an RF channel provides retransmission signals for the high data-rate OWC systems, resulting in error-free transmissions.

The Deutsches Zentrum für Luft- und Raumfahrt (DLR) has developed a hybrid OWC/RF system in the VABENE project [47]. It combines an optical communication system developed by the DLR Institute for Communication and Navigation and a high-resolution camera sensor developed by the Institute for Remote Sensing. It is designed for monitoring and traffic management in large-scale events and natural disasters.

A simulated demonstration of a 1-Gbit/s downlink between a satellite camera sensor, the roof of the Institute of Communications and Navigation, and a service tower was conducted. The experimental results showed that small spacecraft could provide higher data rates through stable optical links, while RF links were independent of environmental conditions and compensated for the lack of optical communication links.

To achieve long-range and high data-rate communications, the National Aeronautics and Space Administration (NASA) Glenn Research Center designed the Teletenna, a hybrid telescope antenna [48], to support deep space communications. It combines optical and RF technology to alleviate engineering challenges and achieve 10–100 times higher data transmissions for deep space optical communications. The OWC link and RF link data rates are up to 84 Mbit/s and 287 Mbit/s, respectively. The Teletenna integrates a co-axial telescope and a Ka-band RF antenna with Cassegrain geometry [49], which is designed to improve the quality of communication systems in deep space missions. The system stability is improved by isolating the reflective and optical elements.

Hybrid Systems in Vehicle Communications

In recent years, research on network connectivity using low earth orbit (LEO) satellites has been increasing, and using OWC/RF hybrid networks for last-mile access in vehicular networking has received widespread attention [50]. Nguyen et al. [51] developed a transmission control protocol (TCP) performance analysis model, shown in Fig. 46.8. They considered an end-to-end network scenario in which a vehicle downloads data from a remote server (TCP source) via LEO satellite Internet access. The satellite is connected to a TCP source placed on an Internet cable.

The physical layer of the system consists of an OWC link and an RF link, both of which are channel coded using Reed–Solomon codes (RS) to improve the bit error performance of the physical layer. The link layer ensures reliable data transmission by selecting repeated automatic retransmission requests and resending the error frames.

In a hybrid OWC/RF vehicular self-assembly network, Gong et al. [52], from the University of Science and Technology of China, used distributed channel assignments and rate control to solve the cross-layer design problem and maximize network throughput. Owing to the limited channel resources in vehicle communication, to ensure the quality of service, the proposed channel allocation algorithm determines the channel usage through linearly programming the channel requirements of the measurement link, and the algorithm converges quickly. Then, it uses a

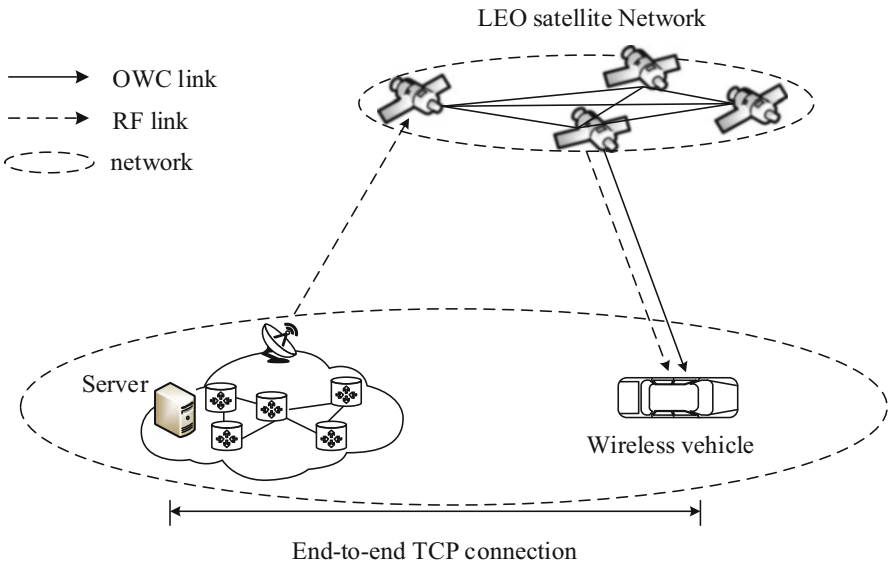

Fig. 46.8 Last-mile satellite Internet access scenario using vehicle Internets [50]

rate adjustment algorithm (the alternate direction multiplier method, ADMM) to control the transmission rate on each path.

Chowdhury et al. [53] demonstrated that OWC/RF hybrid communication can be used to improve the reliability of vehicle-to-vehicle (V2V) communication through the following three scenarios:

1. When a traffic accident occurs on foggy days, the front vehicle cannot transmit the accident information to the rear vehicle because the rear vehicle's optical receiver cannot detect the optical signal. In this case, the RF link can be used for communication.
2. OWC supports long-distance communication between vehicles. When the distance between two vehicles is longer than the RF communication range, they can switch to the OWC link.
3. When the vehicle in front turns left or right, a nonline-of-sight situation will occur, and the optical wireless communication link will be interrupted. At this time, RF-based communication can provide better connectivity.

Hybrid Systems in Underwater Communication

Underwater wireless communication mainly relies on acoustic, RF, and optical means [54]. The advantages and disadvantages of these three underwater wireless communication technologies are compared in Table 46.1. From the table, it can be seen that underwater optical communication has high speed, high confidentiality,

Table 46.1 Differences of three underwater wireless communication technologies

Parameter	RF	Acoustic	Underwater optical
Frequency	30 Hz – 300 Hz or MHz	10 Hz – 100 kHz	10^{12} Hz – 10^{15} Hz
Transmit power	Milliwatt to watt range	Tens of watts	Few watts
Data rate	Mbit/s	Kbit/s	Gbit/s
Transmission distance	$\leq$10 m	$\leq$20 km	10 – 100 m
Performance parameters	Conductivity and dielectric constant	Temperature, salinity	Absorption, scattering, turbidity, and organic matter
Transmission delay	Medium	High	Low
Attenuation	3.5 – 5 dB/m	0.1 – 4 dB/km	0.39 dB/m (attenuation in turbid waters is 11 dB/m)
LOS/NLOS	Both	Both	Only LOS

low latency, and low cost but cannot be used for nonline-of-sight transmissions. The system performance is greatly affected by seawater absorption and scattering, channel turbulence, etc., which is complementary to RF and underwater acoustic communication. Therefore, using two or more underwater communication systems to form a hybrid system can overcome the limitations of a single communication system.

Mohsan et al. [55] investigated a hybrid underwater acoustic/optical wireless communication system for real-time video monitoring between an autonomous underwater vehicle and a base station. The system was equipped with optical and acoustic modems to exploit the advantages of both communication methods. An additional acoustic receiver was equipped to improve communication redundancy, while providing additional data to locate another transmitter and align the optical modem.

During the alignment process, data is sent over the acoustic link until the optical modem is precisely aligned. When the optical modem is aligned, video data is sent using the optical link, thus increasing the system bandwidth. Even when the optical link is not available, the acoustic link remains operational to exchange control signals and send video frames. This hybrid acoustic/optical system can be dynamically configured to maintain a high-speed optical link.

Naik et al. [56] introduced the concept of a reconfigurable intelligent surface to underwater wireless communication systems due to their ability to improve the energy and spectral efficiency of wireless communication links by reconfiguring the propagation environment of radio frequency/optical waves. The reconfigurable intelligent surface is a full duplex relay without amplification. It has a large number of passive reflective elements integrated into its plane to reflect an incident signal in the desired direction and outperforms conventional relay systems (such as amplify-and-forward and decode-and-forward) in terms of communication rate and

complexity. Placing M reconfigurable intelligent surfaces at different locations with sunken objects underwater solves the optical link problem of nonline-of-sight transmissions due to underwater obstacle occlusion. Increasing the number of reconfigurable intelligent surfaces can improve the average signal-to-noise ratio of the underwater OWC/RF hybrid system.

Hybrid Systems in 5G Retransmission

In 5G communication, ultradense and high-traffic cells are connected to a core network through backhaul links; however, they typically have extremely high requirements for capacity, latency, availability, and cost. To solve the 5G backhaul problem, Jaber et al. [57] proposed a 5G cloud radio access network (C-RAN), whose network architecture is shown in Fig. 46.9.

In a 5G C-RAN uplink, users transmit data to a remote radio unit (RRU) through an RF link. The RRU acts as a relay and forwards the received data to a baseband unit (BBU) through an OWC link. This process is defined as a 5G front-end link. The C-RAN architecture utilizes the diversity of traffic peaks to improve the infrastructure utilization and promote the green development of 5G.

The Raytheon Corporation of the United States and NxGen Corporation [58] have developed a low-cost, high-bandwidth 5G backhaul application. It uses multiple orbital-angular-momentum (OAM) modes to multiplex and demultiplex orthogonal and independent optical channels to improve the link throughput and isolate the channels from RF full duplex backhaul links. Using the OAM method to coaxially encapsulate RF and OWC links provides a high-frequency spectral efficiency wireless backhaul link. Compared to optical fiber backhaul, wireless backhaul links based on hybrid OWC/RF configurations have lower latency and can function

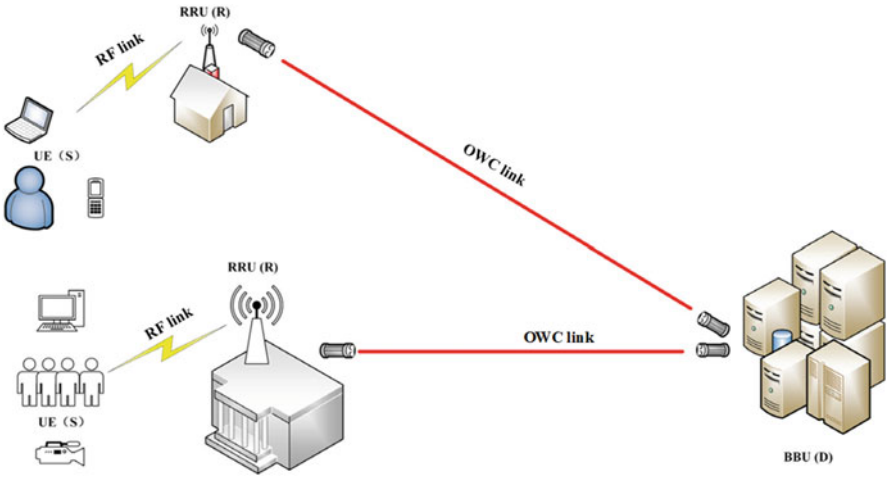

Fig. 46.9 OWC/RF hybrid communication in a 5G cloud wireless access network [57]

even in severe weather, thus meeting the availability and reliability requirements of modern telecommunication networks.

Hybrid System Performance

OWC Subsystem

In an OWC/RF hybrid parallel communication system, the instantaneous signal-to-noise ratio (SNR) of the OWC link can be expressed as [59]

$$\gamma^{\mathrm{OWC}} = \frac{\left(P^{\mathrm{OWC}}\eta^{\mathrm{OWC}}R\xi\right)^2}{\sigma_n^{\mathrm{OWC},2}}\left(h^{\mathrm{OWC}}\right)^2 = \overline{\gamma}^{\mathrm{OWC}}\left(h^{\mathrm{OWC}}\right)^2, \tag{46.1}$$

where P^{OWC} denotes the transmit power of the OWC link, η^{OWC} denotes the atmospheric loss, R denotes the response of the photodetector, ξ denotes the modulation index, $\sigma_n^{\mathrm{OWC},2}$ denotes the noise variance in the OWC link, h^{OWC} denotes the channel gain of the OWC link, and $\overline{\gamma}^{\mathrm{OWC}}$ denotes the average signal-to-noise ratio of the OWC link.

Assuming that the OWC channel obeys an exponential Weibull distribution, the probability density function corresponding to the instantaneous signal-to-noise ratio γ^{FSO} of the OWC link [60] is

$$f_{\gamma^{\mathrm{OWC}}}\left(\gamma^{\mathrm{OWC}}\right) = \frac{1}{2\sqrt{\gamma^{\mathrm{OWC}}\overline{\gamma}^{\mathrm{OWC}}}}\frac{\alpha\rho^2}{(\eta A_0)^{\rho^2}}\left(\sqrt{\frac{\gamma^{\mathrm{OWC}}}{\overline{\gamma}^{\mathrm{OWC}}}}\right)^{\rho^2-1} \cdot \sum_{t=0}^{\infty} B_t G_{1,2}^{2,0}\left[C_t\left(\sqrt{\frac{\gamma^{\mathrm{OWC}}}{\overline{\gamma}^{\mathrm{OWC}}}}\right)^{\beta}\middle|\begin{matrix}1\\0,1-\frac{\rho^2}{\beta}\end{matrix}\right], \tag{46.2}$$

where ρ is the ratio of the received beam radius to the standard deviation of the jitter at the receiving plane, α and β are the shape parameters of the turbulence, η is the scale parameter, $G_{p,q}^{m,n}(\cdot)$ denotes the Meijer G-function, $B_t = \frac{(-1)^t\Gamma(\alpha)}{t!\Gamma(\alpha-t)(1+t)^{1-\frac{\rho^2}{\beta}}}$, $C_t = \frac{(1+t)}{(\eta A_0)^{\beta}}$, $\Gamma(\cdot)$ denotes the gamma function, $A_0 = \mathrm{erf}^2(v)$, where $\mathrm{erf}(\cdot)$ is the complementary error function, $v = \sqrt{\frac{\pi}{2}}\frac{R_a}{w_b}$, R_a is the radius of the receiver aperture, and w_b is the beam radius at transmission distance L.

The cumulative distribution function of γ^{OWC} obtained by integrating Eq. (46.2) is

$$F_{\gamma^{\mathrm{OWC}}}\left(\gamma^{\mathrm{OWC}}\right) = A\left(\sqrt{\frac{\gamma^{\mathrm{OWC}}}{\overline{\gamma}^{\mathrm{OWC}}}}\right)^{\rho^2}\sum_{t=0}^{\infty} B_t G_{2,3}^{2,1}\left[C_t\left(\sqrt{\frac{\gamma^{\mathrm{OWC}}}{\overline{\gamma}^{\mathrm{OWC}}}}\right)^{\beta}\middle|\begin{matrix}\kappa_1\\\kappa_2\end{matrix}\right]. \tag{46.3}$$

RF Subsystem

The instantaneous signal-to-noise ratio of the RF link in the OWC/RF hybrid parallel communication system [29] is expressed as

$$\gamma^{\mathrm{RF}} = \frac{P^{\mathrm{RF}}\eta^{\mathrm{RF}}\left(h^{\mathrm{RF}}\right)^2}{\sigma_n^{\mathrm{RF},2}} = \overline{\gamma}^{\mathrm{RF}}\left(h^{\mathrm{RF}}\right)^2, \tag{46.4}$$

where P^{RF} denotes the transmit power of the RF link, η^{RF} denotes the RF channel loss, h^{RF} denotes the channel state, $\sigma_n^{\mathrm{RF},2}$ denotes the noise variance of the RF link, and $\overline{\gamma}^{\mathrm{RF}}$ denotes the average signal-to-noise ratio of the RF link.

Assuming that the RF channel follows a Nakagami-m distribution, the probability density function corresponding to the instantaneous signal-to-noise ratio γ^{RF} of the RF link [61] is

$$f_{\gamma\mathrm{RF}}\left(\gamma^{\mathrm{RF}}\right) = \left(\frac{m}{\overline{\gamma}^{\mathrm{RF}}}\right)^m \frac{\gamma^{m-1}}{\Gamma(m)} G_{0,1}^{1,0}\left[\frac{m\gamma^{\mathrm{RF}}}{\overline{\gamma}^{\mathrm{RF}}}\middle|\begin{matrix}-\\0\end{matrix}\right], \tag{46.5}$$

where m denotes the parameters of the Nakagami-m distribution, $\Gamma(\cdot)$ denotes the gamma function, and $G_{p,q}^{m,n}(\cdot)$ denotes the Meijer G-function.

The cumulative distribution function of γ^{RF} obtained by integrating Eq. (46.5) is

$$F_{\gamma\mathrm{RF}}\left(\gamma^{\mathrm{RF}}\right) = \frac{1}{\Gamma(m)} G_{1,2}^{1,1}\left[\frac{m\gamma^{\mathrm{RF}}}{\overline{\gamma}^{\mathrm{RF}}}\middle|\begin{matrix}1\\m,0\end{matrix}\right]. \tag{46.6}$$

Hybrid System

Signal-to-Noise Ratio

If a selective combining scheme is adopted at the receiving end, the output signal-to-noise ratio [62] of the hybrid OWC/RF parallel communication system is

$$\gamma = \max\left(\gamma^{\mathrm{OWC}}, \gamma^{\mathrm{RF}}\right). \tag{46.7}$$

The cumulative distribution function [62] corresponding to the instantaneous signal-to-noise ratio γ of the hybrid system is

$$\begin{aligned} F_\gamma(\gamma) &= F_{\gamma\mathrm{RF}}\left(\gamma^{\mathrm{RF}}\right) F_{\gamma\mathrm{OWC}}\left(\gamma^{\mathrm{OWC}}\right) \\ &= \frac{A}{\Gamma(m)}\left(\frac{\gamma}{\overline{\gamma}^{\mathrm{OWC}}}\right)^{\frac{\rho^2}{2}} \sum_{t=0}^{\infty} B_t G_{0,0;\,1,1;\,2,1}^{0,0;\,1,1;\,2,1}\left[\begin{matrix}-\\-\end{matrix}\middle|\begin{matrix}1\\m,0\end{matrix}\middle|\begin{matrix}\kappa_1\\\kappa_2\end{matrix}\middle|\frac{m\gamma}{\overline{\gamma}^{\mathrm{RF}}}, C_t\left(\frac{\gamma}{\overline{\gamma}^{\mathrm{OWC}}}\right)^{\frac{\beta}{2}}\right]. \end{aligned} \tag{46.8}$$

Here, G is the extended generalized bivariate Meiger G-function and γ is the output signal-to-noise ratio of the hybrid parallel system.

Outage Probability

When the instantaneous signal-to-noise ratio falls below the set threshold, the system is disrupted and cannot communicate. The disruption probability of the hybrid system is expressed as [29]

$$P_{\text{out}} = \Pr\{\gamma < \gamma_{\text{th}}\} = F_{\gamma}(\gamma_{\text{th}}) = \frac{A}{\Gamma(m)}\left(\frac{\gamma_{\text{th}}}{\overline{\gamma}^{\text{OWC}}}\right)^{\frac{\rho^2}{2}} \sum_{t=0}^{\infty} B_t G_{0,0;\,1,2;\,2,3}^{0,0;\,1,1;\,2,1}\left[\begin{matrix} - \\ - \end{matrix}\middle|\begin{matrix} 1 \\ m,0 \end{matrix}\middle|\begin{matrix} \kappa_1 \\ \kappa_2 \end{matrix}\middle|\frac{m\gamma_{\text{th}}}{\overline{\gamma}^{\text{RF}}}, C_t\left(\frac{\gamma_{\text{th}}}{\overline{\gamma}^{\text{OWC}}}\right)^{\frac{\beta}{2}}\right], \tag{46.9}$$

where $\Pr\{\cdot\}$ represents the probability, $F_{\gamma}(\cdot)$ represents the cumulative distribution function of the signal-to-noise ratio, $\Gamma(\cdot)$ represents the gamma function, γ_{th} represents the set threshold, ρ is the ratio of the received-beam radius to the jitter standard deviation of the receiving plane, and $\overline{\gamma}^{\text{OWC}}$ $\overline{\gamma}^{\text{RF}}$ represent the average signal-to-noise ratio of the OWC and RF links, respectively. G is the extended generalized bivariate Meiger G-function, β is the shape parameter of the turbulence, $B_t = \frac{(-1)^t\Gamma(\alpha)}{t!\Gamma(\alpha-t)(1+t)^{1-\frac{\rho^2}{\beta}}}$, $C_t = \frac{(1+t)}{(\eta A_0)^{\beta}}$, and m denotes the distribution parameters of the RF channel.

Average Bit Error Rate

The average bit error rate refers to the ratio of the number of error symbols to the total number of symbols in the transmission. It is an important indicator to evaluate the performance of a communication system. If the binary modulation scheme is adopted, the average bit error rate of the hybrid system [63] is expressed as follows:

$$P_b = \frac{Aq^p}{2\Gamma(p)\Gamma(m)}\left(\overline{\gamma}^{\text{OWC}}\right)^{-\frac{\rho^2}{2}} \sum_{t=0}^{\infty} B_t \sum_{\tau=1}^{n} \omega_{\tau} \cdot G_{0,0;\,1,2;\,2,3}^{0,0;\,1,1;\,2,1}\left[\begin{matrix} - \\ - \end{matrix}\middle|\begin{matrix} 1 \\ m,0 \end{matrix}\middle|\begin{matrix} \kappa_1 \\ \kappa_2 \end{matrix}\middle|\frac{mx_{\tau}}{\overline{\gamma}^{\text{RF}}}, C_t\left(\frac{x_{\tau}}{\overline{\gamma}^{\text{OWC}}}\right)^{\frac{\beta}{2}}\right], \tag{46.10}$$

where p and q are the bit error rate parameters describing different binary modulation schemes, ω_{τ} is the weight functions, and x_{τ} is the coordinate special point.

Problems, Challenges, and Solutions

Weather Conditions

Table 46.2 shows the impact of different weather conditions on communication links, taking 40-GHz RF/OWC hybrid communication as an example [5]. As can be seen from Table 46.2, OWC links are greatly affected by weather. In snow, fog, and other weather conditions, the availability and reliability of OWC links cannot be guaranteed, while RF links are very sensitive to rain. In this case, hybrid communication becomes a feasible solution to these challenges.

Table 46.2 [5] Availability of 40-GHz RF and OWC links in different weather conditions

Weather conditions	RF (40 GHz)	OWC	Hybrid
Snow	100%	39.49%	100%
Dense fog	100%	0.51%	100%
Rain	14.29%	85.71%	85.71

Frequency selection is crucial for hybrid systems [63]. An incorrect frequency can lead to severe signal attenuation and a significant reduction in transmission distance. If the frequency is too low and the signal wavelength is long, diffraction phenomena and interference are prone to occur. The frequency of RF links is closely related to weather conditions, communication rates, and other factors. By understanding link attenuation and selecting an appropriate frequency, the impact of weather on the performance of hybrid OWC/RF communication systems can be effectively reduced.

Atmospheric Turbulence

In hybrid communication systems, laser beams generated by OWC links and transmitted through atmospheric channels are affected by atmospheric turbulence. This can lead to phenomena, such as light-intensity flicker, beam drift, and expansion [65, 66], which reduce the reliability of the hybrid system. To address the adverse effects caused by turbulence and ensure the normal operation of the OWC link in a hybrid communication system, the following measures can be taken:

1. For short-range communication, adaptive optic (AO) technology is generally used to compensate [67]. Owing to factors such as the antenna aperture and link bandwidth, the operating range of an AO system is within the Fresnel region. When this region is exceeded, the resulting aberration cannot be adaptively compensated by the antennas at the receiving and transmitting ends.
2. For long-distance communication, automatic optical gain control technology can be used to compensate [68]. At the receiving end, the gain can be adjusted through a feedback circuit to maintain the stability of the output signal and improve the system performance.

Pointing Errors

The OWC link requires a strict alignment between the optical transmitter and optical receiver to establish a reliable connection. However, in practice, owing to factors such as wind load, thermal expansion, and building shaking, laser signals deviate from their original direction, and beam-pointing errors occur between transceivers [69]. Because of the limited receiving aperture, if the pointing errors are too large, the receiving end cannot detect the optical signal, resulting in a communication interruption.

To mitigate the adverse impact of pointing errors on OWC performance [46], beamwidth optimization can be used to control the beamwidth through the

transmission aperture of the OWC system to minimize the geometric loss and error probability. In addition, because RF links are not prone to pointing errors, millimeter-wave RF links can be used as the main data transmission link to reduce the impact of pointing errors on hybrid communication systems; however, in this case, the system communication data rate will also be reduced.

Multipath Effect

In RF communication links, when electromagnetic waves propagate in the channel, they are reflected by objects, causing signals to arrive at the receiver from different paths, producing a multipath effect [70]. Owing to the different propagation paths, the time taken to reach the receiver varies. Each component overlaps with the others, according to its respective phase, causing interference, which leads to signal distortion. Multipath effects can also lead to signal fading.

A decision feedback equalizer can reduce the impact of multipath effects on hybrid communication systems [71]. The equalizer is mainly composed of feedforward and feedback filters. It is a limited-length rake receiver that uses the ratio of signal-to-interference plus noise to measure the signal quality. By eliminating linear interference in the feedforward portion, it can eliminate the intersymbol interference caused by subsequent multipath delays.

Multipath diversity reception technology can distinguish subtle multipath signals in real time, adjust the weights of the identified multipath signals, and composite them into enhanced signals. This not only solves interference problems but also enhances effective signals.

Summary

As an important research direction in the field of optical wireless communication, hybrid OWC/RF communication combines the advantages of both OWC and RF communication methods. This not only overcomes the OWC links' susceptibility to weather but also addresses the limited RF link communication rate; it improves the system reliability while considering the communication rate. Providing solutions for the "last mile" access of mobile communications has broad application prospects in underwater, unmanned aerial vehicles, satellites, and 5G communications.

This chapter described the development of hybrid OWC/RF communication systems over the past 15 years, introduced two main hybrid communication system models, discussed hybrid communication systems in different application scenarios, analyzed the problems and challenges faced by hybrid communication, presented the key technologies to solve these problems, and projected the development trends of hybrid OWC/RF communication [46, 48, 52]. These mainly include the following aspects:

1. Improving the adaptive-switching algorithm of hybrid OWC/RF parallel communication systems to optimize the hybrid system performance, while reducing the number of link switches.
2. In view of the wireless channel asymmetry in actual hybrid communication, studying hybrid modulation and coding techniques [46, 72, 73] can improve the reliability and resource utilization (power, bandwidth, budget, etc.) of hybrid systems.
3. Researching hybrid communication systems in spatial information networks [74] to improve the coverage and real-time information processing capabilities of spatial information networks. Building an interconnected space–space integrated information communication network and maximizing the utilization of spatial information resources.
4. Studying the hybrid communication system in a 5G backhaul design [75] to solve network congestion, latency, and other issues and thereby accelerating the construction of 5G+ and 6G communication systems.

Abstract

A dual-hop hybrid free-space optical/radio frequency (FSO/RF) relay system is considered an effective solution for increasing the capacity and coverage of wireless communication systems between last-kilometer access networks and backbone networks. However, the transmission performance of FSO links is greatly affected by atmospheric turbulence, pointing errors, fog, and snow. The RF access network has a low rate and high delay. To ensure communication quality, a hybrid FSO/RF/terahertz (THz) relay system was designed. Decode-and-forward relaying was selected and hybrid FSO/RF communication based on an adaptive-combining scheme was considered before the relay nodes. THz links were used after the relay nodes to reach the users. Using the statistical characteristics of the different obtained links, expressions for the outage probability and average bit error rate of the system were derived. The effects of different parameters on the performance of hybrid FSO/RF/THz relay systems were studied, and the first-hop adaptive-combining scheme was compared with the single-threshold switching scheme and single-link FSO system. The analysis

results indicated that the hybrid FSO/RF/THz relay system provided better outage and error performance using an adaptive-combining scheme. It improved the system communication rate while considering the communication reliability.

Free-space optical (FSO) communication · Radio frequency (RF) communication · Terahertz (THz) communication · Adaptive-combining scheme

Introduction

Free-space optical (FSO) communications have received considerable attention in the field of wireless communications, owing to their advantages of a high-speed rate, large capacity, high confidentiality, low cost, and ease of deployment. They are the primary choice for connecting radio frequency (RF) access networks and backbone networks.

However, FSO is highly sensitive to problems, such as atmospheric turbulence, pointing errors, and weather conditions (e.g., fog, haze, and snow), which limit the transmission distance and seriously affect the performance of FSO communications [1–3]. On the other hand, RF communication only attenuates severely in rain, is insensitive to atmospheric turbulence and pointing errors, and has strong environmental adaptability. However, RF communication has disadvantages, such as poor interference resistance, low security, and a low transmission rate [4].

In addition, terahertz (THz) communication (0.1–10 THz) is one of the core technologies of B5G and 6G communication and has a frequency band between RF and FSO. It has the advantages of low latency, high directional gain, and high available bandwidth. However, the huge path loss, molecular absorption, pointing errors, and other problems lead to a limited transmission distance; thus, THz is only suitable for short-distance high-rate communication [5, 6].

Hybrid communication combines the respective advantages and disadvantages of FSO, RF, and THz communications. Hybrid communication refers to the use of two or more different communication modes to transmit data or information in a communication system. It can overcome the limitations of a single communication mode and access the complementary advantages of the others. Currently, research on hybrid communication systems mainly focuses on hybrid FSO/RF, FSO/THz, and THz/RF communication systems; few reports exist on communication systems with a mixture of FSO, RF, and THz.

In this study, a hybrid FSO/RF relay system was improved to form a hybrid FSO/RF/THz relay communication system. Before the relay node, a hybrid FSO/RF communication system, based on an adaptive-combining scheme, was used to alleviate the degradation of the system performance of the separate FSO link caused by atmospheric turbulence and other factors. After the relay node, the THz link was utilized instead of the traditional millimeter-wave RF link to access the user, thus

further improving the system communication rate. The outage probability and average bit error rate expressions of the system were derived. The correctness of the derived performance formula was verified by simulating the relationship between different parameters and the performance of the hybrid FSO/RF/THz relay system.

Foreign and Domestic Research Progress

In recent years, many experts and scholars have extensively researched different types of hybrid systems, considering their advantages in outdoor wireless communications, such as high speed, high reliability, long distance, and extensive coverage.

In the early stages of hybrid communication system research, owing to the complementary characteristics of FSO and RF links, research mainly focused on hybrid FSO/RF communication systems. However, in recent years, as research on THz communication has deepened, THz technology has become increasingly mature; therefore, it has also been considered in hybrid communication systems. Hybrid THz/RF communication systems and hybrid THz/FSO communication systems have successively appeared.

In 2009, Schober et al. [7] proposed a novel FSO/RF hybrid system architecture to address the problem of unavailable channel state information. It improved the robustness of the hybrid system by applying joint bit-interleaved coded modulation (BICM) to the bit streams transmitted by the RF and FSO subchannels.

In 2009, Nadeem et al. used a GHz-RF link as a backup link and an FSO link to form a hybrid network, considering the high dependence of the FSO link on weather conditions. They investigated the effects of fog, rain, and snow on the FSO/GHz-RF hybrid network to select the GHz RF link with the best complementary characteristics. The simulation results showed that a 40-GHz-RF link significantly improved the availability of the hybrid system link.

In 2010, Abdulhussein et al. [8] proposed an automatic repeat request (ARQ) scheme with rateless coding for an FSO/RF hybrid system. This scheme allowed the efficient utilization of available FSO and RF channel resources, regardless of the changing channel conditions, without requiring any prior rate selection at the transmitter. The simulation results indicated that, under strong atmospheric turbulence conditions, rateless coding was superior to fixed rate coding.

In 2010, Su et al. [9] proposed a switching mechanism based on the network packet-loss rate for an FSO/RF hybrid communication system. It better reflected the current link conditions and enabled the hybrid link to switch efficiently and in real time, thus ensuring uninterrupted data transmissions.

In 2011, Lee et al. [10] studied the performance of an asymmetric dual-hop relay FSO/RF hybrid system in which the RF link followed a Rayleigh distribution and the FSO link followed the gamma–gamma distribution. The relay node used subcarrier intensity modulation to convert the received RF signal into an optical signal. The simulation results showed that with an increase in the signal-to-noise ratio, the outage performance of the hybrid FSO/RF link was infinitely close to that of an RF/RF link.

In 2013, Ansari et al. [11] analyzed an FSO/RF hybrid communication system with pointing errors. They derived the cumulative distribution function, probability density function, and moment generation function of the system and obtained the average bit error rate expression of the hybrid system. Monte Carlo simulation results showed that the bit error performance of the system deteriorated with an increase in the pointing error.

In 2014, Usman et al. [12] studied FSO/RF hybrid communication systems based on hard-switching technology and compared their performances under single and double FSO thresholds. Numerical simulations showed that using FSO/RF hybrid communication effectively improved the system performance, and the dual FSO threshold-switching scheme achieved a performance level similar to that of a single FSO threshold. It also avoided frequent link switching and extended the FSO link life.

In 2015, to mitigate the effects of multipath fading and atmospheric turbulence on an FSO/RF hybrid system, Gao et al. [13] used diversity transmitting at the source and selective combining at the destination, while the relay node was equipped with only one RF receiving antenna and one relay aperture for information forwarding. This provided some theoretical references for the design of an FSO/RF hybrid communication system.

In 2016, Touati et al. [14] investigated the effects of joint fading on hybrid FSO/RF links. The experimental results showed that in the case of strong turbulence or a low signal-to-noise ratio, the performance of the hybrid FSO/RF system was significantly better than that of the FSO alone, and the shortcomings of the FSO link could be effectively overcome.

In 2016, Wang et al. [15] extended multiuser diversity to FSO/RF hybrid links and proposed a point-to-multipoint system composed of hybrid access points, multiple FSO users, and multiple RF users. In each transmission module, the user with the best link quality was selected to communicate with the hybrid access point through the user-scheduling strategy.

In 2017, Hasna et al. [16] proposed an efficient adaptive hybrid FSO/RF communication system, considering actual communication environments, that multiplexed multiple RF users into a single high-speed FSO link, thereby achieving a higher system capacity. However, with a low signal-to-noise ratio, the application of multiuser diversity only slightly improved the system performance.

In 2019, Amirabadi et al. [17] proposed a novel FSO/RF hybrid system model using receive diversity in a parallel single-hop FSO/RF hybrid system. Simulation results showed that the outage probability of the proposed FSO/RF hybrid system was lower than that of the normal FSO and RF systems with receive diversity under different average signal-to-noise ratios. However, the reduction in the power consumption of this FSO/RF hybrid system came at the cost of increased receiver complexity.

In 2019, Esmail et al. [18] experimentally evaluated an all-optical FSO/RF hybrid communication link for 5G applications under severe dust conditions. The

experimental results showed that the RF link had good communication performance in a dense dust environment, whereas the FSO link faced communication interruptions. This proved that the FSO/RF parallel link was a feasible scheme to overcome the dust effect.

In 2019, Yi et al. [19] studied the performance of a dual-hop FSO/RF hybrid communication system based on decoding-and-forwarding in a 5G cloud radio-access network (C-RAN). Users transmitted data to remote RF units through RF links, and the RF units acted as relay systems to forward the received data to the baseband units. Because of small-scale fading and line-of-sight components, the RF link followed a κ-μ shadow distribution.

In 2020, Ashrafzadeh et al. [20] constructed a new hybrid three-hop relay RF/FSO/FSO system to solve the problems of congestion and nonline-of-sight transmissions in urban environments and alleviate the fading effect caused by turbulence. However, the relay nodes had to be equipped with partial or complete FSO transceivers, which significantly increased the system complexity.

In 2020, Zhao et al. [21] studied the performance of an RF/FSO hybrid aeronautical communication system based on selective combining diversity technology. The transmitter of the system did not require a feedback link to obtain the channel state information, which simplified the system design. With a high signal-to-noise ratio, the RF/FSO hybrid parallel communication scheme with receive diversity was better than low-order modulation in improving the system error performance.

In 2021, Khan et al. [22] analyzed an adaptive FSO/RF hybrid system under different weather conditions. Through adaptive modulation and power allocation, the adaptive FSO/RF hybrid system achieved more than a 1-dB performance gain at the minimum power level and adapted to changing weather conditions.

In 2021, Bhardwaj et al. [23] used the THz band for data transmissions between the core network and access point, which proved the feasibility of a THz/RF relay wireless backhaul scheme. Compared to direct transmissions, the spectral efficiency of the scheme was significantly improved by approximately 25%. In the same year, Bhardwaj et al. [24] also studied the performance of a THz/RF relay system with pointing errors under α-μ fading. The diversity order showed that the influence of the pointing error could be reduced by fully adjusting the normalized beam width; however, the attenuation parameters α and μ had greater influence on the system than the normalized beam width.

In 2021, Wu et al. [25], based on the advantages of subcarrier modulation techniques in turbulent atmospheric channels, investigated the performance of an FSO/RF hybrid system with four subcarrier modulation technologies, including differential binary phase-shift keying (DBPSK), noncoherent binary frequency-shift keying (NBFSK), coherent binary phase-shift keying (CBPSK), and coherent binary frequency-shift keying (CBFSK), when pointing errors were considered. Simulation results showed that the hybrid system based on the CBPSK subcarrier modulation technique performed better than the other three subcarrier modulation techniques.

In 2021, Li et al. [26] proposed a hybrid THz/FSO system that realized high-speed and large-capacity data connections between small cells and core networks. The following year, Li et al. [27] studied the performance of a hybrid dual-hop RF/THz system assisted by a reconfigurable intelligent surface (RIS) for the short transmission distance of the THz link. Simulation results showed that the RIS effectively improved the performance of the hybrid RF/THz system.

In 2022, Zafaruddin et al. [28] proposed a hybrid RF/THz communication system with multiple antenna diversity and analyzed its performance using a fixed-gain forwarding protocol with selective combining and a maximal-ratio combining (MRC) diversity receiver; they demonstrated through simulations that increasing the number of antennas improved the system performance.

In 2022, Vishwakarma et al. [29] studied the ergodic capacity of an FSO/RF hybrid system using an adaptive-combining switching scheme. A closed expression of the ergodic capacity under a high signal-to-noise ratio was derived, and the optimal switching threshold and beam width were determined to obtain the optimal ergodic capacity of the adaptive-combining system. The numerical results showed that the ergodic capacity performance of the FSO/RF hybrid system based on adaptive combining was better than those of the MRC and FSO/RF hybrid communication systems based on hard switching.

In 2022, Yang et al. [30] analyzed the performance of a hybrid THz/FSO system. Considering the joint influence of the channel fading and pointing error of the THz and FSO links, the outage probability of a system with impaired hardware was derived and compared with that of the ideal system. The simulation results showed that path loss, channel fading, pointing errors, and hardware impairment led to a significant decrease in the system performance.

In 2023, Singya et al. [31] proposed a backhaul network based on multihop and mesh hybrid THz/FSO technology for high data-rate communication and studied the performance of the system under integrated access and backhaul (IAB) and non-IAB communication settings. The simulation results showed that the IAB mesh network supported multipath routing and significantly improved the system performance.

In 2023, Li et al. [32] studied a multiuser hybrid RF/THz (M-RF/THz) system and derived the performance expressions of the system under fixed-gain amplify-and-forward (AF) and decode-and-forward (DF) protocols. They proved that the diversity order of AF and DF M-RF/THz systems was mainly determined by the pointing error and channel-fading parameters. Increasing the number of users could improve the diversity gain and system performance.

In 2023, Liu et al. [33] proposed a hybrid dual-hop communication system based on cognitive radio with nonorthogonal multiple access (NOMA)-assisted switching, which solved the problems of scarce spectrum resources and low spectral efficiency of communication links. In addition, they studied the influence of the maximum allowable interference power in the main network, the transmission power in the auxiliary transmitter, and the maximum relay transmission power on the link, which provided a new idea for next-generation wireless communication.

System and Channel Models

Channel Model

The hybrid FSO/RF/THz relay system is shown in Fig. 47.1. It is a dual-hop hybrid communication system that provides users with a high speed rate, low latency, and safe and reliable data transmissions. The decode-and-forward (DF) relay mode is adopted. The communication distance from the source node (S) to the relay node (R) is long. With the hybrid FSO/RF communication system based on adaptive combining, the relay node R to the destination node (D) uses a short-distance THz link to access the users. Because FSO only supports line-of-sight communication and RF is used as a backup link for FSO, the transmitters and receivers of both the FSO and RF links are deployed at the top of the building.

For the first-hop S-R hybrid FSO/RF communication system based on adaptive combining [34], when the instantaneous signal-to-noise ratio γ_F of the FSO link receiver is higher than the set threshold γ_{th}, the signal is transmitted through the FSO link. When γ_F of the FSO link drops below γ_{th}, the receiver sends a one-bit feedback message to activate the RF link, and the communication rate of the FSO link is reduced to that of the RF link.

The signal is transmitted simultaneously through the FSO and RF links, and the maximal-ratio combiner is used to combine the signals received from the two links. Therefore, the merging rules of the hybrid FSO/RF communication system based on the adaptive-merging scheme can be expressed as follows:

$$\gamma_c = \begin{cases} \gamma_F, & \gamma_F \geq \gamma_{th} \\ \gamma_F + \gamma_R, & \gamma_F < \gamma_{th} \end{cases}, \tag{47.1}$$

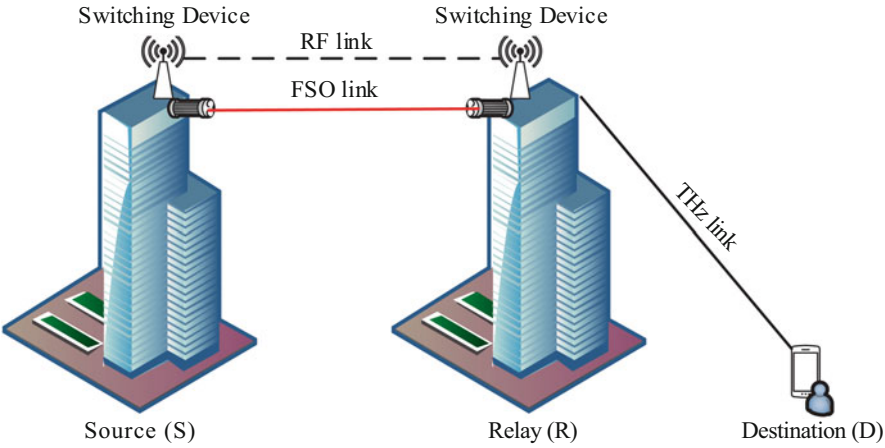

Fig. 47.1 Hybrid FSO/RF/THz relay system model

where γ_c is the output signal-to-noise ratio of the adaptive-combining scheme and γ_R is the instantaneous signal-to-noise ratio of the RF link.

FSO Link

Assuming that the FSO link adopts subcarrier intensity modulation (SIM) and direct detection technology, the optical signal received at relay R can be expressed as

$$y_F = P_F \eta I_l I x + n_F, \tag{47.2}$$

where P_F is the transmission power of the FSO link, η denotes the photoelectric conversion coefficient, and I_l denotes the atmospheric attenuation associated with the FSO link; according to the Beer–Lambert law, $I_l = \exp(-\sigma_l L_F)$, σ_l is the attenuation coefficient, and L_F is the FSO link distance. x represents the signal transmitted at the source node S; n_F represents the additive white Gaussian noise of the FSO link with a mean of 0 and variance of σ_F^2. I represents the effective channel gain of the FSO link, including atmospheric turbulence I_a and pointing errors I_p, where $I = I_a I_p$.

The FSO-link fading I_a caused by turbulence follows a gamma–gamma distribution. Then, the probability density function (PDF) of I_a is

$$f_{I_a}(x) = \frac{2x^{-1}}{\Gamma(\alpha_F)\Gamma(\beta_F)} G_{0\,2}^{2\,0}\left(\alpha_F \beta_F x \middle|_{\alpha_F, \beta_F}^{-}\right), \tag{47.3}$$

where $\Gamma(\cdot)$ represents the gamma function and $G_{p,q}^{m,n}(\cdot)$ denotes the Meijer G-function. The large-scale and small-scale turbulence coefficients, α_F and β_F, are

$$\begin{cases} \alpha_F = \left[\exp\left(\frac{0.49\sigma_{RV}^2}{\left(1+1.11\sigma_{RV}^{12/5}\right)^{7/6}}\right) - 1\right]^{-1} \\ \beta_F = \left[\exp\left(\frac{0.51\sigma_{RV}^2}{\left(1+0.69\sigma_{RV}^{12/5}\right)^{5/6}}\right) - 1\right]^{-1} \end{cases}. \tag{47.4}$$

In Eq. (47.4), the Rytov variance is $\sigma_{RV}^2 = 1.23 C_n^2 k_0^{7/6} L_F^{11/6}$, where the wavenumber $k_0 = \frac{2\pi}{\lambda_F}$ and C_n^2 represents the atmospheric refractive index structure constant.

The fading coefficient is caused by the pointing error during the transmission of the FSO link [35]: $I_p \approx A_{0,F} \exp\left(-\frac{2r^2}{w_{L_{eq}}^2}\right)$, where r represents the radial displacement between the beam center and detector and follows the modified Rayleigh distribution. $A_{0,F}$ represents part of the received optical power at $r = 0$, $A_{0,F} = \mathrm{erf}^2(v)$, $v = \sqrt{\frac{\pi}{2}}\frac{r_a}{w_L}$, r_a denotes the aperture radius, w_L denotes the beam width, and $w_{L_{eq}}$ is the

equivalent beam width, $w_{L_{\mathrm{eq}}}^2 = \frac{w_L^2\sqrt{\pi}\,\mathrm{erf}(v)}{2v\exp(-v^2)}$. Therefore, considering the zero axis pointing error, the PDF of I_{p} is

$$f_{I_{\mathrm{p}}}(x) = \frac{\xi_{\mathrm{F}}^2}{A_{0,\mathrm{F}}^{\xi_{\mathrm{F}}^2}} x^{\xi_{\mathrm{F}}^2-1}, 0 \le x \le A_{0,\mathrm{F}}, \tag{47.5}$$

where the FSO-link pointing error coefficient $\xi_{\mathrm{F}} = \frac{w_{L_{\mathrm{eq}}}}{2\sigma_{j,\mathrm{F}}}$ and $\sigma_{j,\mathrm{F}}$ denotes the standard deviation of the FSO-link jitter.

From $f_I(I) = \int f_{I|I_{\mathrm{a}}}(I|I_{\mathrm{a}}) f_{I_{\mathrm{a}}}(I_{\mathrm{a}})\mathrm{d}I_{\mathrm{a}}$, the PDF of the effective channel gain I of the FSO link under the combined influence of atmospheric turbulence and the pointing error is

$$f_I(I) = \frac{\alpha_{\mathrm{F}}\beta_{\mathrm{F}}\xi_{\mathrm{F}}^2}{A_{0,\mathrm{F}} I_{\mathrm{l}} \Gamma(\alpha_{\mathrm{F}})\Gamma(\beta_{\mathrm{F}})} G_{1,3}^{3,0}\left[\frac{\alpha_{\mathrm{F}}\beta_{\mathrm{F}} I}{A_{0,\mathrm{F}} I_{\mathrm{l}}}\middle|_{\xi_{\mathrm{F}}^2-1,\alpha_{\mathrm{F}}-1,\beta_{\mathrm{F}}-1}^{\xi_{\mathrm{F}}^2}\right]. \tag{47.6}$$

Because the instantaneous and average signal-to-noise ratios of the FSO link are $\gamma_{\mathrm{F}} = \frac{|I|^2 P_{\mathrm{F}}^2 \eta^2}{\sigma_{\mathrm{F}}^2}$ and $\overline{\gamma}_{\mathrm{F}} = \frac{P_{\mathrm{F}}^2\eta^2\xi_{\mathrm{F}}^4}{\sigma_{\mathrm{F}}^2\left(\xi_{\mathrm{F}}^2+1\right)^2} A_{0,\mathrm{F}}^2 I_{\mathrm{l}}^2$, respectively, the PDF of the signal-to-noise ratio γ_{F} of the FSO link can be obtained by using γ_{F} and $\overline{\gamma}_{\mathrm{F}}$ to replace variable I in Eq. (47.6) [14, 36]:

$$f_{\gamma_{\mathrm{F}}}(x) = \frac{\xi_{\mathrm{F}}^2}{2\Gamma(\alpha_{\mathrm{F}})\Gamma(\beta_{\mathrm{F}})x} G_{1,3}^{3,0}\left[\frac{\alpha_{\mathrm{F}}\beta_{\mathrm{F}}\xi_{\mathrm{F}}^2}{\xi_{\mathrm{F}}^2+1}\left(\frac{x}{\overline{\gamma}_{\mathrm{F}}}\right)^{\frac{1}{2}}\middle|_{\xi_{\mathrm{F}}^2,\alpha_{\mathrm{F}},\beta_{\mathrm{F}}}^{\xi_{\mathrm{F}}^2+1}\right]. \tag{47.7}$$

Equation (47.7) is integrated to obtain the cumulative distribution function (CDF) of γ_{F} as follows:

$$F_{\gamma_{\mathrm{F}}}(x) = \frac{2^{\alpha_{\mathrm{F}}+\beta_{\mathrm{F}}-3}\xi_{\mathrm{F}}^2}{\pi\Gamma(\alpha_{\mathrm{F}})\Gamma(\beta_{\mathrm{F}})} G_{3,7}^{6,1}\left(\frac{\alpha_{\mathrm{F}}^2\beta_{\mathrm{F}}^2\xi_{\mathrm{F}}^4 x}{16\left(\xi_{\mathrm{F}}^2+1\right)^2\overline{\gamma}_{\mathrm{F}}}\middle|_{\frac{\xi_{\mathrm{F}}^2}{2},\frac{\xi_{\mathrm{F}}^2+1}{2},\frac{\alpha_{\mathrm{F}}}{2},\frac{\alpha_{\mathrm{F}}+1}{2},\frac{\beta_{\mathrm{F}}}{2},\frac{\beta_{\mathrm{F}}+1}{2},0}^{1,\frac{\xi_{\mathrm{F}}^2+1}{2},\frac{\xi_{\mathrm{F}}^2+2}{2}}\right). \tag{47.8}$$

RF Link

The received signal of the RF link at relay R can be expressed as

$$y_{\mathrm{R}} = \sqrt{P_{\mathrm{R}} h_{\mathrm{l,R}}} h_{\mathrm{R}} x + n_{\mathrm{R}} \tag{47.9}$$

where P_{R} is the transmit power of the RF link, and the path loss of the RF link is $h_{\mathrm{l,R}} = G_{\mathrm{t,R}} + G_{\mathrm{r,R}} - 20\mathrm{lg}\left(\frac{4\pi L_{\mathrm{R}}}{\lambda_{\mathrm{R}}}\right) - \left(\alpha_{\mathrm{oxy}} + \alpha_{\mathrm{rain}}\right)L_{\mathrm{R}}$. $G_{\mathrm{t,R}}$ and $G_{\mathrm{r,R}}$ represent the gain

of the RF-link transmitting and receiving antennas, respectively. L_R and λ_R are the RF-link distance and wavelength, respectively. α_{oxy} and α_{rain} are the attenuation coefficients caused by oxygen and rain absorption, respectively. h_R is the fading coefficient of the RF link, which follows the Nakagami-m distribution, and n_R is the additive Gaussian white noise for the RF link with a mean value of 0 and variance of σ_R^2.

The RF link receives the instantaneous and average signal-to-noise ratios of $\gamma_R = \overline{\gamma}_R |h_R|^2$ and $\overline{\gamma}_R = \frac{P_R h_{l,R}}{\sigma_R^2}$, respectively; therefore, the PDF [37] of γ_R is

$$f_{\gamma_R}(x) = \left(\frac{m}{\overline{\gamma}_R}\right)^m \frac{x^{m-1}}{\Gamma(m)} \exp\left(-\frac{mx}{\overline{\gamma}_R}\right) \tag{47.10}$$

where m denotes the channel fading degree parameter.

Integrating Eq. (47.10) produces the CDF of γ_R as

$$F_{\gamma_R}(x) = \frac{1}{\Gamma(m)} \gamma\left(m, \frac{mx}{\overline{\gamma}_R}\right) \tag{47.11}$$

where $\gamma(\cdot, \cdot)$ denotes the lower bounded incomplete Gamma function.

THz Link

Relay node R uses DF relay forwarding; and then the signal received at destination node D for the second-hop THz link is

$$y_T = \sqrt{P_T} h_{l,T} h_T \widehat{x} + n_T \tag{47.12}$$

where P_T is the transmit power of the THz link, the THz-link path loss $h_{l,T} = \frac{c\sqrt{G_{t,T} G_{r,T}}}{4\pi f_T L_T} \exp\left[-\frac{1}{2}\kappa_a(f_T) L_T\right]$, and c is the speed of light. $G_{t,T}$ and $G_{r,T}$ denote the gains of the transmitting antenna and receiving antenna of the THz link, respectively, and f_T and L_T are the frequency and link distance of the THz link, respectively. $\kappa_a(\cdot)$ denotes the absorption coefficient with respect to temperature, relative humidity, and atmospheric pressure, $\widehat{x}$ denotes the decoded signal at relay R, n_T denotes the additive Gaussian white noise in the THz link with a mean of 0 and a variance of σ_T^2, and h_T denotes the THz-link channel coefficients including the pointing error h_p and the channel fading h_f; $h_T = h_p h_f$.

The THz-link channel coefficients h_T experience α-μ fading with pointing error impairments, so the PDF of h_T, considering the combined effect of channel fading and the pointing error, is

$$f_{h_{\mathrm{T}}}(h_{\mathrm{T}}) = \frac{\xi_{\mathrm{T}}^2 \mu^{\frac{\xi_{\mathrm{T}}^2}{\alpha}} h_{\mathrm{T}}^{\xi_{\mathrm{T}}^2-1}}{A_{0,\mathrm{T}}^{\xi_{\mathrm{T}}^2} \Omega^{\xi_{\mathrm{T}}^2} \Gamma(\mu)} \Gamma\left(\frac{\alpha\mu - \xi_{\mathrm{T}}^2}{\alpha}, \frac{\mu h_{\mathrm{T}}^{\alpha}}{A_{0,\mathrm{T}}^{\alpha} \Omega^{\alpha}}\right) \tag{47.13}$$

where ξ_{T} and $A_{0,\mathrm{T}}$ denote the THz-link pointing error parameter and the partially received optical power, respectively; their solution method refers to the FSO-link pointing error parameter ξ_{F} and the partially received optical power $A_{0,\mathrm{F}}$. α and μ denote the channel-fading parameters, Ω is the α-root mean of the fading channel envelope, and $\Gamma(\cdot, \cdot)$ represents the upper-bound incomplete Gamma function.

The THz link receives the instantaneous signal-to-noise ratio $\gamma_{\mathrm{T}} = \overline{\gamma}_{\mathrm{T}} |h_{\mathrm{T}}|^2$ and the THz-link average signal-to-noise ratio $\overline{\gamma}_{\mathrm{T}} = \frac{P_{\mathrm{T}} h_{\mathrm{l,T}}^2}{\sigma_{\mathrm{T}}^2}$. Therefore, using γ_{T} and $\overline{\gamma}_{\mathrm{T}}$ as substitutes for h_{T} in Eq. (47.13), the PDF [38] of γ_{T} can be obtained as

$$f_{\gamma_{\mathrm{T}}}(x) = \frac{\xi_{\mathrm{T}}^2 \mu^{\frac{\xi_{\mathrm{T}}^2}{\alpha}} x^{\frac{\xi_{\mathrm{T}}^2}{2}-1}}{2A_{0,\mathrm{T}}^{\xi_{\mathrm{T}}^2} \Omega^{\xi_{\mathrm{T}}^2} \Gamma(\mu) \overline{\gamma}_{\mathrm{T}}^{\frac{\xi_{\mathrm{T}}^2}{2}}} \Gamma\left(\frac{\alpha\mu - \xi_{\mathrm{T}}^2}{\alpha}, \frac{\mu x^{\frac{a}{2}}}{A_{0,\mathrm{T}}^{\alpha} \Omega^{\alpha} \overline{\gamma}_{\mathrm{T}}^{\frac{a}{2}}}\right) \tag{47.14}$$

By integrating Eq. (47.14), we obtain the CDF of γ_{T}, as follows:

$$F_{\gamma_{\mathrm{T}}}(x) = \frac{\xi_{\mathrm{T}}^2 \mu^{\frac{\xi_{\mathrm{T}}^2}{\alpha}} x^{\frac{\xi_{\mathrm{T}}^2}{2}}}{\alpha A_{0,\mathrm{T}}^{\xi_{\mathrm{T}}^2} \Omega^{\xi_{\mathrm{T}}^2} \Gamma(\mu) \overline{\gamma}_{\mathrm{T}}^{\frac{\xi_{\mathrm{T}}^2}{2}}} G_{2,3}^{2,1}\left[\frac{\mu x^{\frac{a}{2}}}{A_{0,\mathrm{T}}^{\alpha} \Omega^{\alpha} \overline{\gamma}_{\mathrm{T}}^{\frac{a}{2}}} \middle|_{0, \frac{\alpha\mu - \xi_{\mathrm{T}}^2}{\alpha}, -\frac{\xi_{\mathrm{T}}^2}{\alpha}}^{1-\frac{\xi_{\mathrm{T}}^2}{\alpha}, 1}\right] \tag{47.15}$$

Performance Analysis

Outage Probability

The outage probability refers to the probability that the end-to-end (E2E) signal-to-noise ratio of a communication system will be lower than a set threshold [32, 39]. Therefore, in the first-hop S-R hybrid FSO/RF communication system based on adaptive combining, when the instantaneous signal-to-noise ratio γ_{c} of the output after adaptive combining is lower than the preset outage threshold γ_{out}, the system is in an outage state. The outage probability can be expressed as $P_{\mathrm{out,AC}} = F_{\gamma_{\mathrm{c}}}(\gamma_{\mathrm{out}}) = \Pr[\gamma_{\mathrm{c}} < \gamma_{\mathrm{out}}]$. According to Eq. (47.1), the outage probability of the hybrid FSO/RF communication system based on adaptive combining can be expressed as

$$\begin{aligned} P_{\text{out,AC}} &= F_{\gamma_c}(x) \\ &= \Pr[\gamma_F \geq \gamma_{th}, \gamma_F < x] + \Pr[\gamma_F < \gamma_{th}, \gamma_F + \gamma_R < x] \\ &= \begin{cases} F_1(x), & x \leq \gamma_{th} \\ F_2(x) - F_{\gamma_F}(\gamma_{th}) + F_{\gamma_F}(x), & x > \gamma_{th} \end{cases} \end{aligned} \tag{47.16}$$

where $F_1(x) = \int_0^x f_{\gamma_F+\gamma_R}(t)\mathrm{d}t$ and $F_2(x) = \int_0^{\gamma_{th}} f_{\gamma_F}(t) F_{\gamma_R}(x-t)\mathrm{d}t$. Because the FSO and RF links are statistically independent, $f_{\gamma_F+\gamma_R}(x) = \int_0^x f_{\gamma_F}(t) f_{\gamma_R}(x-t)\mathrm{d}t$. Substituting Eqs. (47.7) and (47.10) into the calculation yields

$$\begin{aligned} f_{\gamma_F+\gamma_R}(x) = \frac{2^{\alpha_F+\beta_F-3}\xi_F^2}{\pi\Gamma(\alpha_F)\Gamma(\beta_F)\Gamma(m)} \left(\frac{m}{\overline{\gamma}_R}\right)^m x^{m-1} \sum_{n=0}^{\infty} (-1)^n \frac{1}{n!} \left(\frac{m}{\overline{\gamma}_R}\right)^n \Gamma(m+n) x^n \\ G_{3,7}^{6,1}\left(\frac{\alpha_F^2 \beta_F^2 \xi_F^4 x}{16\left(\xi_F^2+1\right)^2 \overline{\gamma}_F} \middle| \begin{matrix} 1, \frac{\xi_F^2+1}{2}, \frac{\xi_F^2+2}{2} \\ \frac{\xi_F^2}{2}, \frac{\xi_F^2+1}{2}, \frac{\alpha_F}{2}, \frac{\alpha_F+1}{2}, \frac{\beta_F}{2}, \frac{\beta_F+1}{2}, 1-m-n \end{matrix} \right) \end{aligned} \tag{47.17}$$

Substituting Eq. (47.17) into expressions $F_1(x)$ yield and substituting Eqs. (47.1) and (47.7) into expressions $F_2(x)$ yield

$$\begin{aligned} F_1(x) = \frac{2^{\alpha_F+\beta_F-3}\xi_F^2}{\pi\Gamma(\alpha_F)\Gamma(\beta_F)\Gamma(m)} \left(\frac{m}{\overline{\gamma}_R}\right)^m \sum_{n=0}^{\infty} (-1)^n \frac{1}{n!} \left(\frac{m}{\overline{\gamma}_R}\right)^n \Gamma(m+n) x^{n+m} \\ G_{4,8}^{6,2}\left(\frac{\alpha_F^2 \beta_F^2 \xi_F^4 x}{16\left(\xi_F^2+1\right)^2 \overline{\gamma}_F} \middle| \begin{matrix} 1-n-m, 1, \frac{\xi_F^2+1}{2}, \frac{\xi_F^2+2}{2} \\ \frac{\xi_F^2}{2}, \frac{\xi_F^2+1}{2}, \frac{\alpha_F}{2}, \frac{\alpha_F+1}{2}, \frac{\beta_F}{2}, \frac{\beta_F+1}{2}, 1-m-n, -n-m \end{matrix} \right) \end{aligned} \tag{47.18}$$

$$\begin{aligned} F_2(x) = F_{\gamma_F}(\gamma_{th}) - \frac{2^{\alpha_F+\beta_F-3}\xi_F^2}{\pi\Gamma(\alpha_F)\Gamma(\beta_F)} e^{-\frac{mx}{\overline{\gamma}_R}} \sum_{n=0}^{\infty} \frac{1}{n!} \left(\frac{m\gamma_{th}}{\overline{\gamma}_R}\right)^n \sum_{k=0}^{m-1} \frac{1}{k!} \left(\frac{mx}{\overline{\gamma}_R}\right)^k \\ \sum_{j=0}^{k} \binom{k}{j} \left(\frac{-\gamma_{th}}{x}\right)^j G_{3,7}^{6,1}\left(\frac{\alpha_F^2 \beta_F^2 \xi_F^4 \gamma_{th}}{16\left(\xi_F^2+1\right)^2 \overline{\gamma}_F} \middle| \begin{matrix} 1-n-j, \frac{\xi_F^2+1}{2}, \frac{\xi_F^2+2}{2} \\ \frac{\xi_F^2}{2}, \frac{\xi_F^2+1}{2}, \frac{\alpha_F}{2}, \frac{\alpha_F+1}{2}, \frac{\beta_F}{2}, \frac{\beta_F+1}{2}, -n-j \end{matrix} \right) \end{aligned} \tag{47.19}$$

Considering the DF relay, the E2E outage probability of the hybrid FSO/RF/THz relay communication system is

$$P_{\text{out}} = 1 - (1 - P_{\text{out,AC}}) \times (1 - P_{\text{out,T}}) \tag{47.20}$$

where $P_{\text{out,T}}$ denotes the outage probability of the second-hop R-D THz link and $P_{\text{out,T}} = F_{\gamma_T}(x)$. Thus, Eq. (47.20) can again be expressed as $P_{\text{out}} = F_{\gamma_c}(x) + F_{\gamma_T}(x) - F_{\gamma_c}(x) \times F_{\gamma_T}(x)$, and the outage probability of the system can be determined by substituting Eqs. (47.15) and (47.16).

Average Bit Error Rate

According to the definition, the average bit error rate (BER) [40] of a communication system can be expressed as $\overline{P}_{\mathrm{e}} = \int_0^{\infty} P(\mathrm{e}|x) f_{\gamma}(x)\mathrm{d}x$, where $P(\mathrm{e}|x)$ denotes the conditional error probability corresponding to different modulation schemes. Therefore, assuming that multiple phase-shift keying (MPSK) modulation is adopted, $P(\mathrm{e}|x) \approx \frac{A}{2}\mathrm{erfc}(\sqrt{x}B)$, and the average BER of the first-hop S-R hybrid FSO/RF communication system based on adaptive combining is

$$\overline{P}_{\mathrm{e,AC}} = \int_0^{\infty} \frac{A}{2}\mathrm{erfc}\left(\sqrt{x}B\right) f_{\gamma_{\mathrm{c}}}(x)\mathrm{d}x \tag{47.21}$$

where $B = \sin(\pi/M)$. When $M = 2$ (BPSK), $A = 1$; when $M > 2$, $A = 2$.

By differentiating the CDF of Eq. (47.16), the PDF of γ_{c} is

$$f_{\gamma_{\mathrm{c}}}(x) = \begin{cases} f_{\gamma_{\mathrm{F}}+\gamma_{\mathrm{R}}}(x), & x \le \gamma_{\mathrm{th}} \\ f_{\gamma_{\mathrm{F}}}(x) + G(x), & x > \gamma_{\mathrm{th}} \end{cases} \tag{47.22}$$

where $G(x) = \int_0^{\gamma_{\mathrm{th}}} f_{\gamma_{\mathrm{F}}}(t) f_{\gamma_{\mathrm{R}}}(x-t)\mathrm{d}t$. Substituting Eqs. (47.7) and (47.10) into the calculation,

$$G(x) = \frac{2^{\alpha_{\mathrm{F}}+\beta_{\mathrm{F}}-3}\xi_{\mathrm{F}}^2}{\pi\Gamma(\alpha_{\mathrm{F}})\Gamma(\beta_{\mathrm{F}})\Gamma(m)}\left(\frac{m}{\overline{\gamma}_{\mathrm{R}}}x\right)^m \sum_{i=0}^{\infty}\frac{1}{i!}\left(-\frac{m}{\overline{\gamma}_{\mathrm{R}}}x\right)^i \sum_{j=0}^{m+i-1}\frac{(-\gamma_{\mathrm{th}})^j}{x^{j+1}} \times \binom{m+i-1}{j} G_{3,7}^{6,1}\left(\frac{\alpha_{\mathrm{F}}^2\beta_{\mathrm{F}}^2\xi_{\mathrm{F}}^4\gamma_{\mathrm{th}}}{16\left(\xi_{\mathrm{F}}^2+1\right)^2\overline{\gamma}_{\mathrm{F}}}\middle|\begin{matrix}1-j, \frac{\xi_{\mathrm{F}}^2+1}{2}, \frac{\xi_{\mathrm{F}}^2+2}{2} \\ \frac{\xi_{\mathrm{F}}^2}{2}, \frac{\xi_{\mathrm{F}}^2+1}{2}, \frac{\alpha_{\mathrm{F}}}{2}, \frac{\alpha_{\mathrm{F}}+1}{2}, \frac{\beta_{\mathrm{F}}}{2}, \frac{\beta_{\mathrm{F}}+1}{2}, -j\end{matrix}\right) \tag{47.23}$$

Substituting Eq. (47.22) into Eq. (47.21) yields

$$\overline{P}_{\mathrm{e,AC}} = \underbrace{\int_0^{\gamma_{\mathrm{th}}} \frac{A}{2}\mathrm{erfc}\left(\sqrt{x}B\right) f_{\gamma_{\mathrm{F}}+\gamma_{\mathrm{R}}}(x)\mathrm{d}x}_{I_1} + \underbrace{\int_{\gamma_{\mathrm{th}}}^{\infty} \frac{A}{2}\mathrm{erfc}\left(\sqrt{x}B\right)\left[f_{\gamma_{\mathrm{F}}}(x) + G(x)\right]\mathrm{d}x}_{I_2} \tag{47.24}$$

Because $\mathrm{erfc}(x) = 1 - \mathrm{erf}(x)$, the first term I_1 in (47.24) can be expressed as

$$I_1 = \frac{A}{2}\left[\underbrace{\int_0^{\gamma_{\text{th}}} f_{\gamma_{\text{F}}+\gamma_{\text{R}}}(x)\mathrm{d}x}_{F_1(\gamma_{\text{th}})} - \underbrace{\int_0^{\gamma_{\text{th}}} \text{erf}\left(\sqrt{x}B\right) f_{\gamma_{\text{F}}+\gamma_{\text{R}}}(x)\mathrm{d}x}_{I_{11}}\right] \tag{47.25}$$

Substituting Eq. (47.17) into the expression of I_{11} in Eq. (47.25) yields

$$I_{11} = \frac{2^{\alpha_{\text{F}}+\beta_{\text{F}}-2}\xi_{\text{F}}^2}{\pi^{3/2}\Gamma(\alpha_{\text{F}})\Gamma(\beta_{\text{F}})\Gamma(m)}\left(\frac{m\gamma_{\text{th}}}{\overline{\gamma}_{\text{R}}}\right)^m \sum_{n=0}^{\infty}\frac{(-1)^n\left(B\sqrt{\gamma_{\text{th}}}\right)^{2n+1}}{n!(2n+1)}\sum_{k=0}^{\infty}\frac{(-1)^k}{k!}\left(\frac{m\gamma_{\text{th}}}{\overline{\gamma}_{\text{R}}}\right)^k$$
$$\Gamma(m+k)G_{4,8}^{6,2}\left(\frac{\alpha_{\text{F}}^2\beta_{\text{F}}^2\xi_{\text{F}}^4\gamma_{\text{th}}}{16\left(\xi_{\text{F}}^2+1\right)^2\overline{\gamma}_{\text{F}}}\middle|\begin{matrix}\frac{1}{2}-n-m-k,1,\frac{\xi_{\text{F}}^2+1}{2},\frac{\xi_{\text{F}}^2+2}{2}\\ \frac{\xi_{\text{F}}^2}{2},\frac{\xi_{\text{F}}^2+1}{2},\frac{\alpha_{\text{F}}}{2},\frac{\alpha_{\text{F}}+1}{2},\frac{\beta_{\text{F}}}{2},\frac{\beta_{\text{F}}+1}{2},1-k-m,-n-k-m-\frac{1}{2}\end{matrix}\right) \tag{47.26}$$

Therefore, I_1 can be obtained by substituting Eqs. (47.18) and (47.26) into Eq. (47.25).

Similarly, the second term I_2 in (47.24) can be expressed as

$$\begin{aligned} I_2 = &\underbrace{\int_0^{\infty}\frac{A}{2}\text{erfc}\left(\sqrt{x}B\right)f_{\gamma_{\text{F}}}(x)\mathrm{d}x}_{\overline{P}_{\text{e,F}}} - \frac{A}{2}\underbrace{\int_0^{\gamma_{\text{th}}} f_{\gamma_{\text{F}}}(x)\mathrm{d}x}_{F_{\gamma_{\text{F}}}(\gamma_{\text{th}})} \\ &+\underbrace{\int_0^{\gamma_{\text{th}}}\frac{A}{2}\text{erf}\left(\sqrt{x}B\right)f_{\gamma_{\text{F}}}(x)\mathrm{d}x}_{I_{21}} + \underbrace{\int_{\gamma_{\text{th}}}^{\infty}\frac{A}{2}\text{erfc}\left(\sqrt{x}B\right)G(x)\mathrm{d}x}_{I_{22}} \end{aligned} \tag{47.27}$$

Substituting Eqs. (47.7) and (47.23) into the expressions for $\overline{P}_{\text{e,F}}$, I_{21}, and I_{22} in Eq. (47.27), and obtaining them in turn,

$$\overline{P}_{\text{e,F}} = \frac{2^{\alpha_{\text{F}}+\beta_{\text{F}}-4}A\xi_{\text{F}}^2}{\pi^{3/2}\Gamma(\alpha_{\text{F}})\Gamma(\beta_{\text{F}})}G_{4,7}^{6,2}\left(\frac{\alpha_{\text{F}}^2\beta_{\text{F}}^2\xi_{\text{F}}^4}{16B^2\left(\xi_{\text{F}}^2+1\right)^2\overline{\gamma}_{\text{F}}}\middle|\begin{matrix}1,\frac{1}{2},\frac{\xi_{\text{F}}^2+1}{2},\frac{\xi_{\text{F}}^2+2}{2}\\ \frac{\xi_{\text{F}}^2}{2},\frac{\xi_{\text{F}}^2+1}{2},\frac{\alpha_{\text{F}}}{2},\frac{\alpha_{\text{F}}+1}{2},\frac{\beta_{\text{F}}}{2},\frac{\beta_{\text{F}}+1}{2},0\end{matrix}\right) \tag{47.28}$$

$$I_{21} = \frac{2^{\alpha_{\text{F}}+\beta_{\text{F}}-3}A\xi_{\text{F}}^2}{\pi^{3/2}\Gamma(\alpha_{\text{F}})\Gamma(\beta_{\text{F}})}\sum_{n=0}^{\infty}\frac{(-1)^n\left(B\sqrt{\gamma_{\text{th}}}\right)^{2n+1}}{n!(2n+1)}$$
$$G_{3,7}^{6,1}\left(\frac{\alpha_{\text{F}}^2\beta_{\text{F}}^2\xi_{\text{F}}^4\gamma_{\text{th}}}{16\left(\xi_{\text{F}}^2+1\right)^2\overline{\gamma}_{\text{F}}}\middle|\begin{matrix}\frac{1}{2}-n,\frac{\xi_{\text{F}}^2+1}{2},\frac{\xi_{\text{F}}^2+2}{2}\\ \frac{\xi_{\text{F}}^2}{2},\frac{\xi_{\text{F}}^2+1}{2},\frac{\alpha_{\text{F}}}{2},\frac{\alpha_{\text{F}}+1}{2},\frac{\beta_{\text{F}}}{2},\frac{\beta_{\text{F}}+1}{2},-n-\frac{1}{2}\end{matrix}\right) \tag{47.29}$$

$$I_{22}=\frac{2^{\alpha_F+\beta_F-4}A\xi_F^2}{\pi^{3/2}\Gamma(\alpha_F)\Gamma(\beta_F)\Gamma(m)}\left(\frac{m\gamma_{th}}{\overline{\gamma}_R}\right)^m\sum_{i=0}^{\infty}\frac{1}{i!}\left(\frac{-m\gamma_{th}}{\overline{\gamma}_R}\right)^i\sum_{j=0}^{m+i-1}\binom{m+i-1}{j}(-1)^j$$
$$G_{3,7}^{6,1}\left(\frac{\alpha_F^2\beta_F^2\xi_F^4\gamma_{th}}{16\left(\xi_F^2+1\right)^2\overline{\gamma}_F}\middle|\begin{matrix}1-j,\frac{\xi_F^2+1}{2},\frac{\xi_F^2+2}{2}\\ \frac{\xi_F^2}{2},\frac{\xi_F^2+1}{2},\frac{\alpha_F}{2},\frac{\alpha_F+1}{2},\frac{\beta_F}{2},\frac{\beta_F+1}{2},-j\end{matrix}\right)G_{2,3}^{3,0}\left(B^2\gamma_{th}\middle|\begin{matrix}1,1-m-i+j\\ -m-i+j,0,\frac{1}{2}\end{matrix}\right) \tag{47.30}$$

Therefore, I_2 can be obtained by substituting Eqs. (47.8), (47.28), (47.29), and (47.30) into Eq. (47.27). Then, the derived I_1 and I_2 can be substituted into Eq. (47.24) to obtain the average BER of the first-hop S-R hybrid FSO/RF communication system based on adaptive combining, $\overline{P}_{e,AC}$.

The average BER of the second-hop RD THz link can be expressed as

$$\overline{P}_{e,T}=\int_0^{\infty}\frac{A}{2}\mathrm{erfc}\left(\sqrt{x}B\right)f_{\gamma_T}(x)\mathrm{d}x \tag{47.31}$$

Substituting Eq. (47.14) into Eq. (47.31) yields

$$\overline{P}_{e,T}=\frac{A\xi_T^2\mu^{\frac{\xi_T^2}{\alpha}}}{2\sqrt{\pi}A_{0,T}^{\frac{\xi_T^2}{2}}\Omega^{\xi_T^2}\Gamma(\mu)\overline{\gamma}_T^{\frac{\xi_T^2}{2}}}\frac{2^{\frac{\alpha\mu-\xi_T^2}{\alpha}-\frac{1}{2}}\alpha^{\frac{\xi_T^2}{2}-1}}{(2\pi)^{\frac{\alpha}{2}}B^{\frac{\xi_T^2}{2}}}$$
$$\times G_{2+2\alpha,4+\alpha}^{4,2\alpha}\left[\frac{\mu^2\alpha^{\alpha}}{4B^{\alpha}A_{0,T}^{2\alpha}\Omega^{2\alpha}\overline{\gamma}_T^{\alpha}}\middle|\begin{matrix}\frac{1-\xi_T^2/2}{\alpha},\ldots,\frac{\alpha-\xi_T^2/2}{\alpha},\frac{1-\xi_T^2/2-1/2}{\alpha},\ldots,\frac{\alpha-\xi_T^2/2-1/2}{\alpha},\frac{1}{2},1\\ 0,\frac{1}{2},\frac{\alpha\mu-\xi_T^2}{2\alpha},\frac{\alpha\mu-\xi_T^2+1}{2\alpha},\frac{1-\xi_T^2/2-1}{\alpha},\ldots,\frac{\alpha-\xi_T^2/2-1}{\alpha}\end{matrix}\right] \tag{47.32}$$

Considering the DF relay, the E2E average BER of the hybrid FSO/RF/THz relay communication system is

$$\overline{P}_e=\overline{P}_{e,AC}+\overline{P}_{e,T}-2\times\overline{P}_{e,AC}\times\overline{P}_{e,T} \tag{47.33}$$

Thus, the average BER of the system can be determined by substituting Eqs. (47.24) and (47.32) into Eq. (47.33).

Simulation Results

To analyze the performance of the hybrid FSO/RF/THz relay system and verify the accuracy of the analysis results, simulations were performed based on the outage probability and BER expressions derived in section "Performance Analysis," and the system simulation parameter settings are shown in Table 47.1.

Figures 47.2, 47.3, and 47.7 show the outage probability and bit error performance of the first-hop S-R hybrid FSO/RF system in the hybrid FSO/RF/THz relay

Table 47.1 Simulation parameter settings

FSO link		RF link		THz link	
Parameter	Value	Parameter	Value	Parameter	Value
Wavelength λ_F	1550 nm	Carrier frequency f_R	28 GHz	Carrier frequency f_T	300 GHz
Opt-to-elect. conversion η	1	Link distance L_R	500 m	Link distance L_T	100 m
Strong turbulence C_n^2	1×10^{-12} $m^{-2/3}$	Transmit antenna gain $G_{t,R}$	44 dBi	Transmit antenna gain $G_{t,T}$	55 dBi
Moderate turbulence C_n^2	1×10^{-13} $m^{-2/3}$	Receive antenna gain $G_{r,R}$	44 dBi	Receive antenna gain $G_{r,T}$	55 dBi
Turbulence coefficient (strong) α_F, β_F	4.7206, 1.2066	Oxygen absorption α_{oxy}	15.1 dB/km	Humidity ϕ	50%
Turbulence coefficient (moderate) α_F, β_F	5.6137, 4.0062	Rain attenuation α_{rain}	0 dB/km	Atmosphere pressure p	101,325 Pa
Link distance L_F	500 m			Temperature T	296 K
Receiving aperture r_a	20 cm			Jitter standard deviation $\sigma_{j,T}$	5–15 cm
Jitter standard deviation $\sigma_{j,F}$	5–20 cm				

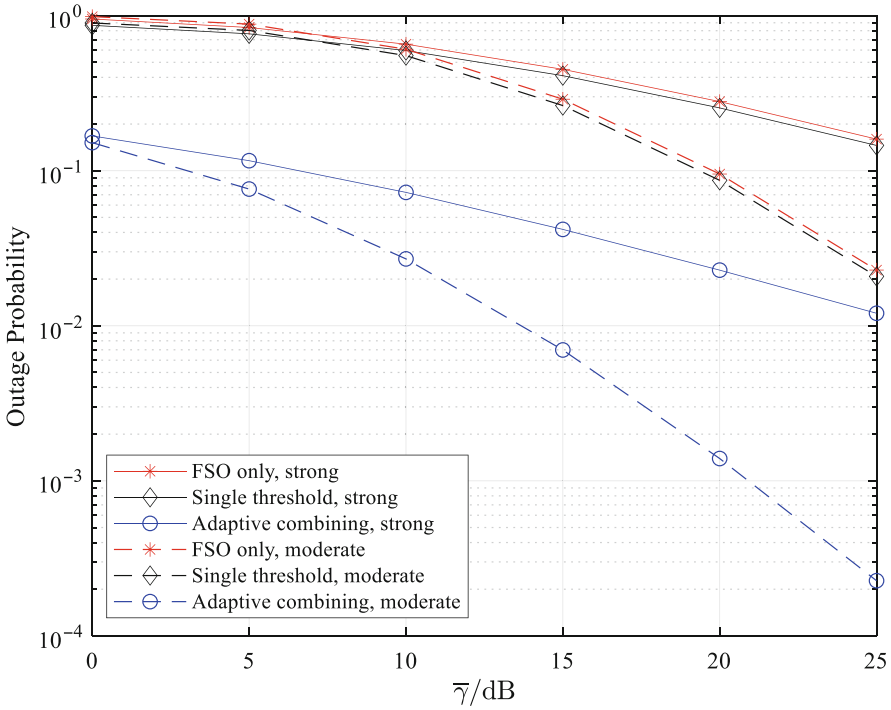

Fig. 47.2 Comparison of the outage performance of the adaptive-combining scheme, single-threshold switching scheme, and single-link FSO

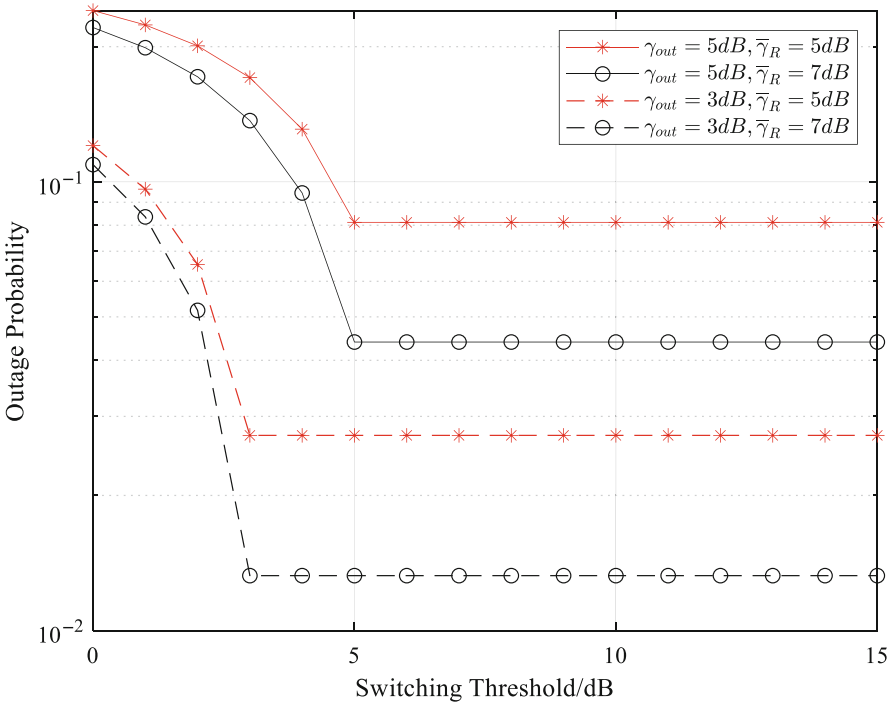

Fig. 47.3 Relationship between the outage probability and switching threshold of the adaptive-combining scheme

system, where $\overline{\gamma}_F = \overline{\gamma}$ is the average signal-to-noise ratio for the FSO link. Figures 47.4, 47.5, 47.6, 47.8, and 47.9 show the performance of the hybrid FSO/RF/THz relay system under the influence of different parameters, where the average signal-to-noise ratios of the FSO, RF, and THz links are $\overline{\gamma}_F = \overline{\gamma}_R = \overline{\gamma}_T = \overline{\gamma}$, respectively.

Figure 47.2 compares the outage performances of the single-link FSO, single-threshold switching, and adaptive-combining schemes under moderate and strong turbulence conditions, where $m = 1$, $\overline{\gamma}_R = 8$dB, $\xi_F = 4.5747$, $\gamma_{th} = 10$dB, and $\gamma_{out} = 3$dB. As shown in Fig. 47.2, compared with moderate turbulence, the outage probability of the system under strong turbulence conditions increases, indicating that an increase in the turbulence intensity leads to the deterioration of the system outage performance.

In addition, it can be observed from Fig. 47.2 that the outage performance of the adaptive-combining system is better than those of the single-link FSO and single-threshold switching scheme. The main reason for this phenomenon is that when the FSO-link quality deteriorates, the single-link FSO has no backup link. The FSO link must be used for transmission all the time, whereas the single-threshold switching scheme can activate the RF link for transmission at this time. However, link switching may occur frequently, which reduces the system transmission

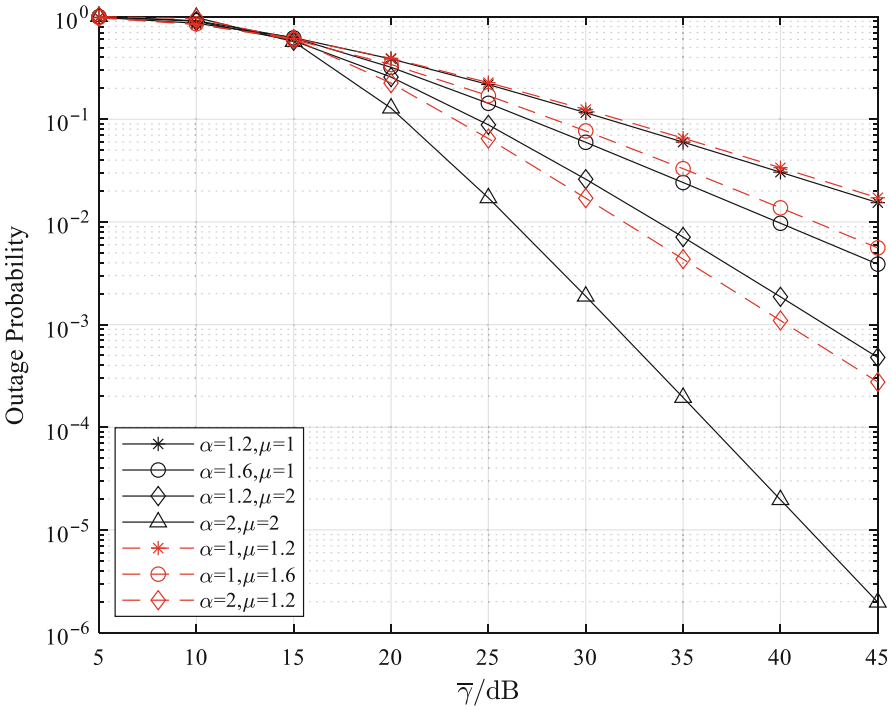

Fig. 47.4 Outage probability of the system under the influence of different fading parameters

performance. The adaptive-combining scheme overcomes the shortcomings of both, so it has better system performance.

Figure 47.3 shows the relationship curve between the outage probability and the switching threshold of the adaptive-combining scheme, where $C_n^2 = 1 \times 10^{-12}\mathrm{m}^{-2/3}$ (moderate turbulence), $m = 2$, $\overline{\gamma}_\mathrm{F} = 10\mathrm{dB}$, and $\xi_\mathrm{F} = 4.5747$. As shown in Fig. 47.3, when $\gamma_\mathrm{out} > \gamma_\mathrm{th}$, the system outage probability gradually decreases with an increase in the switching threshold. When $\gamma_\mathrm{out} \leq \gamma_\mathrm{th}$, the system outage probability reached its minimum value, and the outage probability remains constant. Therefore, the switching threshold must be set above the outage threshold to obtain the best outage performance.

Moreover, increasing the average signal-to-noise ratio $\overline{\gamma}_\mathrm{R}$ of the RF link can improve the system outage performance. This is because as $\overline{\gamma}_\mathrm{R}$ increases, the RF-link quality increases, thereby providing a better-quality backup link for the FSO link.

Figure 47.4 shows the relationship between the average signal-to-noise ratio and the hybrid FSO/RF/THz outage probability under different fading parameters, where $C_n^2 = 1 \times 10^{-12}\mathrm{m}^{-2/3}$ (moderate turbulence), $\xi_\mathrm{F} = 4.5747$, $\xi_\mathrm{T} = 3.4450$, $m = 1$, and $\gamma_\mathrm{out} = 5\mathrm{dB}$. It can be seen from Fig. 47.4 that as the values of α and μ increase, the fading severity of the THz link decreases, improving the outage performance of the system.

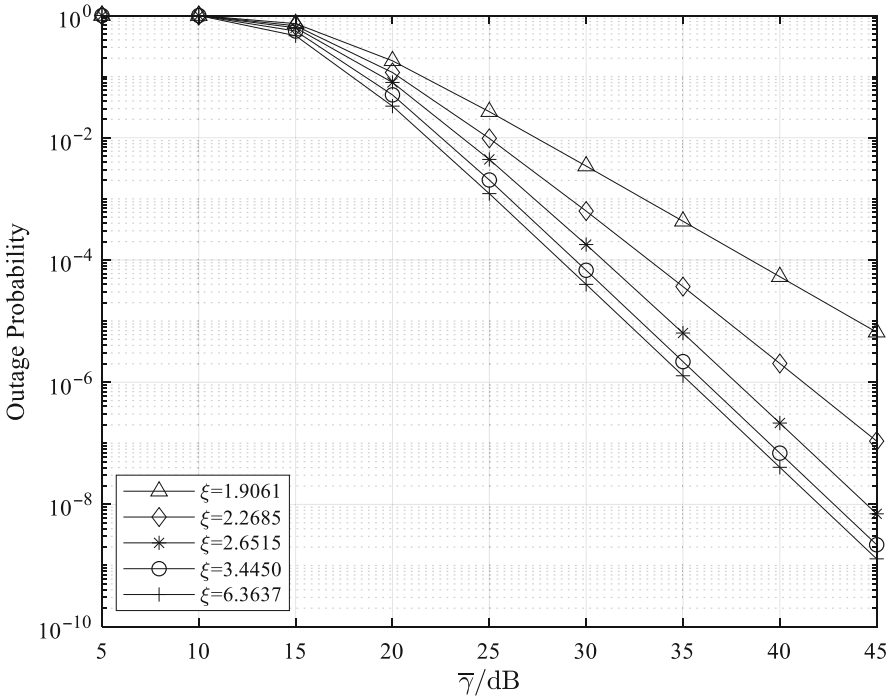

Fig. 47.5 Outage probability of the system under different pointing errors

In addition, the outage performance of the system is compared when varying α, and then when varying μ: $\{\alpha = 1.2, \mu = 1\}$, $\{\alpha = 1.6, \mu = 1\}$, $\{\alpha = 2, \mu = 1\}$ and $\{\alpha = 1, \mu = 1.2\}$, $\{\alpha = 1, \mu = 1.6\}$, $\{\alpha = 1.2, \mu = 2\}$. It can be observed that when the degree of fading is comparable, the outage probability of the system is lower when $\alpha > \mu$ than when $\alpha < \mu$.

Figure 47.5 shows the curves of the average signal-to-noise ratio versus the outage probability of the hybrid FSO/RF/THz system under different pointing errors, where $\xi_F = \xi_T = \xi$, $C_n^2 = 1 \times 10^{-12}\text{m}^{-2/3}$ (moderate turbulence), $m = 1$, $\alpha = 3$, $\mu = 2$, and $\gamma_{out} = 5\text{dB}$. From Fig. 47.5, it can be seen that the smaller the value of pointing error ξ, the greater the impact on the system, resulting in a higher probability of system interruption; therefore, increasing the pointing error can improve the outage performance of the system. However, after the pointing error has increased to a certain value, continuing to increase its value will have a reduced effect on the system outage performance.

Figure 47.6 shows the relationship between the outage probability and average signal-to-noise ratio. The outage performances of a single FSO, single RF, single THz, first-hop adaptive-combining hybrid FSO/RF system, and end-to-end hybrid FSO/RF/THz relay system were studied, where $\xi_F = 4.5747$, $\xi_T = 3.4450$, and $\gamma_{out} = 5\text{dB}$.

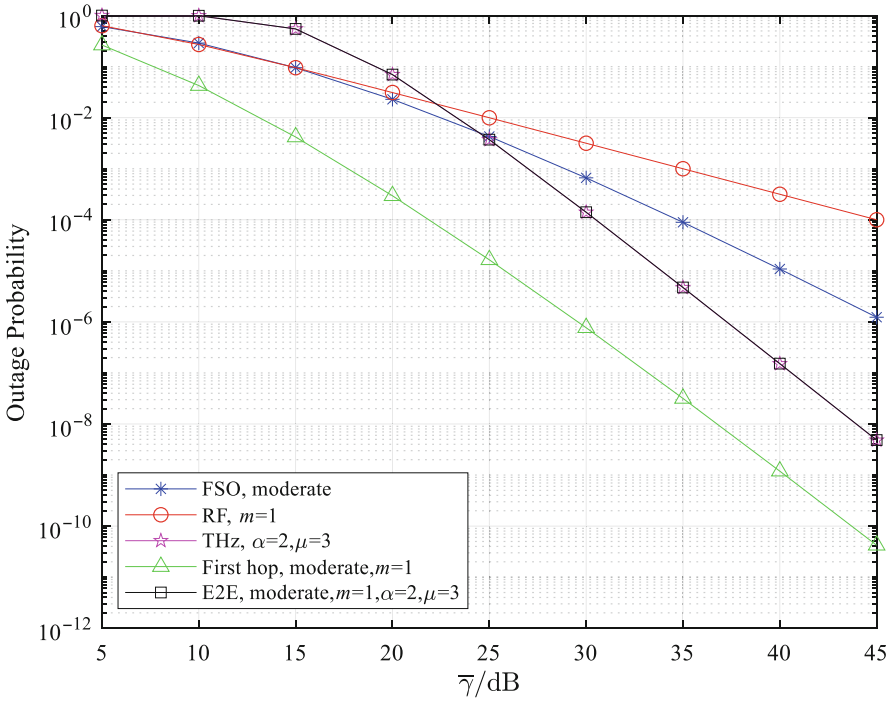

Fig. 47.6 Relationship between the system outage probability and average signal-to-noise ratio

It can be observed from Fig. 47.6 that the outage performance of the THz link is the worst in the low signal-to-noise ratio region. With an increase in the average signal-to-noise ratio, the quality of the THz link continuously improves. In the high signal-to-noise ratio region, the outage performance of the THz link is better than that of the FSO and RF links. In addition, it can be seen from Eq. (47.20) that the outage probability of the dual-hop relay system is determined by the hop with the worst outage performance. Therefore, the outage performance of the end-to-end hybrid FSO/RF/THz relay system shown in Fig. 47.6 is consistent with that of the second-hop THz link.

Figure 47.7 compares the BER performance of the system with a single FSO link, single threshold-switching scheme, and adaptive-combining scheme under moderate and strong turbulence conditions, where $M = 2$, $m = 1$, $\overline{\gamma}_{\mathrm{R}} = 5\mathrm{dB}$, $\xi_{\mathrm{F}} = 4.5747$, and $\gamma_{\mathrm{th}} = 7\mathrm{dB}$.

Figure 47.7 shows that reducing the turbulence intensity of the FSO link effectively improves the error performance of the system. It is also observed that the error performance of the adaptive-combining system is better than those of the single-link FSO and single-threshold switching schemes under both moderate and strong turbulence conditions.

Figure 47.8 shows the relationship curve between the average signal-to-noise ratio and BER of the hybrid FSO/RF/THz system under different fading parameters

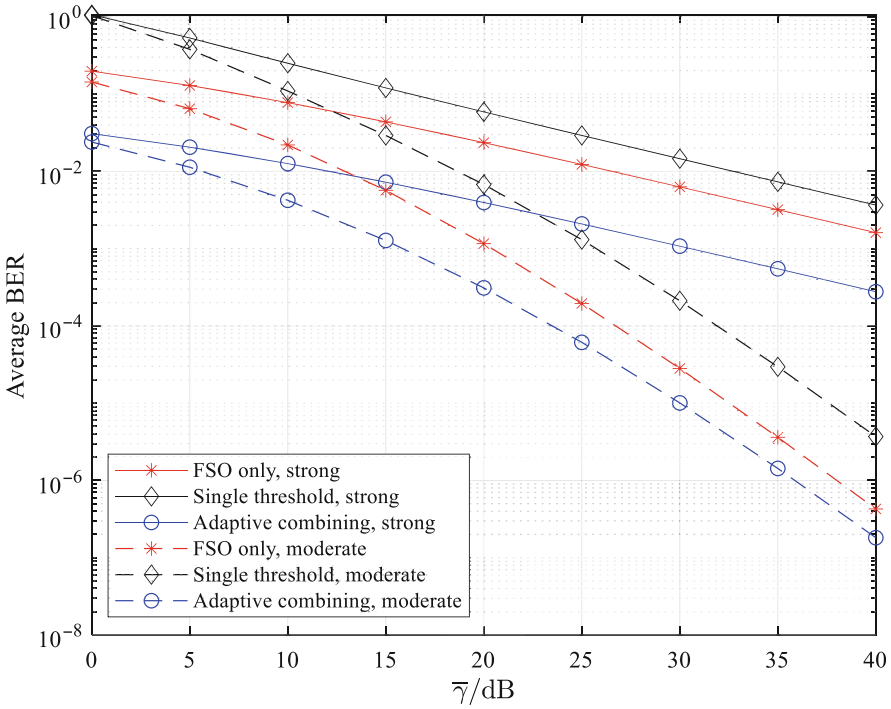

Fig. 47.7 Comparison of the BER performance of the adaptive-combining scheme with those of the single-threshold switching scheme and single-link FSO

and pointing errors, where $\xi_F = \xi_T = \xi$, $C_n^2 = 1 \times 10^{-12} m^{-2/3}$ (moderate turbulence), $M = 2$, $m = 1$, and $\gamma_{th} = 7$dB.

From Fig. 47.8, it can be seen that the pointing-error parameters of the FSO and THz links, as well as the fading parameters α and μ of the THz link, have an impact on the BER performance of the system. The smaller the values of α, μ, or ξ, the more serious the fading and pointing errors of the system. Increasing the value of α, μ, or ξ can reduce the BER of the system and improve the communication quality of the system.

Figure 47.9 shows the relationship between the average BER and average signal-to-noise ratio of the system. The BER performances of a single FSO, single RF, single THz, first-hop adaptive-combining hybrid FSO/RF system, and end-to-end hybrid FSO/RF/THz relay system were studied, where $M = 2$, $\xi_F = 4.5747$, $\xi_T = 3.4450$, and $\gamma_{th} = 7$dB.

As can be seen in Fig. 47.9, in the low signal-to-noise ratio region, the BER performance of the end-to-end hybrid FSO/RF/THz relay system remains consistent with that of the THz link until it enters the high signal-to-noise ratio region, where it approaches that of the first-hop adaptive-combining hybrid FSO/RF system until the two are basically overlapped. This verifies the accuracy of Eq. (47.33).

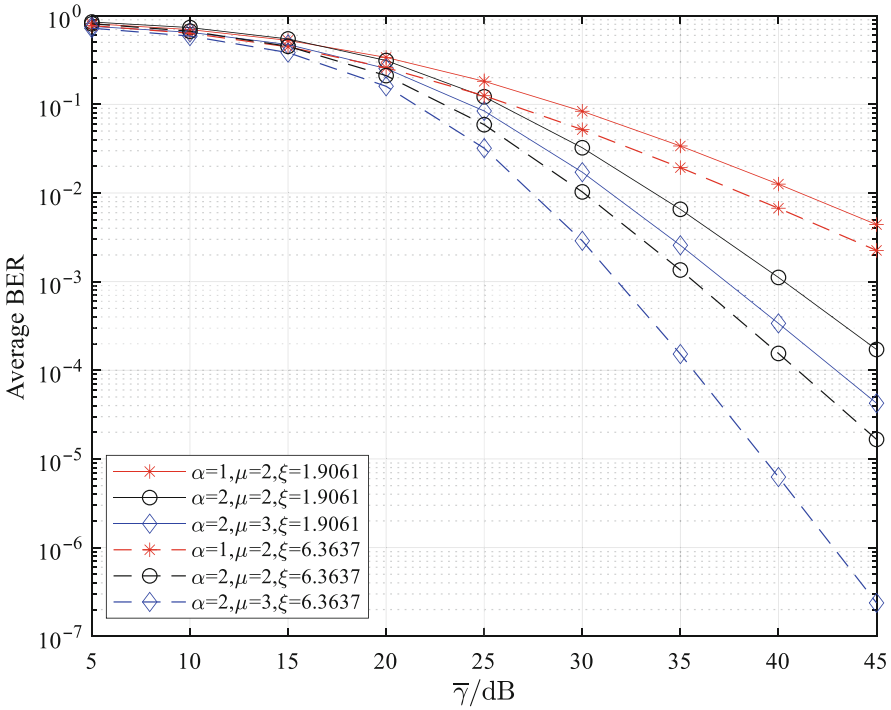

Fig. 47.8 Average BER of the system under different fading parameters and pointing errors

Conclusion

This study designed a hybrid FSO/RF/THz relay communication system that used hybrid FSO/RF communication based on adaptive combining as the backhaul network before the relay node. It then connected to users through the THz link, which provided safe, reliable, low-latency, and high-speed data transmissions.

Considering atmospheric turbulence and pointing errors in the FSO link, and fading and pointing errors in the THz link, the performance equations of the hybrid FSO/RF/THz communication system were derived using the obtained statistical characteristics of the FSO, RF, and THz links.

The simulation results showed that compared with the single-threshold switching scheme and the single-link FSO system, the adaptive-combining scheme in the first hop of the relay system provided better system performance, and the optimal switching threshold of the adaptive-combining scheme was obtained. Moreover, by evaluating the performance of the hybrid FSO/RF/THz relay system under different fading conditions and pointing errors, it was found that both channel fading and pointing errors reduced the system performance. In the high signal-to-noise ratio region, the hybrid FSO/RF/THz relay system provided better outage and BER performance.

Abstract

The transmission capacity of optical wireless communication systems has approached the Shannon limit. The emergence of orbital angular momentum (OAM), as a new lateral space-dimension resource, can exponentially improve the capacity and spectral efficiency of optical wireless communication networks. Adopting OAM-related technologies can provide a potential solution for realizing ultra-high-speed and high-capacity cross-scene optical communications in the future. After comparing and summarizing the relevant domestic and foreign OAM research results, this chapter introduces the OAM research work in the

field of optical wireless communication at Xi'an University of Technology. It is mainly divided into space generation, propagation characteristics, separation and detection, and OAM beam applications. Finally, the future development trends and prospects of OAM technology in the field of optical wireless communication are discussed, providing new ideas and reference values for subsequent researchers to explore in this field.

Introduction

Allen's significant discovery of a spiral-structured light-beam distribution carrying orbital angular momentum (OAM) at Woerdman's Optical Quantum Laboratory in 1992 [1] triggered a wave of OAM research. This unique spatial-domain distribution has promising applications for expanding the channel capacity. The specially structured optical field carrying OAM has also been widely used in scientific fields, such as ultra-high-capacity optical communication [2], particle capture [3], optical metrology [4], and quantum science [5].

Optical wireless communication uses a laser as a carrier wave to transmit data, such as video and voice. It has the advantages of a high transmission rate, flexible networking, strong resistance to electromagnetic interference, etc. It also has good applications in solving the "last mile" bottleneck problem and complex and harsh environment communication [6].

When a vortex beam is transmitted in free space, its absorption, scattering, and attenuation by atmospheric turbulence can cause beam spreading, wandering, and scintillation, resulting in a large communication bit error rate and even communication interruptions [7]. Therefore, the study of OAM technology with a high transmission rate, high security, and strong immunity is one of the research hotspots in the field of optical wireless communication.

Basic OAM Concepts

It is well known that light, an electromagnetic wave, has a wave–particle duality. Its fluctuation is familiar to us, while its particle nature, including energy and momentum, is less understood. Light has linear momentum in the longitudinal direction along the propagation direction, as well as spin angular momentum (SAM) associated with polarization properties, and transverse-spin angular momentum perpendicular to the propagation direction, which exists independently of the SAM.

OAM Properties

Beams with OAM are called vortex beams, and they have been widely studied and explored by the academic community in recent years. Figure 48.1 shows the spiral-wavefront distribution of a vortex beam with different topological charges. The uncertainty of the phase of the spiral wavefront causes coherent-phase extinction of the light intensity. This forms a phase singularity at the center of the vortex beam, which is the point where the light intensity is zero; the OAM is also zero at this time. The optical field of the vortex beam can be expressed as $E(x, y) = u(r, z) \exp(il\theta) \exp(-ikz)$, where $u(r, z)$ is the amplitude function, k is the wavenumber, and z is the beam propagation distance.

Each vortex beam has a spiral phase factor term $\exp(il\theta)$, where θ is the spatial azimuthal angle; l is the topological charge, that is, one cycle around the phase singularity, and the change in phase is l times 2π, producing l winding spiral wavefronts. Each photon in the beam carries $l\hbar$ OAM ($\hbar = h/2\pi$ is the reduced Planck constant); that is, the optical OAM corresponds to an infinite number of eigenmodes, which can construct Hilbert spaces of infinite dimensions; thus, the information capacity and security can be theoretically increased significantly [8].

OAM Beam Types

Common vortex beams are generally classified into three types: Laguerre–Gaussian (LG), Bessel–Gaussian (BG), and Airy vortex (AV). All these beams carry OAM, but they have different characteristics. For example, the BG beam has

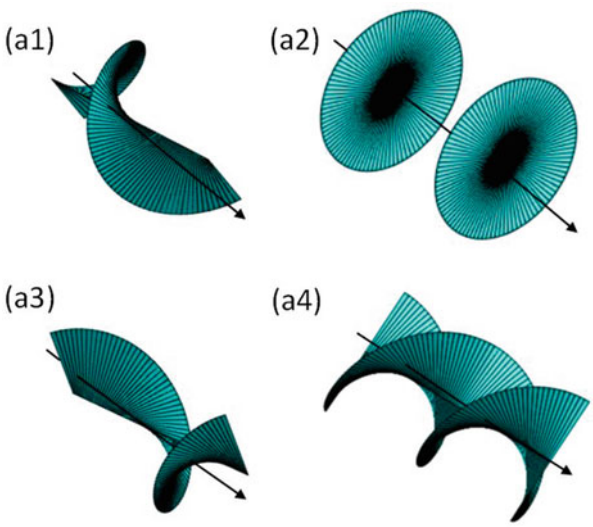

Fig. 48.1 Helical wavefront distribution with different topological charges. (a1) $l = -1$; (a2) $l = 0$; (a3) $l = 1$; and (a4) $l = 2$

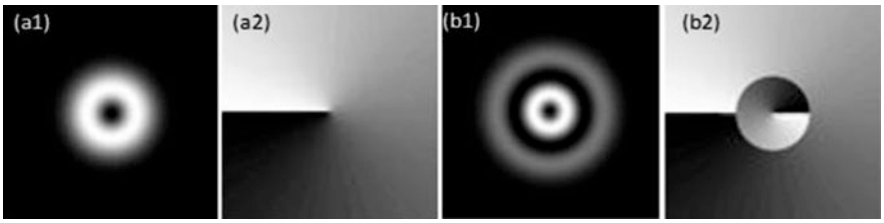

Fig. 48.2 Intensity and phase distribution of LG beams under different l and p. (a1) LG_0^1 beam intensity distribution; (a2) LG_0^1 phase distribution; (b1) LG_1^1 beam intensity distribution; and (b2) LG_1^1 phase distribution

non-diffraction characteristics and good directionality, and the AV beam has self-acceleration and self-bending characteristics.

The LG beam has the characteristics of a Gaussian beam, is easy to prepare in the laboratory, and is one of the most commonly used vortex beam sources. Different combinations of the topological charge l and radial index p can form different forms of LG_{lp} beams. Figure 48.2 shows the light intensity and phase distribution of LG beams at different l and p. The beam profile has a doughnut-shaped distribution, and the number of light rings is equal to $p + 1$.

Research Progress on Vortex Beam Generation

Single Vortex Beam Generation

In 1994, Barnett et al. explored the relationship between the axis symmetric beam and OAM under the non-paraxial approximation. They found that the beam carried OAM as long as it contained the $\exp(il\theta)$ term through theoretical derivation. This laid the foundation for introducing various OAM beams in addition to the Laguerre–Gaussian beam [9].

In 1989, Coullet et al. used a laser resonant cavity to directly generate OAM beams; however, this method required high axisymmetry of the resonant cavity and large intracavity losses, which made it difficult to generate high-quality vortex beams [10].

In 2013, Lee et al. demonstrated direct LG mode generation at the first Stokes wavelength of a diode-side-pumped Nd:$GdVO_4$ self-Raman laser, which was the first intracavity frequency conversion using self-Raman scattering (SRS) [11]. In 2014, Lee et al. demonstrated that the emission of a Stokes wavelength doubled into a 586-nm vortex wave using intracavity Nd:$GdVO_4$ crystals generated from SRS, with a final emission efficiency of 727 mW and a diode-to-visible light conversion efficiency of 4% [12].

In 1992, Heckenberg et al. generated OAM vortex beams using computer-generated holograms (CGH). Holographic gratings can also be generated by methods such as etching scratches on glass plates or holographic photography [13].

In 2012, Escuti et al. designed a forked polarization grating (FPG) that could efficiently generate OAM beams and convert between modes; the relative power between modes could also be controlled by polarization. This method had a diffraction efficiency higher than 90% and was applicable to any wavelength except ultraviolet and infrared [14].

In 2019, Rosales et al. used multilevel OAM holograms to generate structured OAM light fields, illustrating theoretically and experimentally that at least three layers of spiral phase plate (SPP) phases were required to generate OAM beams, whereas the combination with phase diagrams could delay their retention time in three dimensions [15].

In 1993, Beijersbergen et al. used a mode converter consisting of two cylindrical lenses to convert a Hermite–Gaussian (HG) beam into a high-purity LG beam [16].

In 2002, Shvedov et al. used a single optical wedge to produce a single-mode OAM vortex beam. Producing multiple wedges stacked according to certain rules produced higher-order modes [17].

In 2016, Forbes et al. combined spatial light modulators (SLMs) for OAM beam generation and used SLM modulation to generate different types and forms of OAM beams by modifying and writing digital holograms in real time [18].

In 2012, Koh et al. generated a series of convergent OAM electron beams with topological charges up to 90 using a spiral zone plate (SZP) with micromachining technology [19].

In 2021, Hu et al. used a digital micromirror device (DMD) to generate and characterize complex vector modes. They generated vector beams, such as LG, Ince–Gaussian, Mathieu–Gaussian, and parabolic–Gaussian, using a binary encoding scheme based on random spatial multiplexing. Finally, vector-mode characterization techniques, such as the real-time Stokes polarization reconstruction method, were described [20].

In 2015, Padgett et al. designed a generalized photon sieve to generate OAM beams. It reduced the number of pinholes from thousands to hundreds, compared to the original photon sieve, and could generate LG beams with different radial and angular indices, as well as superposition states [21].

In 2017, Devlin et al. used a two-dimensional metasurface consisting of dynamic and geometric phases to generate OAM beams. The metasurface was a J-plate composed of rectangular nanoantennas of different sizes, which allowed any orthogonal polarization state to be converted to independent OAM modes, compared to previous Q-plates, and could be used with high-power laser beams [22].

In 2021, Dorrah et al. designed a total angular momentum (TAM) board that enabled two main classes of functions. The first type was a polarization-switchable device that switched between two generated vortex beams by changing the incident orthogonal polarization state. The other type was effective for any incident polarization state and allowed flexible control of the optical OAM, SAM, phase, polarization, and amplitude along the propagation direction [23].

In 2019, Sheng et al. designed a flat-plate spiral phase plate (SPP) to generate vortex beams; it could flexibly adjust the OAM angular quantum number and SPP

height of the generated vortex beams. The accuracy of the generated beams increased with an increase in the phase order [24].

In 2014, Brunet et al. added a material with a refractive index lower than that of the cladding in the annular region of a ring fiber, and simulated the generation and transmission of 28 OAM modes, while the experiment accommodated 36 modes [25]. In 2017, Pidishety et al. used an all-fiber mode-selective coupler consisting of a single-mode fiber and a ring-core fiber to excite OAM beams by direct phase-matched coupling with a final excitation-mode purity of 75% [26].

In 2020, Hassan et al. proposed a circular-core photonic crystal fiber (PCF) with a large air hole in the center, which supported stable transmissions of up to 38 OAM modes with a larger bandwidth and flat dispersion variation [27]. In the same year, Israk et al. designed a large-bandwidth PCF consisting of three twisted and coiled structural cavities, which supported up to 56 OAM modes with flat dispersion variation and limited losses below 1.7407×10^{-11}dB/m [28].

In 2020, Cognée et al. demonstrated that a plasmonic photon-resonant microdisk cavity using an addressed waveguide could produce a correlated beam with controlled OAM and SAM [29]. The following year, Butt et al. proposed and compared three μ-ring resonant-cavity structures for standard strip, slot, and hybrid plasma waveguides. They found that silicon-strip waveguide ring resonators were simple to fabricate but had low sensitivity; hybrid plasma had the best sensitivity; and the slot waveguide was superior in terms of quality factor and detection limit [30].

Generation of Superimposed Vortex Beams

In 2003, Stabinis et al. superimposed two intersecting LG beams interferometrically, resulting in a more pattern-rich composite optical vortex. The number and position of the composite vortices could be changed by varying the propagation length of the vortices, topological charge of each beam, phase difference, intersection angle, and amplitude ratio [31].

In 2006, Galvez et al. superimposed two LG beams coaxially to produce a composite vortex beam with a novel phase singularity. They focused on the effect of the optical intensity ratio of the two LG beams on the light intensity distribution of the superimposed state of the LG beams [32].

In 2009, Baumann et al. studied the effect of the relative amplitude and phase on the off-axis propagation of the colinear superposition of LG beams and provided an explanation using the Gouy phase [33].

In 2009, Yang et al. studied the colinear composite superposition of planar and annular vortices and proposed a method to obtain the location and distribution properties of such colinear superposition vortices [34].

In 2010, Ando et al. analyzed the structural properties of different phase singularities of double and multiple LG-mode superposition states with different angular and radial indices, and verified the singularity properties by theoretical derivations and experiments [35].

In 2012, Fang et al. generated fractional-order double-ring vortex beams theoretically and experimentally, and double-ring beams with different spacings and notches were obtained by varying the topological charge number. The results showed that the fractional-order double-ring vortex beam could be controlled individually between them; it had more control diversity than the integer-order and single fractional-order beams [36].

In 2015, Zhu et al. proposed a pattern search-assisted iterative (PSI) algorithm using a generated phase diagram. It simultaneously generated multi-OAM mode beams with up to 100 randomly spaced OAM modes and controlled their relative power distributions with a diffraction efficiency higher than 93%, along with a low standard deviation and relative root-mean-square error [37].

In 2016, Huang et al. used an out-of-cavity mode-selection method to achieve the coaxial superposition of multiple LG beams using a modified CGH to produce a high-quality composite vortex beam [38].

In 2020, Mateusz et al. proposed a method for generating high-symmetry composite vortex beams. The method allowed the intensity relations between the structures to be controlled so that they could rotate, while being able to superimpose more than two such structures. Their results showed that the optical vortex superposition of two such structures generated a highly symmetric composite vortex beam [39].

In 2021, Kumar et al. designed a hybrid binary-forked grating (hBFG), which was computationally generated by removing the central region around the corresponding forked dislocation and replacing it with a BFG corresponding to different topological charges. Optimizing the geometric parameters of this grating allowed the generation of a composite vortex beam consisting of three different topological charges and higher-order radial indices, while controlling the intensity and radius of the individual modes [40].

In 2022, Kotlyar et al. studied the superposition of several identical parallel single-ring LG beams and found that when the weighting factor of the superposition was real, the net topological charge of the superposition was equal to the sum of the individual components, regardless of whether it was for the initial plane or the far field. The phase delay between the beams changed the number of superimposed net topological charges [41] (Table 48.1).

Optical OAM has been studied since 1992. In the beginning, OAM beams were generated in a laser resonant cavity [10], that is, an optical vortex laser. This active scheme is generally divided into direct-generation [42], ring-beam pumping [43, 44], central damaged-cavity [45, 46], and thermally induced membrane-aperture methods [47, 48].

A new method of generating computer-controlled vortex lasers [49, 50] has emerged in recent years. It applies SLMs to act as a piece of resonant mirror inside the laser cavity, while the computer enables the flexible customization of the vortex beam with arbitrary properties. These methods of actively generating vortex beams from solid-state laser cavities require special components designed inside the cavity or higher pump optical power. They are simple and easy to operate; however, they cannot generate vortex beams with simultaneous high conversion efficiency, high orders, and multimodality.

Table 48.1 Domestic and foreign research progress on vortex beam generation

Year	Researcher	Research progress
1989	Coullet	Generated a beam in a laser resonator
1992	Heckenberg	CGH
1993	Beijersbergen	Mode converter
2002	Shvedov	Single light wedge
2003	Stabinis	Superposition of interference
2006	Galvez	Effect of light intensity ratio on LG beam superposition state
2009	Baumann	Effect of phase difference on composite vortex beams
2009	Yang	Interference superposition of planar vortex beams
2010	Ando	LG beam superposition state with different topological charges and radial indices
2012	Fang	Superposition of fractional double vortex beams
2012	Koh	SZP
2012	Escuti	Fork-shaped polarization grating
2013	Lee	Diode side-pumped self-Raman Nd:$GdVO_4$ laser
2014	Brunet	Hollow-core step fiber
2014	Brunet	Hollow-core step fiber
2015	Zhu	PSI algorithm generates the phase diagram
2015	Padgett	Generalized photon sieve
2016	Huang	Improved computer hologram to generate multi-LG coaxial superposition
2016	Forbes	SLM with modified CGH in real time
2017	Devlin	Two-dimensional metasurface
2019	Sheng	Flat-plate SPP
2020	Hassan	Circular-core PCF
2020	Cognée	Plasma-resonant microdisk cavity for waveguide addressing
2020	Mateusz	Highly symmetrical composite vortex beams
2021	Hu	DMD represents complex vector patterns
2021	Dorrah	TAM plate
2021	Kumar	Improved hBFG generation
2022	Kotlyar	Parallel single-ring LG superposition

A passive scheme, which mainly uses various optical components outside the resonant cavity to convert other types of beams into vortex beams, is implemented using various and flexible methods, such as CGH [13–15], SZP [19], mode converters [16], optical wedges [17], SPP [24], SLM [18, 53], DMD [20], and photonic sieves [21]. Among these, the CGH diffraction method is easy to operate and inexpensive; however, its diffraction efficiency is low. Methods to optimize the CGH quality using iterative algorithms have also been proposed, such as the Gerchberg–Saxton (GS) iterative algorithm [51] and the pixelwise hybrid input-output (PHIO) method [52].

The SZP method is similar to CGH, but the diffraction uses spherical waves instead of plane waves and is more suitable for the field of electron microscopy. Mode converters produce beams with high purity; however, their operation is

complicated. The optical-wedge block system is simple and reliable, but the components require high processing accuracy. An SPP generates high beam purity but can only produce OAM beams with fixed modes and parameters.

A DMD is inexpensive and can produce OAM modes at high switching rates, but its diffraction efficiency is not ideal. Photon sieves have a wider available waveband and a higher spatial resolution; however, the diffraction efficiency is not high. SLM is convenient for adjusting parameters and has a higher diffraction efficiency; however, the energy threshold is limited.

In the q-plate and J-plate [22], a birefringent crystal allows the transition from the local polarization state to the OAM mode, and generates a higher-purity OAM beam. The J-plate can be used with a high-power laser beam. Finally, metamaterials, metasurfaces [22, 23], fiber-optic devices [25–28], and photonic integrated devices [29, 30] have evolved. Such systems are compact, easy to integrate, and can generate a variety of efficient OAM modes.

In terms of superposition-state vortex beams, the classical method of an SLM-loaded CGH is still mainly used [36–38, 40]. Only the forms of the superposition states vary, from the initial double-superposition state of petal-like and circular hole splitting to the superposition of three, four, or even more LG beams. The types of superposition include fractional-order superposition as well as radial-index superposition.

These multispecies and multimodal superimposed vortex beams can also be controlled by the beam parameters of a single state to transform the superimposed light field structure and light intensity ratio [31–33, 39, 41]. This injects new vitality and lays a solid foundation for enhancing the transmission capacity of large-scale optical wireless OAM communication systems.

Research Progress on Vortex Beam Transmissions

Vortex Beam Transmission Characteristics

In 2001, the International Telecommunication Union (ITU) proposed an ITU-Radiocommunication Sector (ITU-R) atmospheric structure-constant model capable of varying with height to study vortex beam transmissions in turbulence with a slanted path [54].

In 2005, Paterson et al. studied the detection-probability distribution of a vortex light field after turbulent scattering and found that the narrower the beam, the smaller the OAM scattering, and the wider the beam, the smaller the scintillation [55].

In 2008, Anguita et al. used the Kolmogorov atmospheric turbulence spectrum as a model to analyze the system capacity of multiplexed OAM systems when transmitted in free space and proposed a bit error rate (BER) evaluation method [56].

In 2008, Gbur et al. investigated the transmission of vortex beams in weak-to-strong turbulence and showed that the topological charge of the beam was, in principle, a robust quantity that was not lost after long-distance transmission and could be used as a carrier for optical communication [57].

In 2009, Tyler et al. studied the disturbances of OAM beams after turbulent atmospheric transmissions, where the quantitative derivation of the quantum information loss rate was encoded on single-photon OAM states in turbulent transmissions [58].

In 2009, Pu et al. theoretically and experimentally demonstrated the beam expansion of vortex beams in atmospheric turbulence and found that vortex beams were less affected by turbulence than non-vortex beams [59].

In 2011, Pu et al. also investigated the transmission characteristics of elliptical vortex beams at different turbulence intensities. It was found that the smaller the ratio of the short axis to the long axis of the ellipse, the smaller the scintillation index; this indicated that the choice of elliptical vortex beams for transmission could reduce the scintillation index [60]. In 2012, the group investigated the far-field diffraction intensity distribution of off-axis LG beams using the Fresnel diffraction theory and determined the law of the topological charge sign affecting the direction of the singularity movement [61].

In 2012, Lukin et al. numerically simulated the beam spreading of low-order vortex beams in atmospheric turbulence and found that the average spreading of vortex beams was smaller than that of Gaussian beams. In addition, the larger the topological charge number, the smaller the beam spreading and the less it was affected by turbulence [62].

In 2013, Aksenov et al. investigated the wander variance of LG beams in turbulent flows using numerical simulations. The results showed that the spot-wander variance of the LG beam was smaller when the topological charge number was larger, the radial index was larger, the outer scale was smaller, and the beam wander of the Gaussian beam was larger than that of an LG beam [63].

In 2014, Banakh et al. studied the LG beam spreading effect in atmospheric turbulence and simulated the intensity distribution of the LG beam after propagation. The results showed that the turbulent spreading of the LG beam relative to the diffraction spreading did not depend on the mode but on the diffraction region at the emission aperture; instead, the absolute turbulent spreading of the LG beam increased with increasing topological charge [64].

In 2016, Ge et al. studied the relative beam width variation of LG beams in turbulence and found that a longer transmission distance, stronger turbulence, smaller topological charge, larger beam waist, and shorter wavelength led to a larger beam width variation and LG beam spreading when influenced by turbulence [65].

In 2016, Filimonov et al. numerically simulated and analyzed the OAM variation when an LG beam propagated in atmospheric turbulence and studied the effect of beam and receiver axis alignment errors on the mean and variance of OAM fluctuations [66].

In 2017, Porfirev et al. studied the propagation characteristics of vortex beams in a random aerosol medium. It was found that, at short distances, vortex beams were mostly less stable than Gaussian beams; however, at long distances, vortex beams were more stable, probably because of their ability to recover after passing an obstacle [67].

In 2018, Tian et al. conducted a numerical simulation of a longitudinal OAM multiplexing (LOAMM) system under atmospheric turbulence, using a stepwise Fourier-transform method. The results showed that the detection probability spectrum of the system was inversely proportional to the OAM modes, turbulence intensity, and propagation distance under finite-aperture conditions, and the performance of the LOAMM system was better than that of OAM space-division multiplexing (SDM) [68].

In 2019, Luo et al. used the generalized Huygens–Fresnel principle and the Rytov approximation to derive expressions for the transmission intensity of arbitrary-order vortex beams and their arrays in turbulence. They numerically simulated the beam spreading and evolution to obtain the mean-square beam widths for different beam and turbulence parameter variations. They concluded that vortex beam arrays were less affected by turbulence than single-mode vortex beams, and that radial vortex beam arrays eventually evolved into Gaussian-like beams [69].

In 2020, Yan et al. analyzed the far-field optical-intensity distributions of super-Gaussian and Gaussian vortex beams in turbulence using the Fresnel diffraction principle and obtained the variation in the distortion-dispersion degree of the two beams with different parameters [70].

In 2022, Lazrek et al. simulated the evolution of the beam spreading and mean intensity of a vortex cosine-hyperbolic Gaussian beam (vChGB) in ocean turbulence, based on the extended Huygens–Fresnel diffraction principle, and analyzed the effect of parameters, such as the mean-square temperature and dissipation rate of the temperature to the salinity-fluctuation ratio, on the beam propagation [71].

Beam Transmission Characteristics of Partially Coherent Vortex Beams

In 2009, Cai et al. derived an analytical formula for the cross-spectral density of partially coherent standard and elegant LG beams, after passing through a paraxial-axis ABCD optical system, and compared their light intensity and spreading characteristics in free space; they were found to be closely related to the initial coherent state of the source [72, 73].

In 2011, Cui et al. analyzed the angular width and beam transmission factor (M2 factor) of a partially coherent LG beam after transmission in atmospheric turbulence, using the extended Huygens–Fresnel principle and second-order moments of the Wigner distribution function (WDF) [74].

In 2015, Tang et al. investigated the effects of isotropic and anisotropic random media on the transmission characteristics of MGSMV beams in terms of the light intensity distribution and spatial-coherence distribution [75].

In 2017, Yao et al. discussed the effect of non-Kolmogorov turbulence on the beam width and angular spreading of multi-Gaussian–Schell-model vortex (MGSMV) beams and found that the anti-turbulence performance of MGSMV beams was better than that of multi-Gaussian–Schell-model (MGSM) and Gaussian–Schell-model (GSM) beams [76].

In 2018, Gbur et al. introduced the twisted-vortex Gaussian–Schell mode beam (tvGSM), a new partially coherent OAM vortex beam determined by the potential vortex order of the random beam and the "bending" parameter of the beam ensemble. The transmission characteristics and OAM density of the beam were also analyzed [77].

In 2021, Hyde et al. proposed a twisted space-time optical vortex (STOV) beam, derived the mutual-coherence function and linear and angular momentum densities, and simulated the synthesis of a STOV beam and its propagation in free space with different degrees of coherence [78].

In 2022, Hricha et al. studied the focusing characteristics and focal shift of a partially coherent vortex cosine-hyperbolic Gaussian beam (PCvChGB) when it passed through a lens system and concluded that the spatial-coherence length, Fresnel number, and beam parameters had a significant effect on the mean intensity distribution and focal shift of the beam-focusing region [79].

Vector Vortex Beam Transmission Characteristics

In 2009, Haus et al. studied the light intensity distribution model, polarization degree, and scintillation index of vector vortex beams after transmission through atmospheric turbulence, in combination with random phase-screen theory. They compared the transmission characteristics with those of standard Gaussian beams and scalar vortex beams and found that the scintillation of vector vortex beams was less than that of scalar vortex beams under the same light source conditions [80].

In 2013, Martinez-Herrero and Prado discussed the evolution of the polarization structure of partially coherent radially polarized vortex beams [81].

In 2015, Jiang et al. studied the polarization characteristics of elliptically polarized vortex beams in turbulent flows and analyzed the effects of the polarization ellipticity, topological charge number, and beam width on the average polarization intensity and degree [82]. In the same year, Cheng et al. introduced a linearly polarized butterfly–Gaussian vortex beam with a butterfly–Gaussian structure in the far-field plane and discussed the effects of parameters, such as topological charge number, linear polarization angle, off-axis distance, and scattering length, on the far-field diffraction structure of a linearly polarized butterfly–Gaussian vortex beam [83].

In 2016, Guo et al. derived the cross-spectral density matrix of a partially coherent radially polarized vortex (PCRPV) beam after an ABCD optical system and found that the vortex phase reduced the degradation of the intensity distribution caused by coherence, as well as depolarization. They also experimentally generated a PCRP vortex beam [84].

In 2016, Eyyuboğlu et al. studied the scintillation properties of vector vortex beams in a strong turbulence region by using a random phase-screen method. It was found that the scintillation effect gradually diminished with an increasing topological charge number, but the rate of diminution gradually slowed [85].

In 2018, Tang et al. introduced a new radially polarized beam, the multiple cosine Gaussian–Schell-model (MCSGSM) beam, and also analyzed the light intensity, coherence degree, polarization degree, and polarization state of the MCSGSM beam in non-Kolmogorov turbulence. They found that its polarization state had a self-splitting property [86].

In 2020, Joshi et al. theoretically and experimentally investigated the coherent polarization variation of a high-order vector vortex beam. The results showed that the transverse degree of polarization (DOP) of a partially coherent vector vortex beam (PCVVB) depended on the spatial correlation of the beam, whereas the state of polarization (SOP) remained constant [87].

In 2021, Joshi et al. studied the statistical properties of PCVVBs embedded in V points and found that the modulation of the spatial coherence length in the source plane could effectively control the coherence intensity, as well as the DOP and SOP distributions [88].

In 2022, Manisha et al. studied the far-field intensity, SOP, and DOP distributions of a non-isotropic PCVVB, both theoretically and experimentally, and found that the variations in these distributions were related to the Poincaré–Hopf index and non-isotropic parameters of the input beam [89]. In the same year, Arora et al. theoretically and experimentally demonstrated the perturbation of a uniform linearly polarized beam to a vector singularity. The amount of radial displacement of the beam center of mass caused by this perturbation could indicate the strength of the perturbation [90].

Adaptive Wavefront Correction for Vortex Beams

In 2009, Starikov et al. used a Shack–Hartmann (SH) wavefront sensor with a singular reconstruction technique and a bimorphic piezoelectric-ceramic reflector to correct the phase of distorted vortex beams, which greatly improved the Strehl ratio and optical-system resolution [91]. In 2012, Garanin et al. used a flexible deformation mirror and the SH algorithm for wavefront correction of continuous- and pulsed-wave lasers. The results showed a significant improvement in the corrected Strehl ratio and an order-of-magnitude reduction in the beam aberration [92].

In 2012, Leach et al. used two aberration-correction methods, the SH algorithm and the Gerchberg–Saxton (GS) algorithm, to correct a distorted OAM beam after turbulence and found that both methods improved the purity of the single OAM state and the free-space optical (FSO) channel capacity, but the GS algorithm was somewhat better [93].

In 2007, Jesacher et al. used the GS algorithm and a spatial light modulator loaded with its hologram to correct an LG beam, which was better for low-order mode correction [94].

In 2018, Baranek et al. corrected a vortex beam optical aberration by introducing an optimized spiral phase modulation with the GS algorithm and combining it with the SLM into an adaptive correction system. The results showed that the accuracy

and efficiency of the GS-algorithm aberration correction could be significantly improved by using the vortex image spot as the target-intensity mode during the iterative process [95].

In 2015, Xie et al. proposed the stochastic parallel-gradient descent (SPGD) algorithm, based on a Zernike polynomial, to correct multiple distorted OAM beams. The crosstalk between modes was reduced by 5 dB, and the Zernike polynomial coefficients of the corrected modes were obtained from the feedback loop [96].

In 2018, Xu et al. investigated a dual-correction method using a combination of the liquid-crystal adaptive optics (AO) technique and phase-diversity (PD) algorithm. The AO correction technique compensated for the distortion caused by turbulent perturbations for the first correction. Then, the PD algorithm was used to correct the residual wavefront distortion [97].

In 2020, Gao et al. designed a turbulence-aberration correction convolutional neural network (TACCNN) model, which was able to correct and compensate for the turbulence aberration of a vector vortex beam by supervised learning of a large number of experimental samples. The mode purity was improved from 19% to 70% [98].

In 2021, Zhan compared the correction effect of the SH, SPGD, and GS algorithms through an improved underwater-turbulence model using experimental studies and found that the GS algorithm had the best correction effect, the SPGD algorithm the second best, and the SH algorithm the worst [99] (Table 48.2).

The propagation properties of OAM beams in atmospheric turbulence have been gradually studied and explored by a wide range of scholars since 2000. At the beginning, turbulence effects were studied, such as beam spreading [58, 59, 62, 64, 65, 69, 71], beam wander [58, 61, 63, 111], light intensity scintillation distribution [55, 58, 60], energy attenuation, and spiral spectrum dispersion [58, 100]. Coherent optics has also developed rapidly, and vortex beams have been extended from fully coherent to partially coherent [72–79], scalar to vector light [80–90], and integer order to fractional order.

Studies on the transmission properties of different light sources, such as elliptical vortices [60, 109], off-axis vortices [61], flat-top vortices [101], standard and elegant vortices [102], array vortices [69], super-Gaussian [70], vChGB [71, 103], and others [104, 105, 108, 109], have also appeared. The evaluation indices also range from the optical-intensity phase distribution, spiral-spectral distribution, relative beam width, and scintillation index to the transmission factor, complex coherence, beam quality, polarization characteristics, mode probability density, and scattering characteristics [112]. However, most of these properties are still at the theoretical and simulation stage, and further exploration and research in experimental studies are needed [106, 107].

Adaptive wavefront correction gradually developed from the SH algorithm [91–93], with wavefront sensors at the beginning, to the GS algorithm [94, 95], SPGD algorithm [96, 110], and PD algorithm [97], without wavefront sensors. The evaluation indexes also ranged from the optical-intensity correlation coefficient,

Vortex Beam Separation Measurement

In 2002, Leach et al. proposed a method for OAM state detection based on a Mach–Zehnder interferometer to separate multimode OAM states, but only the odd–even superposition of OAMs could be detected separately [113].

In 2003, Vasnetsov et al. proposed a method to measure the OAM topological charge of a vortex beam using the rotational Doppler effect. They detected the continuous rotation of the interferometric pattern by an experimental method using an off-axis aperture and derived the measured topological charge according to the law of beam rotation [114].

In 2009, Ghai et al. studied the light intensity distribution of a vortex beam after diffraction through a single slit, and the OAM of the vortex beam was determined by observing the direction and magnitude of the curvature of the stripe [115].

In 2014, Silva et al. derived the OAM magnitude and sign of the incident light, based on the distribution rule of diffraction patterns of LG beams, after passing through triangular and square apertures. They found that square apertures could detect topological charges up to 20 orders, which was twice as high as triangular apertures [116].

In 2014, Emile et al. conducted double-slit interference experiments using a vortex beam, and the experimental setup was simple and easy to operate. The direction and magnitude of the movement of the interference fringe could be observed by the naked eye, and the direction and magnitude of the incident vortex beam OAM were obtained [117].

In 2014, Zhou et al. designed a dynamic double-slit interference-detection system by taking two slits on an opaque screen, and alternating the output optical power between high and low by scanning the center of the slit. Using this property, the OAM of the beam could be measured. The scheme was simple to implement, inexpensive, robust to beam incidence deviation and mode impurities, and could measure higher-order OAM modes [118].

In 2016, Fu et al. extended the detection range of Dammann vortex gratings from −12 to +12 to −24 to +24 by synthesizing Dammann vortex gratings with −12 to +12-order spiral phase diagrams. They detected single-mode or superposition-state OAM by the appearance of solid bright spots in far-field diffractive diagrams [119].

In 2016, Li et al. improved the gradually changing-period amplitude grating by proposing a gradually changing-period phase grating. They then introduced a blazing grating and replaced its structural parameters with special trigonometric functions to concentrate the energy at the first-order diffraction level, thus improving the detection accuracy [120].

In 2017, Taira et al. demonstrated for the first time that the off-axis diffraction of an incident LG beam using a simple circular aperture could detect an incident vortex beam. The singularities of the vortex beam were continuously split along the direction perpendicular to the circular aperture motion, and the number and orientation of the split-vortex singularities coincided with the topological charge magnitude and sign of the incident beam, respectively [121].

In 2018, Acevedo et al. numerically simulated and experimented on the Fraunhofer diffraction of OAM using rectangular and pentagonal apertures. It was found that the rectangular apertures could only detect the topological charge magnitude of the vortex beam, and the detection range was only 0–5, while the non-equilateral pentagonal apertures could detect both the topological charge magnitude and sign, and the detection range was 0–20, which was twice as large as that of the triangular apertures [122].

In 2020, Li et al. designed a gradually changing-period spiral-spoke grating (GCPSSG), which combined a spiral phase diagram with an axicon hologram and a gradually changing-period phase grating to detect up to 160 topological charges. The grating was well tolerant to environmental vibrations and beam alignment [123].

In 2017, Kotlyar et al. detected vortex beams using astigmatic transformations, introduced by methods such as cylindrical lenses or tilted spherical lenses, and found that cylindrical lenses were the most effective, with a maximum measured topological charge of 100 [124].

In 2018, Li et al. coupled an incident OAM beam into a single-surface plasmon polarized beam with different splitting angles using an on-chip plasmon nanograting. The magnitude and sign of the OAM could be detected using this method [125].

In 2018, Zhang et al. proposed a convolutional neural network (CNN)-based multilayer representation-learning method to measure multiple OAM states after turbulence, with a detection accuracy of approximately 95.2% in six typical turbulent flows [126].

In 2020, Giordani et al. used enhanced CNN and support vector machine (SVM) algorithms, such as principal component analysis (PCA) and dimensionality reduction (DR) algorithms, which could effectively extract the properties of high-dimensional photon-vector vortex beam systems with a final recognition classification accuracy of more than 90% [127].

In 2021, Rasouli et al. designed a parabolic linear grating to detect the radial index and topological charge of OAM beams. The first-order diffraction level pattern in the simulation and experiments consisted of an $(l + p + 1) \times (p + 1)$ two-dimensional array of optical intensity points. The results showed that vortex beams with a radial index of up to five could be measured [128].

In 2022, Wang et al. proposed the detection of high-order OAM beams and multi-OAM beams using a far-field diffraction fringe generated by a forked grating, while the accuracy and reliability of fringe detection could be improved by increasing the number of bifurcations and offsets [129].

In 2010, Berkhout et al. proposed a coordinate-conversion method that used two static optical elements to effectively separate and measure OAM light states. This method converted a vortex beam containing a spiral phase into a beam with a transverse-phase gradient and then separated the OAM states of single-mode or superimposed vortex beams, according to the distribution of horizontal positions. It finally enabled the separation and measurement of 11 OAM states [130].

In 2013, Mirhosseini et al. improved the coordinate-transformation method proposed by Berkhout by combining the replication-technique (fan-out) algorithm of the beam, so that the lateral phase-gradient distribution after the separation of different modes of vortex light became finer and the overlap between adjacent modes became lower. The separation efficiency increased from 77% to 92%, compared to the normal polar-coordinate transformation, which was beneficial for the efficient separation and detection of OAM superposition states [131].

In 2017, Ruffato et al. designed high-resolution pure-phase diffraction-optics devices and used them for separating and detecting OAM modes with a separable topological charge range of -14 to $+14$, eventually reaching a crosstalk value of -15 dB. The device is expected to be integrated into optical platforms or optical fibers for optical processing [132]. In the same year, Ruffato et al. proposed a compact OAM-mode sorter with logarithmic polar-coordinate transformations, which integrated the coordinate-transformation and phase-correction functions on a phase mask, improving the compactness of the OAM-mode demultiplexer and simplifying the alignment operation [133].

In 2017, Zhao et al. [134] proposed a coordinate-transformation method for separating OAM modes with a radially varying phase, where the OAM topological charge number and radially varying phase determined the horizontal and vertical positions. Simulation and experimental results showed that two to three OAM superposition modes could be separated, and the separation efficiency was improved compared with that in Refs. [130, 131].

In 2018, Chen et al. spirally transformed an OAM beam by representing the phase diagram corresponding to the OAM beam as a spiral line and then converting the collected spiral lines to parallel lines to achieve n-fold spot broadening. Simulations

and experiments showed that this method improved the optical refinement by nearly a factor of three compared to the log-polar transformation and finally separated high-resolution OAM modes [135].

In 2019, Ruffato et al. integrated a beam expander and phase corrector on the same side of a transparent quartz plate to implement a compact OAM-mode sorter. This method enabled OAM-mode separation and detection from −10 to +10 and extended the feasibility to non-paraxial conditions, significantly improving the integration and alignment of the system [136].

In 2019, Fontaine et al. generated and separated 210 LG modes using a multi-plane light converter (MPLC) system consisting of seven phase plates, SLMs, and a reflector [137]. Then, an MPLC inverse-design method was proposed by combining the particle-swarm algorithm and wavefront-matching algorithm to efficiently search the design parameters [138].

In 2021, Huang et al. designed a diffraction-depth neural network (D^2NN) with hybrid OAM-mode generation, detection, and switching functions to achieve full optical signal-processing communication for OAM keying, multiplexing, demultiplexing, and mode switching with a diffraction efficiency and mode-switching purity of more than 96% [139] (Table 48.3).

OAM separation and detection are generally divided into interference [113, 117, 118] and diffraction methods [115, 116, 119–124]. Interference methods include double-slit [117] and dynamic double-slit interference [118], in addition to common plane-wave and spherical-wave interference. Previous interference methods mainly detected OAM beams, based on the orientation and number of interference fringes, whereas dynamic double-slit interference pioneered the use of double-slit diffraction from a rotating opaque screen to detect higher-order OAM beams, based on the power fluctuation of the received interference spot.

Diffraction methods are available for detection using various apertures [115–117, 121, 122] and synthetic gratings [119, 120, 123, 128, 129]. Synthetic gratings are mainly composed of forked [129], gradually changing-period [140, 141], annular [142], Dammann [119], and conical curves [128]. They can be used to measure the performance, which can improve the maximum measured topological charge and diffracted spot-energy distribution. Ultimately, the magnitude and sign of the topological charge number were determined by judging the fringes and orientation of the Hermite–Gaussian-like diffracted spot.

Another class of diffraction methods is called coordinate-transformation methods [130–136]. The coordinate-transformation method separates and detects the OAM beam using two static optical coordinate-transformation and phase-correction elements. It converts the doughnut-type spot into a striped rectangular spot and obtains the mode distribution of the incoming OAM beam, based on the calculation of the spot position and coordinate scale. On this basis, the accuracy of the diffracted spot can be improved using fan-out algorithms [131]. Alternatively, two phase diagrams can be synthesized into a single-phase mask to improve the detection alignment and system integration.

Finally, there is currently a multilayer light-diffraction neural network that integrates generation detection and transformations [137–139]. The number of

Table 48.3 Domestic and foreign research progress in vortex beam separation and detection

Year	Researcher	Research progress

measurable separated topological charges has increased linearly, and the entire detection system is moving toward high performance, more compactness, and smaller integration.

OAM Technology in Optical Wireless Communication Systems at Xi'an University of Technology

Ke et al. at Xi'an University of Technology have been systematically researching optical wireless communication technology since 2002. They have achieved good results through exploring and researching technologies in signal modulation, error-correction codes, demodulation, wavefront correction, automatic acquisition, tracking, and pointing, optical-antenna design, optical-fiber coupling, atmospheric turbulence transmissions, and system performance [6]. As exploiting existing dimensional resources has reached a bottleneck, the optical communication capacity crisis has

become an urgent problem. The OAM-structured optical field with spatially varying phases has attracted increasing attention and input from scholars.

Since 2008, Ke et al. have studied OAM technology in optical wireless communication. They have conducted simulation and experimental research on OAM beam generation, transmission characteristics, crosstalk analysis, wavefront correction, separation and detection, and application, according to various aspects of OAM-multiplexed communication systems, and made good progress [143]. The research-content structure diagram is shown in Fig. 48.3.

In 2015, Li et al. generated fractional-order vortex beams and their arrays with a topological charge spacing of 0.5, using fractional-order forked gratings and their superposition. They found that the fractional-order vortex beams were stronger than the integer-order optical intensity distribution, which was beneficial for long-distance transmissions [144].

In 2018, Ge et al. experimentally investigated using few-mode fibers to generate an ordered LG beam. The highest excitation efficiency of 18.39% was produced for a low-order vortex beam, when the fiber incidence angle was adjusted to 2.895° [145].

In 2019, Chen et al. improved the inverted-parabolic fiber structure based on Ref. [142] by adding a low refractive index layer to increase the effective refractive index difference. It generated vortex beams of up to the third order [146].

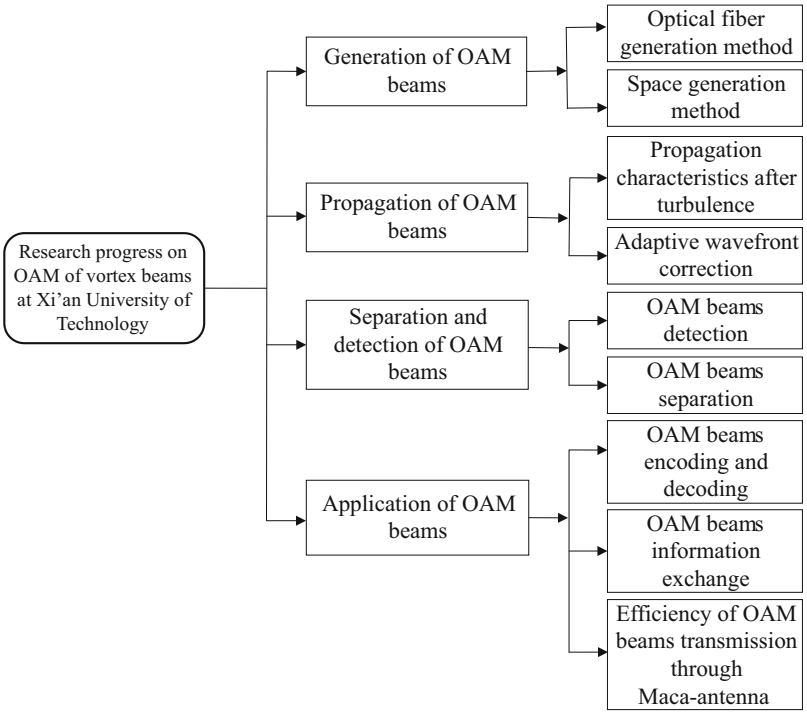

Fig. 48.3 OAM technology research-content structure diagram

In 2020, Wang et al. improved the photonic-crystal fiber (PCF) structure by replacing parts of the circular air holes with rectangular air holes to ensure a high refractive index difference between the cladding and the fiber core, and prevent the leakage of higher-order modes to the cladding. This PCF structure generated and supported the transmission of 50 OAM modes; that is, it had a topological charge $l = 1$–13 [147].

In 2017, Xu et al. used the superposition of forked gratings to generate equal and unequal opposite-sign petal-like superimposed vortex beams, with the number of split petals being the sum of the absolute values of the topological charges of the two beams [148]. In the same year, Xue et al. proposed the superposition of spiral phase diagrams to generate a superimposed vortex beam with the same number of circular aperture splittings. The number of bright spots was equal to the absolute value of the difference between the topological charge numbers of the two beams [149].

In 2018, Shi et al. studied the superposition state generation of high-order radial LG beams, based on Ref. [32], and analyzed the effect of different parameters on the superposition state [150].

In 2019, Zhao et al. simulated the superposition state generation of multiple LG beams of the same or different signs in an arithmetic sequence in the on-axis and off-axis cases and studied its distribution law [151].

In 2020, Zhang studied the generation of orthogonal multi-ring superposition-state vortex beams through simulations and experiments [152].

In 2008, Lv et al. studied the scattering of a single spherical particle with an OAM beam by analogizing the LG beam to a Gaussian-beam model. They obtained the distribution pattern of the scattering intensity and scattering cross section, based on the generalized Mie theory and a local approximation [153].

In 2009, Lv et al. proposed a high-order Bessel diffraction-free beam coding and decoding method for optical OAM by converting LG beams into high-order Bessel diffraction-free beams [154].

In 2009, Yang et al. studied the probability distribution and variation of the single-photon average OAM of high-order elliptical Hermite–Gaussian beams and found that the average OAM varied with the magnitude of different material–matter interactions [155].

In 2011, Lv et al. used the complex Gaussian function expansion method to analyze the effect of the obscuration ratio on the transmission characteristics of LG beams of different wavelengths, using a physical model of LG beams passing through two different aperture optical systems. They found that the effect of the obscuration ratio on the LG beams was greater as the lens-aperture spacing increased and the wavelength became longer [156].

In 2011, Lv et al. used the von-Kármán turbulence spectrum to establish a two-photon entanglement degree model. They analyzed the effects of the transmission distance, turbulence intensity, topological charge number, wavelength, and beam waist on the entangled photons and the entanglement degree [157].

In 2013, Wang et al. investigated the joint detection probability of OAM-entangled photon pairs generated by the conversion process under

spontaneous parameters and found that the beam waist radius and angular and radial indices affected the joint detection probability of the entangled photon pair [158].

In 2014, Yang et al. investigated the transmission characteristics of LG beams on an atmospheric-turbulent slanted path and obtained the spiral spectrum distribution at different turbulence intensities, beam waist radii, topological charge numbers, zenith angles, and receiving apertures [159].

In 2015, Guo et al. designed an eight-stage structure phase-information coding and decoding method to improve the capacity and efficiency of OAM communication [160].

In 2018, Ning et al. studied the optical intensity and phase distribution of multiplexed OAM beams at different turbulence intensities and transmission distances, while analyzing their spiral spectra to obtain the system BER at different turbulence intensities [161].

In 2018, Wang et al. studied the diffraction-transmission characteristics of an LG beam after passing through a Maksutov–Cassegrain antenna (Maca-antenna) optical system. They found that the larger the topological charge number, the higher the emission efficiency of the LG beam after passing through the antenna; it increased to more than 80% [162].

In 2020, Wang et al. analyzed the transmission characteristics of Laguerre–Gaussian–Schell mode vortex beams (LGSMV) in non-Kolmogorov turbulence and derived the far-field light intensity expressions, while obtaining the phase singularity and light intensity distribution variations for different turbulence and beam parameters [163].

In 2020, Chen et al. investigated the information exchange, mode switching, and channel reconfiguration under different OAM modes using simulations and experiments [164].

In 2021, Li et al. analyzed the crosstalk suppression of OAM-MIMO systems in turbulence and compared the improvement of the constellation diagram and BER diagram of the system under the multiuser kurtosis (MUK) modified constant modulus algorithm (MCMA) and cross-correlation (CC)-MCMA algorithm [165].

In 2017, Wang et al. studied the normalized light intensity distribution of partially coherent LG beams under Kolmogorov turbulence and obtained the variation curves of the light intensity distribution with different parameters [166].

In 2019, Wang et al. analyzed the transmission characteristics of partially coherent vector vortex beams—that is, electromagnetic Gaussian–Schell mode vortex beams (EGSMV)—in non-Kolmogorov turbulence and obtained the variation of the polarization direction angle and degree under different parameters [167].

In 2018, Wang et al. investigated adaptive wavefront sensorless correction for distorted vortex beams using the SPGD algorithm. They found that this algorithm could correct wavefront distortions for both single-mode and multimode OAM beams; however, the SPGD algorithm corrected single-mode OAM beams better than it did multimode [168].

In 2020, Cui et al. used a wavefront-free distortion correction technique, based on the PD algorithm for vortex beams, and verified the feasibility by simulation and

experiment. They found that the correction effect of vortex beams improved with the decrease of topological charge number [169].

In 2018, Wang et al. compared and analyzed the far-field diffraction characteristics of an LG beam after passing through circular, square, triangular, single-slit, and double-slit apertures. They found that the topological charge number magnitude and sign of the incident beam could be judged based on the number of spots or stripes in the diffracted light field and their orientation [170].

In 2018, Xie et al. used a variety of gradually changing-period gratings and annular gratings to detect LG beams and proposed that the detection performance of these gratings could be improved by using phase correction diagrams and fan-out phase diagrams. It eventually improved the maximum value of the detectable topological charge number [8].

Generation of Vortex Beams Carrying OAM

To achieve better OAM-multiplexed communication, it is necessary to first generate a vortex beam carrying OAM. Common methods for generating vortex beams are fiber generation and space generation.

Optical-Fiber Generation Method

Vortex beams generated by spatially structured devices cause a certain amount of energy loss. Using optical fibers to generate vortex beams can reduce the light energy loss when passing through structured devices; thus, the conversion efficiency of the fiber-generation method is higher.

Few-Mode Fiber-Generation Method

A few-mode fiber (FMF) is an optical fiber with only fundamental and low-order modes. The HI1060 few-mode fiber was selected for the experiment, and the relationship curve between the incident angle and excitation efficiency is shown in Fig. 48.4a. In the experiment, when the incident angle was controlled between 2.895° and 5.729°, the fundamental mode of the first-order vortex light could be formed in the few-mode fiber. The excitation efficiency of the first-order vortex light was maximized when the incident angle was 2.895°, and its excitation efficiency was 18.39%. Figure 48.4b shows a diagram of the experimental setup for vortex light generation in the few-mode fiber.

Figure 48.5a, b show the simulated and experimental diagrams of the first-order vortex-mode spot in the fiber, respectively. Figure 48.5c, d show the simulated and experimental spot diagrams of the LP_{11} mode, respectively. The LP_{11} mode is formed because of the degeneracy between the multiple vector modes in the fiber.

Improved Inverted-Parabolic Fiber Structure

To increase the effective refractive index difference between the core and cladding, a low refractive index layer is added to improve the few-mode fiber structure into an inverted-parabolic distribution type so that it can contain a larger number of modes.

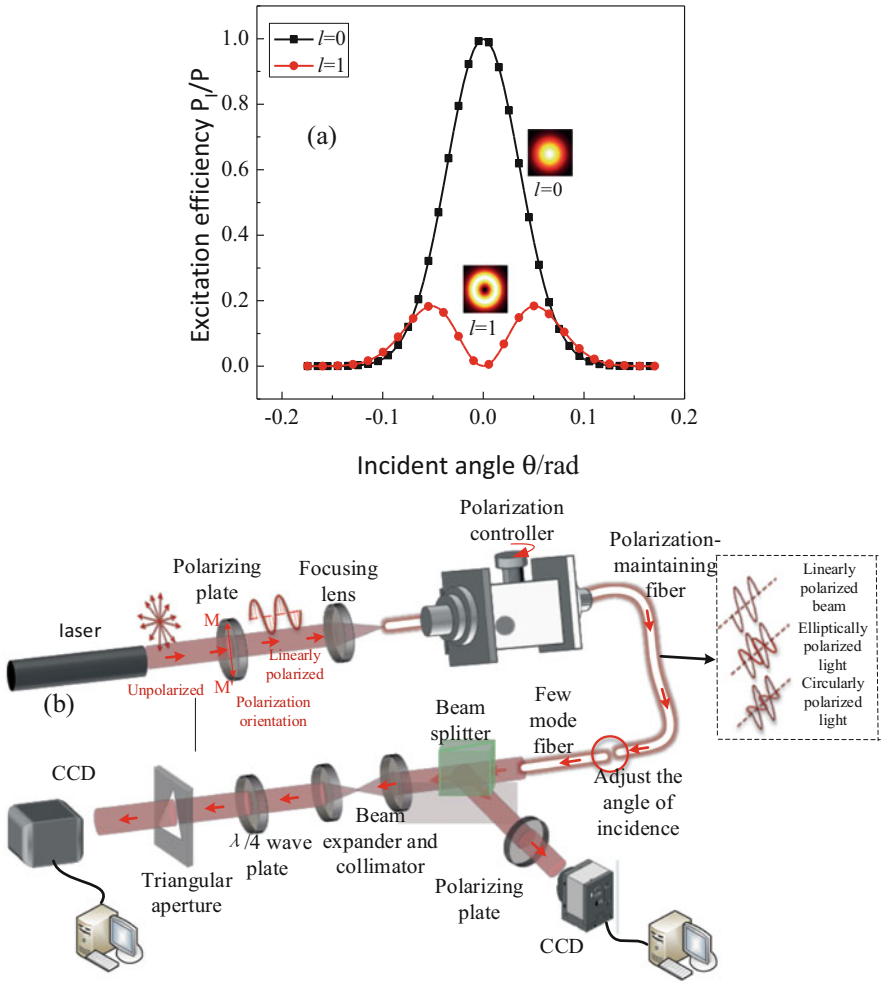

Fig. 48.4 Few-mode fiber experiment. (**a**) Relationship between the incident angle and excitation efficiency of a few-mode fiber; (**b**) experimental-setup diagram of a low-order vortex beam generated by a few-mode fiber [171]

In Fig. 48.6a, the refractive index distribution curves of the improved and original fiber structures are shown in black and red, respectively.

The relationship between the effective refractive index and wavelength is shown in Fig. 48.6b. The diagram shows that the fiber structure can contain nine modes in the fiber core refractive index range and transmit up to third-order OAM modes. The light intensity and phase distribution of the generated third-order OAM modes are shown in Fig. 48.7.

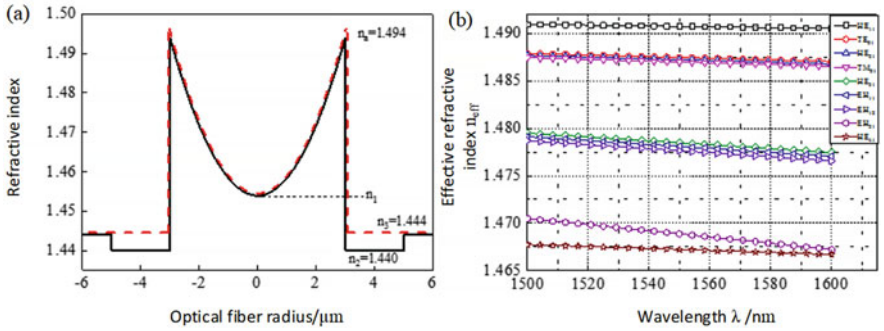

Fig. 48.6 Refractive index curve of the fiber structure. (**a**) Refractive index distribution of improved fiber structure; (**b**) relationship between vector effective refractive index and wavelength [172]

Improved Photonic-Crystal Fiber Structure

By combining rectangular and circular air holes, the cladding layer has a larger air-filling ratio, which increases the refractive index difference with the annular high refractive index layer and prevents the leakage of higher-order modes into the cladding layer. Moreover, this structure is less deformable and more stable. The cross section and quarter cross section of the modified PCF structure are shown in Fig. 48.8a.

The odd and even modes of the HE modes are superimposed to generate the optical field and phase diagram of the OAM modes, as shown in Fig. 48.8b. The first and second rows are the HE_{21}^{even} and HE_{21}^{odd} modes, respectively. The HE_{41}^{even} and HE_{41}^{odd} modes are superimposed to generate the optical field and phase-distribution diagram of the OAM_{11}^{+} modes and OAM_{31}^{+} modes. Based on the OAM mode-generation process and analyzing the vector modes in the PCF, it was concluded that this PCF could support the transmission of $l = 1$ to 13 vector-mode topological charges in the 850-nm band range. Thirteen $OAM_{\pm l,m}^{\pm}$ mode groups were synthesized, with a total of 50 OAM modes. Compared to the 26 modes in Ref. [174] and 58 modes in Ref. [175], the band is wider and the number of modes is larger (Table 48.4).

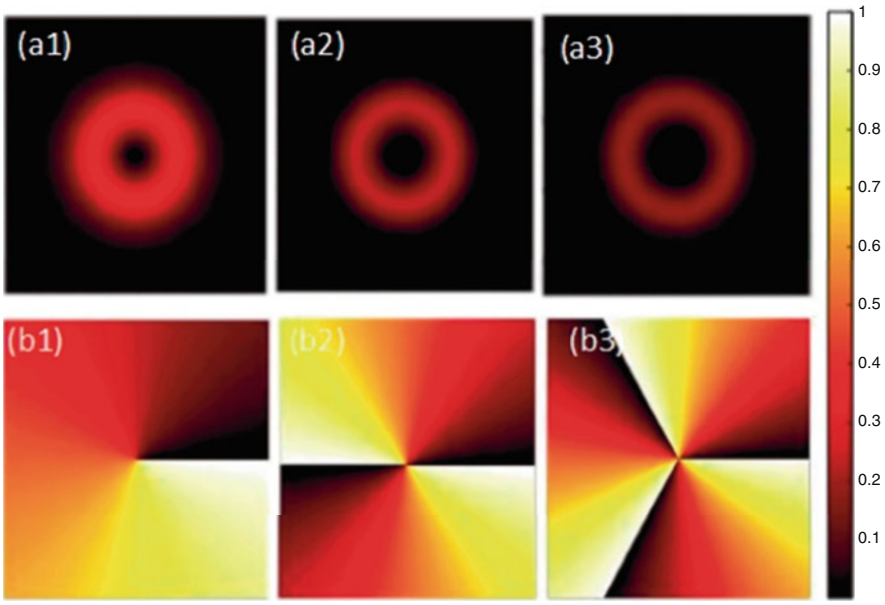

Fig. 48.7 Intensity and phase distribution of vortex beams generated by improved fiber. (a1) OAM_{11}; (b1) OAM_{21}; (c1) OAM_{31}; (a2) distribution of OAM_{11}; (b2) distribution of OAM_{21}; (c2) distribution of OAM_{31} [172]

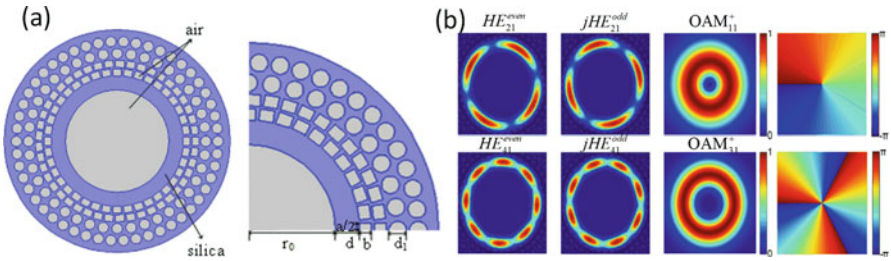

Fig. 48.8 Improved OAM in PCF. (**a**) Improved structural PCF cross section; (**b**) OAM-mode generation in this PCF [173]

Spatial-Generation Method

Generally, direct-generation methods, mode-conversion methods, spiral phase plates (SPPs), and CGH are used to generate vortex beams using a spatial structure. Here, we mainly utilize the CGH method and use a programmed holographic grating or phase diagram to load the spatial light modulator for modulation by a computer. Then, an OAM vortex beam of the desired structure can be obtained.

Table 48.4 Summary of optical fiber vortex beam generation

Fiber-generation method	Structure principle	Performance analysis
FMF	Adjust incident angle of FMF	Excitation efficiency of 18.39% with±1order vortex beam
Inverted-parabolic fiber structure	Addition of low refractive index layer	Produces first- to third-order vortex beams
Improved photonic crystal fiber	Rectangular air holes with circular air holes	Produces first- to third-order vortex beams in the 850-nm range

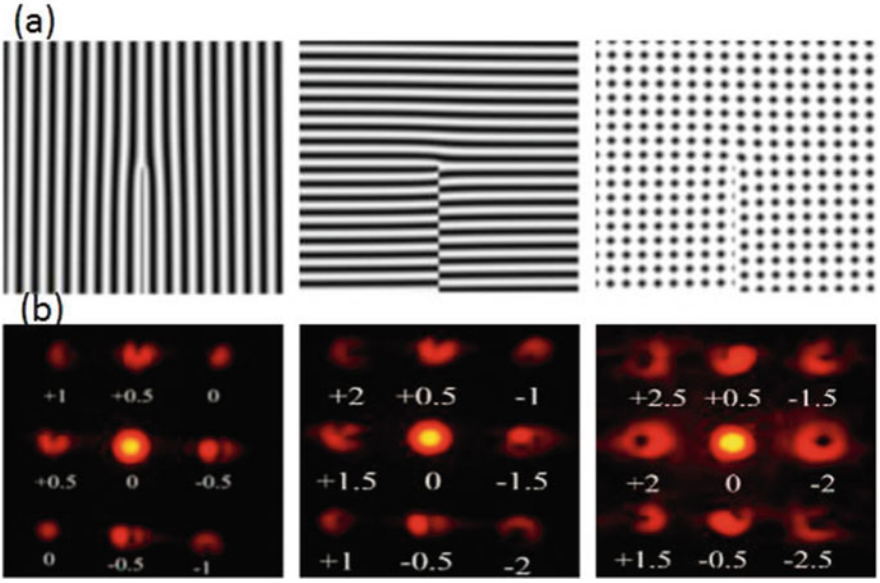

Fig. 48.9 Fractional vortex beam generation. (**a**) Fractional composite fork-grating generation; (**b**) fractional vortex beam array [176]

Fractional-Order LG Beam Generation

The vertical dislocation $l = 0.5$ and a transverse fractional-order forked grating are superimposed to obtain a fractional-order composite forked grating, as shown in Fig. 48.9a. Figure 48.9b shows the experimental diagram of the fractional-order vortex beam array; the notch distribution becomes larger as the value of the topological charge fraction increases.

LG Beam Superposition State Generation

First, different superposition states of vortex light can be generated by superposition gratings, as shown in Fig. 48.10a, which are the superposition of $l = 2$, $l = -3$, $l = 3$, and $l = -3$ fork gratings, respectively. The Gaussian beam strikes on top of the superimposed grating to produce a superimposed OAM vortex beam, as shown in Fig. 48.10b in simulation and experimentally.

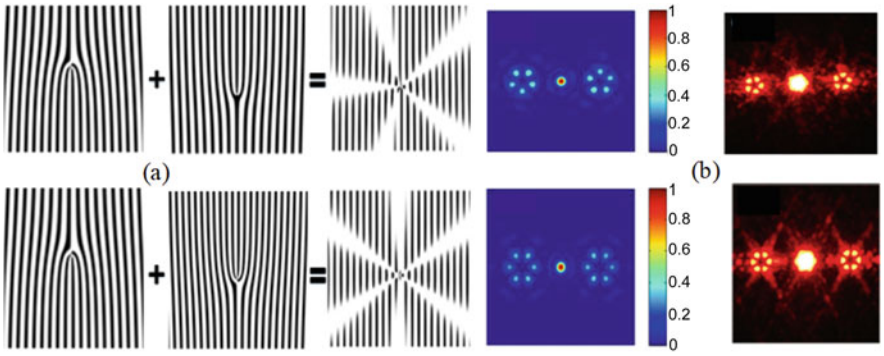

Fig. 48.10 Superposition state preparation of an LG beam. (**a**) Superposition of fork gratings; (**b**) LG beam superposition state with different topological charges [177]

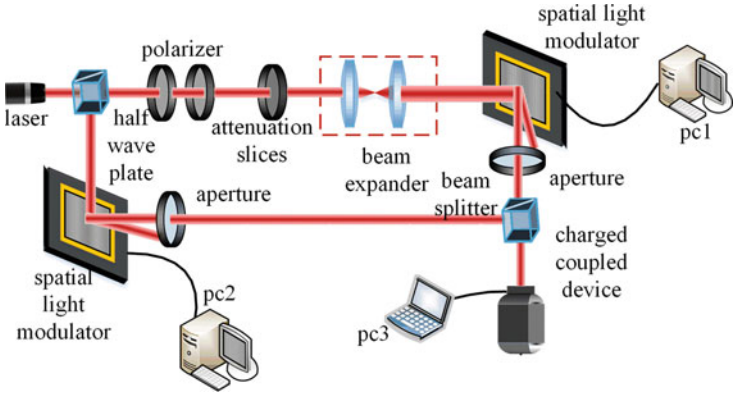

Fig. 48.11 Diagram of experimental setup for superposition state generation

The experimental setup for interferometric superposition state generation is shown in Fig. 48.11. It mainly uses two SLMs loaded with two forked gratings for coaxial superposition interference, but it is also possible to load the superposition grating onto one SLM to achieve efficient coherent superposition.

In addition to the LG beam superposition state prepared using the superposition of forked gratings, spiral phase diagrams can also be used. The superimposed phase diagrams of $l = 1, 5$ and $l = 2, 4$ are shown in Fig. 48.12 (a1) and (b1). The experimental setup was similar to that shown in Fig. 48.11.

The generated superimposed vortex beams are shown in Fig. 48.12(a2–a3) and (b2–b3), which are the simulated and experimental diagrams corresponding to the

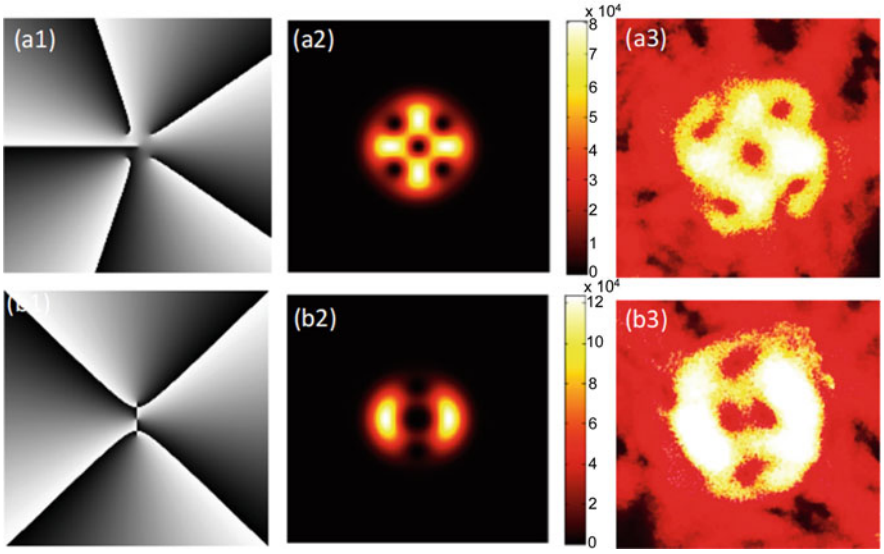

Fig. 48.12 Superimposed LG beams generated by phase patterns. (a1–a3) $l = 1, 5$ phase-diagram superposition and corresponding simulation and experimental diagrams; (b1–b3) $l = 2, 4$ phase-diagram superposition and corresponding simulation and experimental diagrams [178]

superimposed state of the same number, respectively. At this point, a circular splitting spot is formed and the number of bright spots is $N = |l_1 - l_2|$.

Another type of orthogonal superposition state generation takes advantage of the orthogonality between different OAM modes to orthogonally superimpose two vortex beams with different topological charge numbers; using this double-ring structure for information transmission can reduce inter-mode crosstalk.

The simulated (a1–a3) and experimental (b1–b3) diagrams of the double-ring vortex beam, after the orthogonal superposition of the same number of l values, are shown in Fig. 48.13. It has the same experimental setup as shown in Fig. 48.11. The only difference is that the outgoing beam needs to pass through a polarizer after the SLM reflection to control its angle, so that the two vortex beams finally incident on the polarization combiner are in an orthogonal state.

Finally, a multi-LG beam superposition state was generated, and the light field distribution of the superposed vortex beams with different topological charge numbers was obtained according to the theoretical calculation analysis, as shown in Fig. 48.14. The tolerances shown in Fig. 48.14(a1–d1) and (a2–d2) are the simulation results of the same number of multi-LG mode superpositions for $\Delta = 1$ and $\Delta = 2$, respectively.

As can be seen from the figure, because the coaxial superimposed light intensity diagram shows bright and dark spots, Fig. 48.14(a1–d1) all show one bright spot. There is a singularity in the center of the superimposed light field with dark spots on the outer side, and the number of dark spots is $1 \times (n - 1)$. Figure 48.14(a2–d2) all show two bright spots, and the number of dark spots on the outer side is $2 \times (n - 1)$.

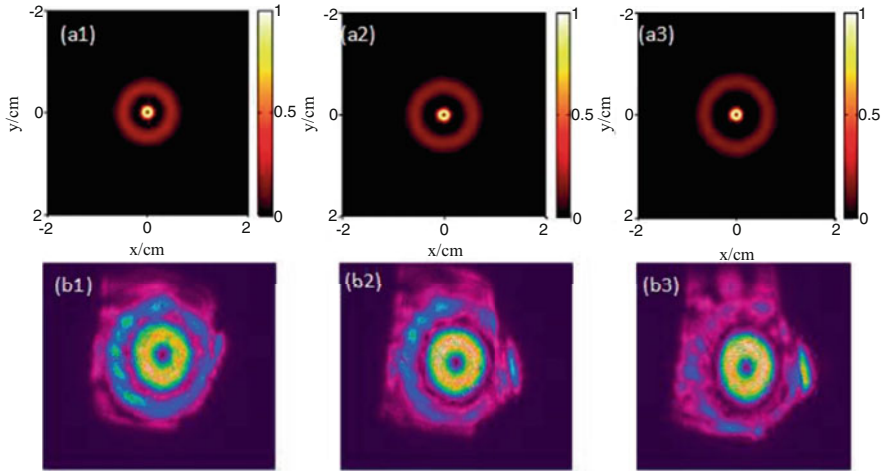

Fig. 48.13 Simulation and experimental diagram of orthogonal superposition states of the same sign l value. (a1–b1) $l = 1, 5$; (a2–b2) $l = 1, 7$; (a3–b3) $l = 1, 9$ [179]

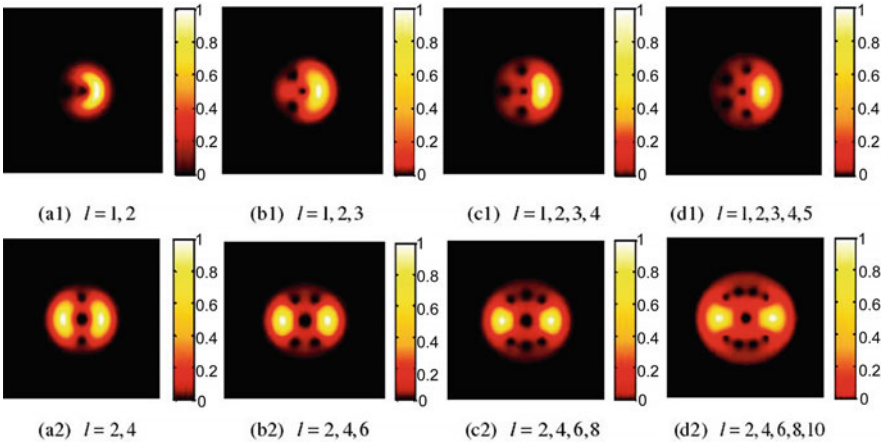

Fig. 48.14 Light intensity distribution diagram after multiple superimposed LG beams of the same sign [180]

The result is the same for different numbers, except that the spots change from circle-like to petal-like at this time.

High-Order Radial LG Beam Superposition State Generation

A higher-order radial LG beam superposition state is used in OAM-multiplexed communication systems to improve the capacity, spectrum utilization, and received power of the communication system. Figure 48.15(a1–a3) show the superimposed light fields of LG_0^3 and LG_1^3, LG_0^3 and LG_2^3, LG_0^3 and LG_3^3, respectively; the light

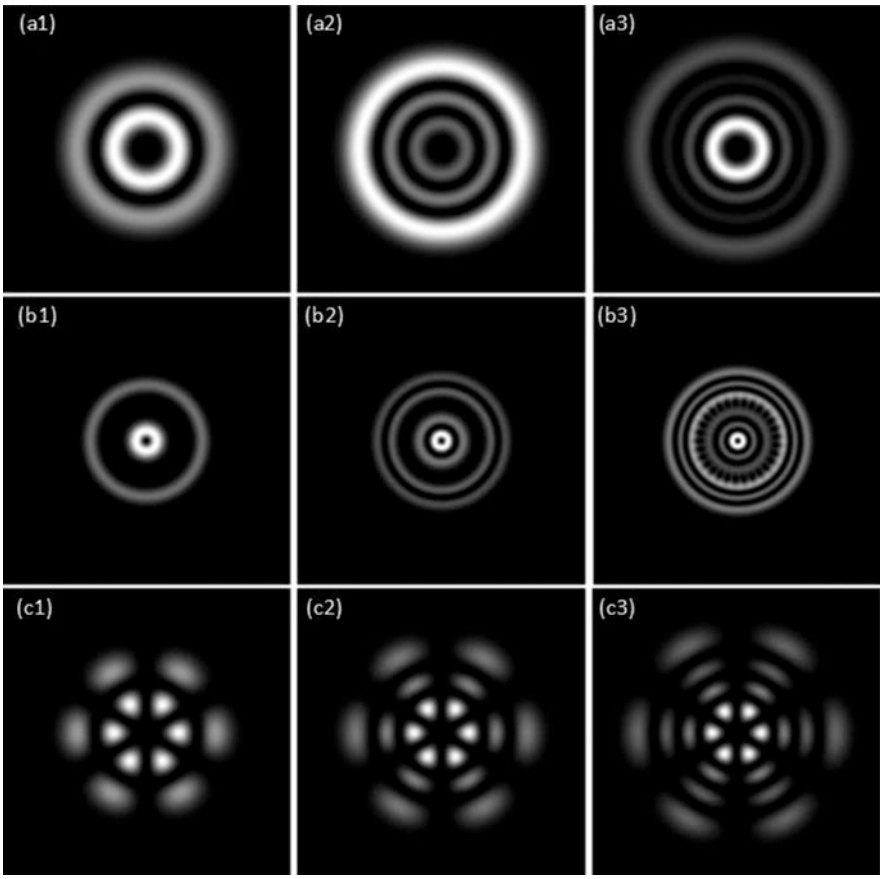

Fig. 48.15 High-order radial LG beam superposition. (a1–a3) Same topological charge number and different radial index; (b1–b3) same radial index and different topological charge number; (c1–c3) same radial index and topological charge with opposite numbers of each other [181]

intensity distribution is in the form of multiple bright rings and their bright ring numbers $\sigma = \max\{p_1, p_2\} + 1$.

Figure 48.15(b1–b3) show the superimposed light fields of LG_0^1 and LG_0^{30}, LG_1^1 and LG_1^{30}, LG_2^1 and LG_2^{30}, respectively. The number of bright rings $\sigma = n(p + 1)$ and n represents the number of coaxially superimposed LG beams. Figure 48.15(c1–c3) show the superimposed light fields of LG_1^3 and LG_1^{-3}, LG_2^3 and LG_2^3, LG_3^3 and LG_3^3, respectively. They are distributed in the shape of a petal with a symmetric distribution of layer circles, and the total number of bright "petals" is $(p + 1)|l_2 - l_1|$ (Table 48.5).

Vortex Beam OAM Transmission

Here, the transmission characteristics of LG beams in oblique-range turbulence and partially coherent Gaussian–Schell mode (GSM) vortex beams in turbulence are

Table 48.5 Summary of spatial vortex beam generation

Spatial-generation method	Shape and properties of light spots
Fractional grating	Fractional vortex beam array
Grating superposition	The number of petal-like spots is superimposed with different signs $N = \|l_1\| + \|l_2\|$
Phase superposition	The same sign is superimposed as a circular split spot $N = \|l_1 - l_2\|$
LG beam orthogonal superposition	Double or triple-ring superposition spot
Arithmetic distribution of multiple LG beams with the same number superposition	Number of dark spots on the outside of circular-split light spots $\Delta \times (n-1)$
Double high-order radial LG beam superposition	Multiple rings $\sigma = \max\{p_1, p_2\} + 1$, $\sigma = n(p+1)$, many-petal shape $(p+1)\|l_2 - l_1\|$

discussed first. They are followed by an analysis of the crosstalk characteristics of multiplexed vortex beams in turbulence, the transmission characteristics of partially coherent vortex beams in Kolmogorov and non-Kolmogorov turbulence spectra, and the evolution and transmission characteristics of vector partially coherent vortex beams and their arrays in turbulence. Finally, the crosstalk-suppression performance of an OAM-MIMO system under turbulence with different algorithms is analyzed.

Transmission Characteristics After Turbulence

After the LG beam is transmitted through slanted atmospheric turbulence, it causes OAM-mode dispersion and inter-mode crosstalk, as shown in Fig. 48.16(a1–d3), for the distribution of the spiral-spectral components with the transmission distance for different near-ground refractive index structure constants, incident light wavelengths, receiving apertures, zenith angles, and topological charge numbers, respectively.

It can be observed that the OAM divergence slows as the transmission distance increases. In contrast, the larger the parameters, except for the opposite wavelength, the stronger the OAM spiral spectrum dispersion. Therefore, the selection of a long wavelength, small receiving aperture, small zenith angle, and small topological charge number can reduce the OAM dispersion.

Subsequently, the transmission characteristics of the GSM vortex beam under Kolmogorov turbulence were investigated. Figure 48.17a–f show the normalized light intensity distribution curves for different turbulence intensities, transmission distances, topological charge numbers, coherence lengths, beam waist radii, and wavelengths, respectively.

It can be seen that the stronger the turbulence intensity, the longer the transmission distance, the smaller the topological charge number, the smaller the coherence length, and the larger the beam waist width, the more easily the beam is converted into a Gaussian distribution, and the more influenced by turbulence it is; whereas, the wavelength has no effect.

The OAM beam is affected by turbulence when it is transmitted in free space, which leads to inter-mode crosstalk and OAM-mode dispersion. This increases the BER and reduces the performance of the communication system. Figure 48.18

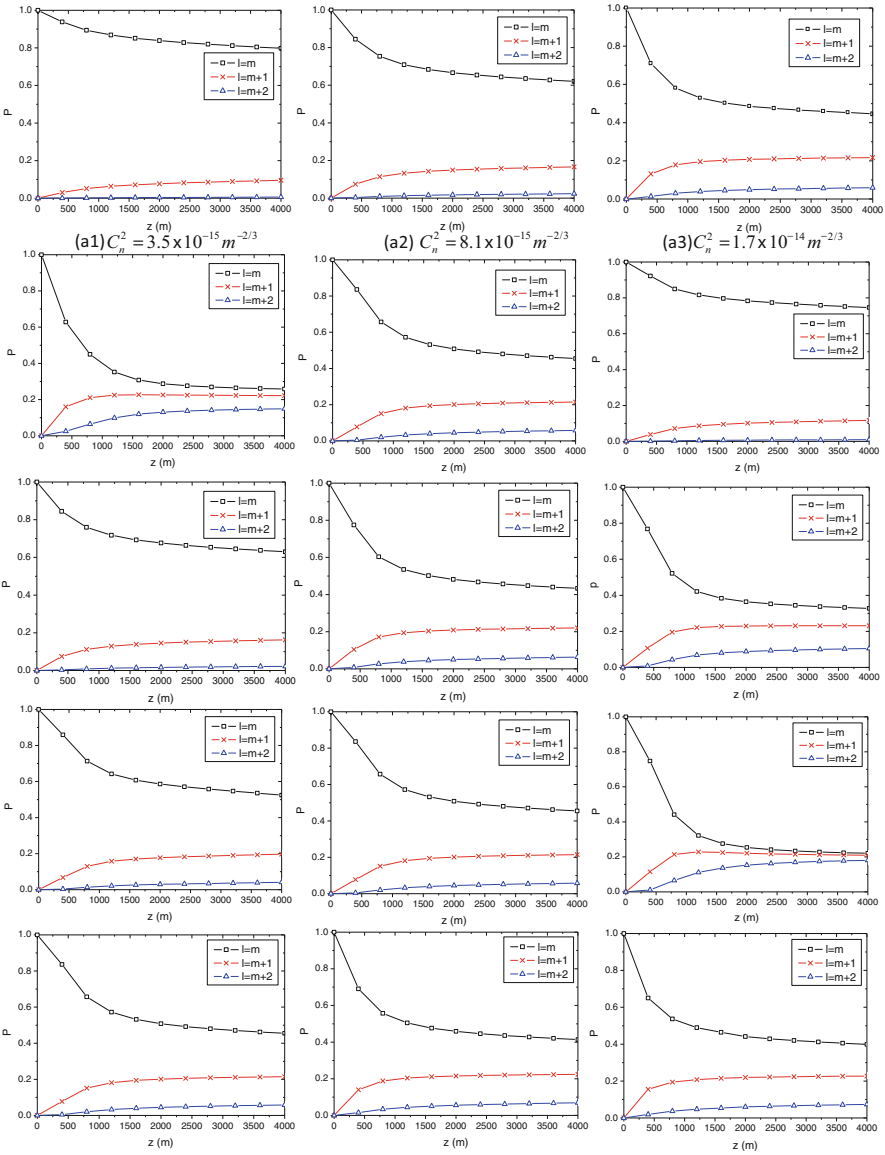

Fig. 48.16 Distribution of helical-spectrum components with propagation distance under different parameters. (a1–a3) Near-ground refractive index structure constant: $C_n^2(0) = 3.5 \times 10^{-15} m^{-2/3}$, $8.1 \times 10^{-15} m^{-2/3}$, $1.7 \times 10^{-14} m^{-2/3}$; (b1–b3) wavelength: $\lambda = 351nm$, $632nm$, $1068nm$; (c1–c3) receiving aperture: $R = 2$cm, 3cm, 4cm; (d1–d3) zenith angle: $\alpha = \pi/4$, $\pi/3$, $\pi/2$; (e1–e3) OAM index: $m = 3$, 10, 20 [159]

(a1–a4) and (b1–b4) show the spiral spectrum distribution of the multiplexed OAM beams of $l = 2$, 4, 6, 8 at different turbulence intensities and transmission distances, respectively.

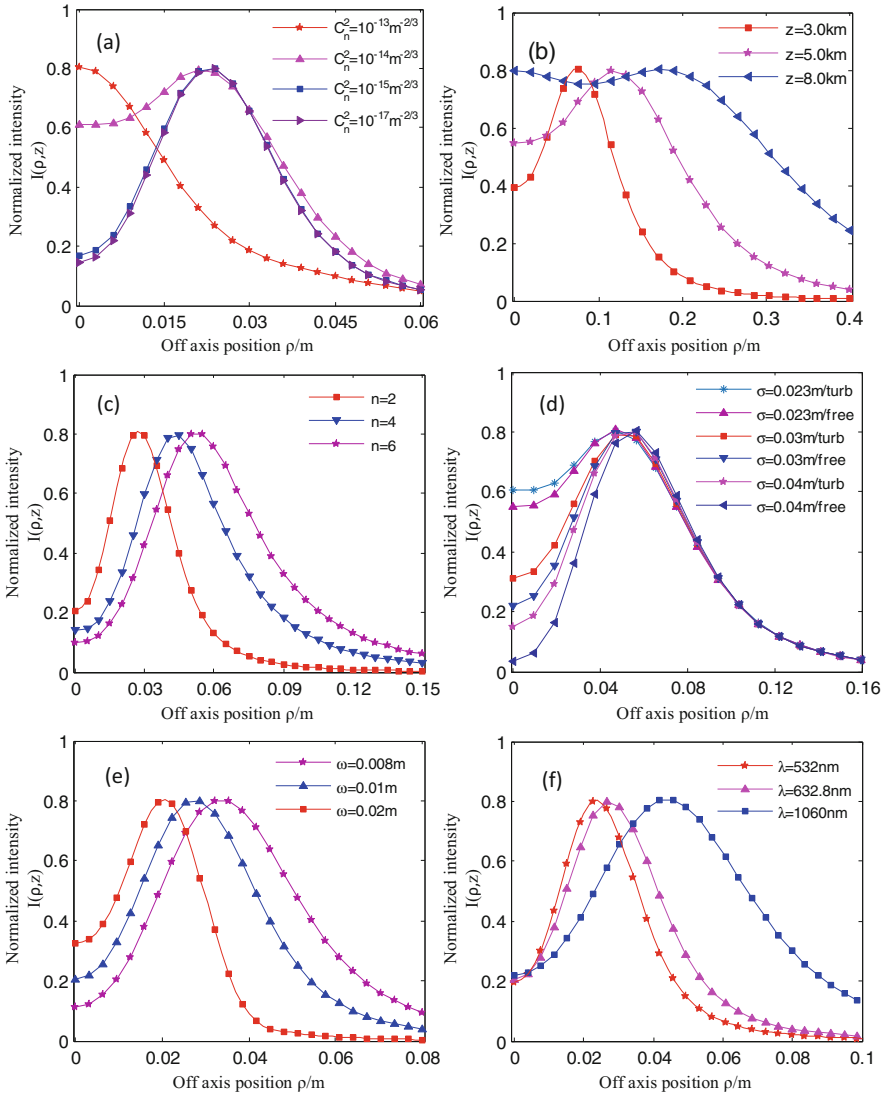

Fig. 48.17 Normalized intensity distribution of GSM vortex beams under different parameters. (**a**) Turbulence intensity; (**b**) transmission distance; (**c**) topological charge number; (**d**) coherence length; (**e**) beam waist radius; (**f**) wavelength [182]

With the increase in turbulence intensity and transmission distance, the mode dispersion degree of each OAM state gradually becomes severe; however, it can still be discerned by the relative power. The dispersion is the most serious at (a4) and (b4), where each OAM mode is dispersive to other modes and the original beam information can no longer be identified.

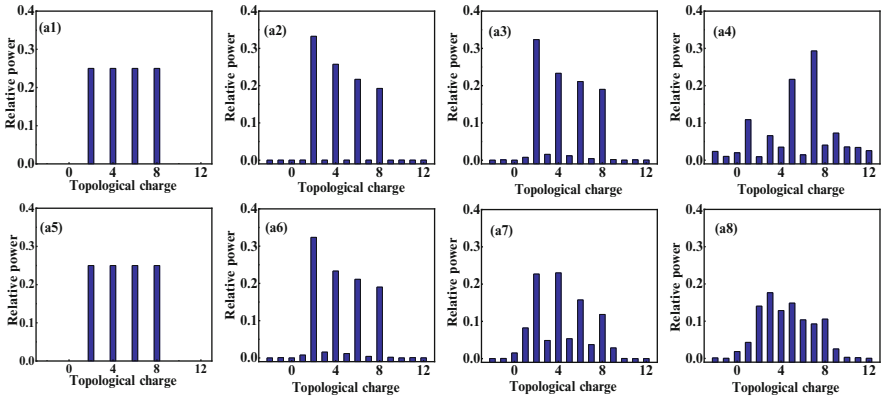

Fig. 48.18 Spiral spectrum distribution of OAM-multiplexed beams under different turbulence intensities and transmission distances. (a1) no turbulence; (a2) $C_n^2 = 1 \times 10^{-17} m^{-2/3}$; (a3) $C_n^2 = 1 \times 10^{-15} m^{-2/3}$; (a4) $C_n^2 = 1 \times 10^{-13} m^{-2/3}$; (a5) $z = 0$ m; (a6) $z = 1000$ m; (a7) $z = 3000$ m; (a8) $z = 5000$ m [183]

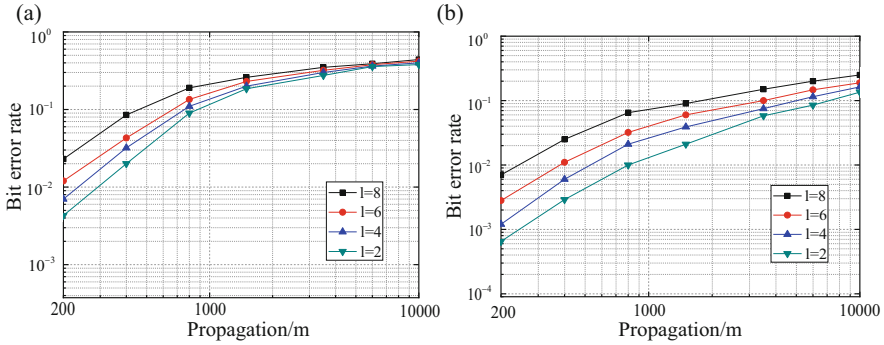

Fig. 48.19 Bit error rate curve of the system under different turbulence intensities (**a**) $C_n^2 = 5 \times 10^{-14} m^{-2/3}$ (**b**) $C_n^2 = 1 \times 10^{-17} m^{-2/3}$ [183]

In Fig. 48.19, as the transmission distance increases, the BER gradually increases, and when the transmission reaches 10,000 m, the BER stabilizes at about 0.4 because the noise reaches saturation. The turbulence intensity decreases to about 0.2 when it becomes smaller, while the larger the topological charge in the multiplexed beam, the higher the BER.

Beam arrays not only increase the emitted power of the light source but also suppress turbulence. This is a hot research topic in high-energy laser synthesis and space-optical communication. Figure 48.20a–c show the light intensity distribution of a radial partially coherent vortex beam array with radial radii of $r_n = 5w_0$, $r_n = 7w_0$, and $r_n = 10w_0$, respectively, after non-Kolmogorov turbulent transmissions of 0.5, 1.5, 2, 2.5, and 3 km.

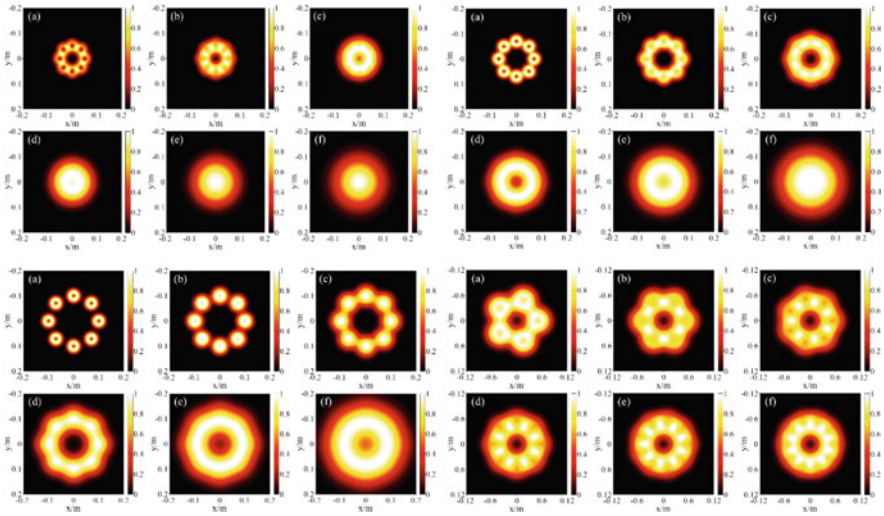

Fig. 48.20 Light intensity distributions of radial partially coherent vortex beam arrays transmitted through non-Kolmogorov turbulence for 0.5 km, 1 km, 1.5 km, 2 km, 2.5 km, and 3 km under different parameters. (**a**) $r_n = 5w_0$; (**b**) $r_n = 7w_0$; (**c**) $r_n = 10w_0$; (**d**) $N = 5$–10 [184]

With the increase in transmission distance, the beam of each array gradually transforms into a Gaussian-like beam distribution. The larger the radial radius, the longer the transmission distance required to convert to a Gaussian distribution. In the same turbulent case, a larger radius is required for conversion to a Gaussian distribution. Figure 48.20d shows the light intensity distribution after transmission with different numbers of arrays at $r_n = 5w_0$ and $z = 1$ km. This illustrates that when the number of radial arrays is greater, the light intensity distribution is closer to the circular distribution, that is, a shorter distance is required to convert to a Gaussian distribution.

Figure 48.21a–d show the light intensity distribution and curves of a partially coherent vortex beam array after non-Kolmogorov turbulent transmissions at different wavelengths, beam waist radii, outer scales, and turbulence intensities, respectively. From these figures, it can be seen that the transmission distance required to convert to a Gaussian distribution is shorter for larger wavelengths, beam waists, and turbulence intensities, which are more influenced by turbulence. The change in the outer scale had almost no effect on the light intensity distribution. The array beam was most affected by turbulence when the generalized exponential factor was $\alpha = 3.15$, as shown in Fig. 48.21d.

The partially coherent vortex beam in a Laguerre–Gaussian–Schell-mode vortex (LGSMV) beam is a new type of vortex field consisting of a Laguerre–Gaussian–Schell (LGSM) beam after spiral phase modulation. Figure 48.22a, b show the light intensity distribution curves of the LGSMV beam with $l = 3$ after non-Kolmogorov turbulent transmissions at the generalized exponential factors $\alpha = 3.1$ and $\alpha = 3.5$ for different outer scales L_0 and inner scales l_0, respectively.

It can be observed that the variation in the outer scale has almost no effect on the beam intensity. Moreover, the smaller the inner scale, the more gradually the LGSMV light intensity distribution broadens. When $\alpha = 3.1$ is the strongest turbulence, the inner scale has a greater influence on the LGSMV beam intensity distribution; when $\alpha = 3.5$, it has less influence.

Figure 48.23a, b show the relative beam width versus transmission distance curves for LGSMV beams with different orders and topological charges, respectively, after turbulent transmission. Figure 48.23a indicates that the relative beam width gradually decreases as n increases. Figure 48.23b indicates that the relative beam width increases as the topological charge number increases. Figure 48.23c indicates that the relative beam width increases more rapidly as the generalization factor increases for a larger turbulence intensity.

Figure 48.24a, b show the variation curves of the relative beam width of the LGSMV beam after non-Kolmogorov turbulence and free-space transmission at different wavelengths and coherence lengths, respectively. The shorter the wavelength and the larger the coherence length, the faster the relative beam width

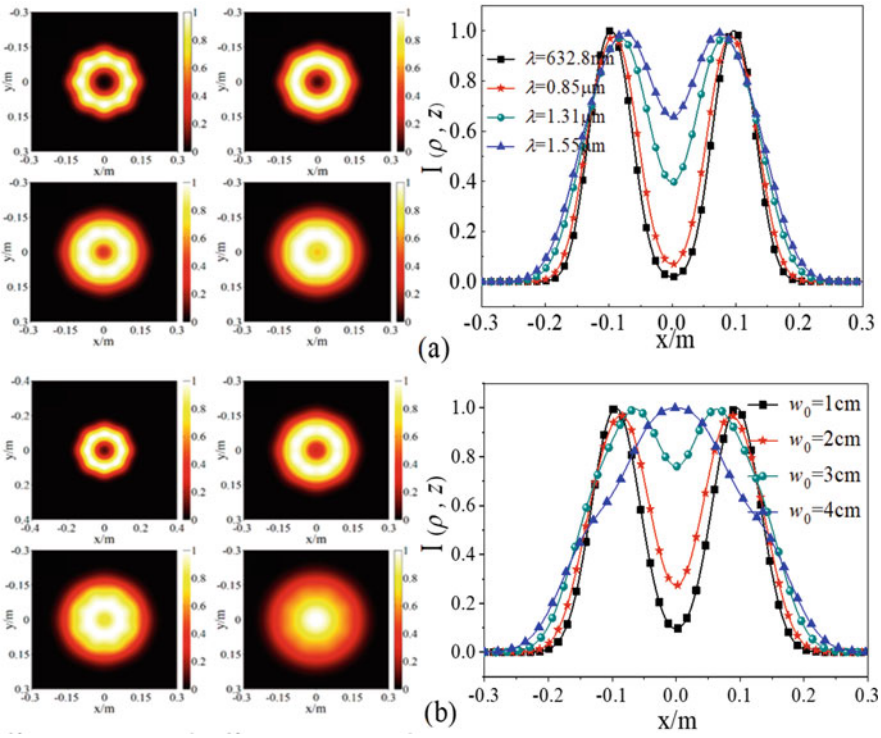

Fig. 48.21 Intensity distribution and curves of radial partially coherent vortex beam arrays transmitted through non-Kolmogorov turbulence at different parameter values. (**a**) Wavelength; (**b**) beam waist radius; (**c**) coherence length; (**d**) turbulence intensity [184]

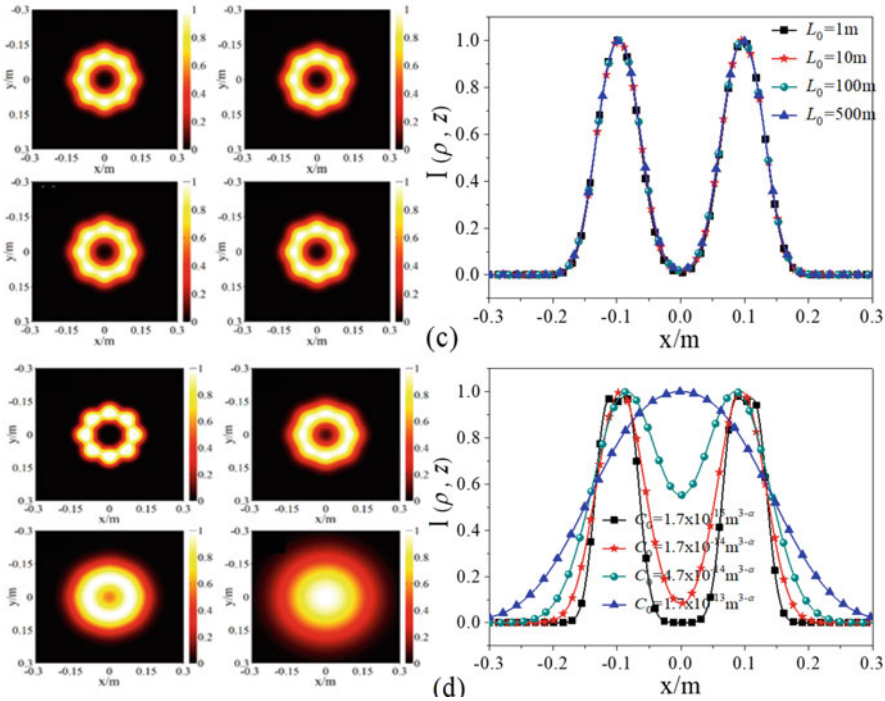

Fig. 48.21 (continued)

increases with the transmission distance, and the more serious the effect of atmospheric turbulence on the beam spreading.

An electromagnetic Gaussian–Schell vortex beam (EGSMV) was obtained by spiral phase modulating an electromagnetic Gaussian–Schell mode beam (EGSM), and the effects of the amplitude component and internal and external atmospheric turbulence scales on the degree of polarization (DoP) were analyzed.

Figure 48.25 shows the DoP distribution of the EGSMV beam at different wavelengths. It can be seen that when the wavelength is longer, the DoP distribution of the EGSMV beam after turbulence is more dispersed and the beam is more influenced by turbulence.

Figure 48.26 shows the DoP distribution curves of the EGSMV beam with $l = 1$ at different beam waist radii after a turbulent transmission. Regardless of whether the beam waist radius components w_{0x} and w_{0y} are equal, the DoP distribution of the EGSMV beam after a turbulent transmission becomes more dispersed as the beam waist radius increases.

Figure 48.27 shows the DoP distribution curves after the turbulent transmission of an EGSMV beam with $l = 1$ for different amplitude components, A_x and A_y. It can be seen that the DoP distribution of the partially coherent light source EGSMV beam after a turbulent transmission is related to the amplitude ratio A_x/A_y, not to amplitude

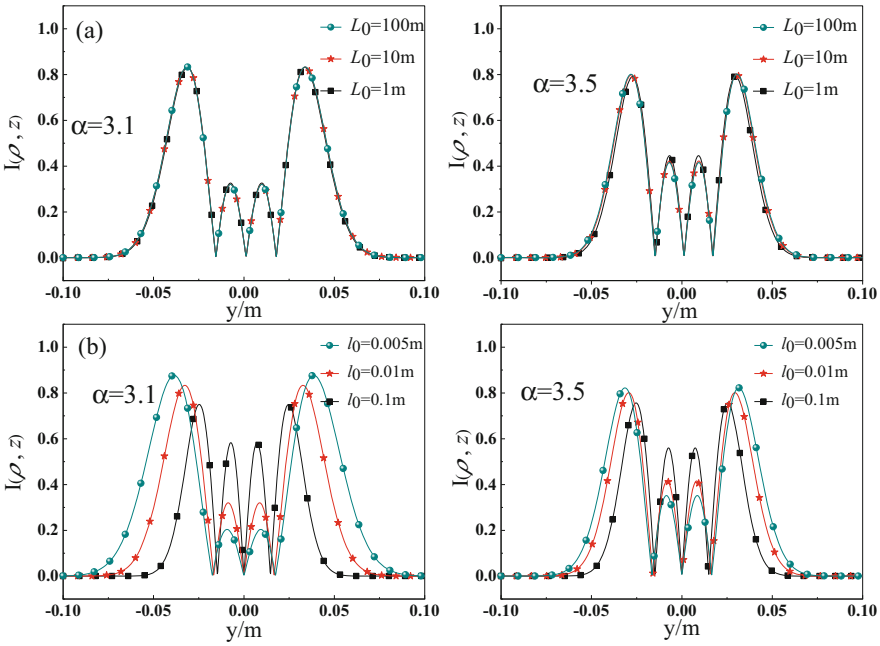

Fig. 48.22 Light intensity distribution curves of LGSMV beams transmitted by non-Kolmogorov turbulence at different inner and outer scales. (**a**) Outer scale; (**b**) inner scale [184]

A_x or A_y alone. When A_x/A_y is larger, the DoP distribution is more divergent and the beam is more influenced by turbulence.

Figure 48.28 shows the DoP distribution curves of the EGSMV beam at different inner and outer turbulence scales. For the same outer scale case, the larger the inner scale, the more concentrated the DoP, and the larger the DoP at a point on the axis, the less influenced by turbulence. The outer atmospheric turbulence scale has almost no effect on the DoP distribution.

In space quantum communication, the photons in the entangled state are not only affected by the absorption and scattering of photons by atmospheric particles but also by the decoherence of the atmospheric turbulence on the entangled photon pairs. This leads to the evolution of the entangled photons into separable states, which can degrade the performance of space quantum communication.

Figure 48.29a–d show the symbiotic entanglement and entanglement-variation curves of different OAM-entangled photon pairs under different turbulence intensities, respectively. It was found that the larger the transmission distance and turbulence intensity, the faster was the decay; the larger the OAM value, the slower was the decay. From the maximum entangled state at the beginning, that is, when the entanglement degree is 1, it gradually changes to an entangled state and finally becomes separable.

Figure 48.30 shows the joint detection probability distribution of OAM-entangled photon pairs in the atmospheric channel at different transmission distances, signal

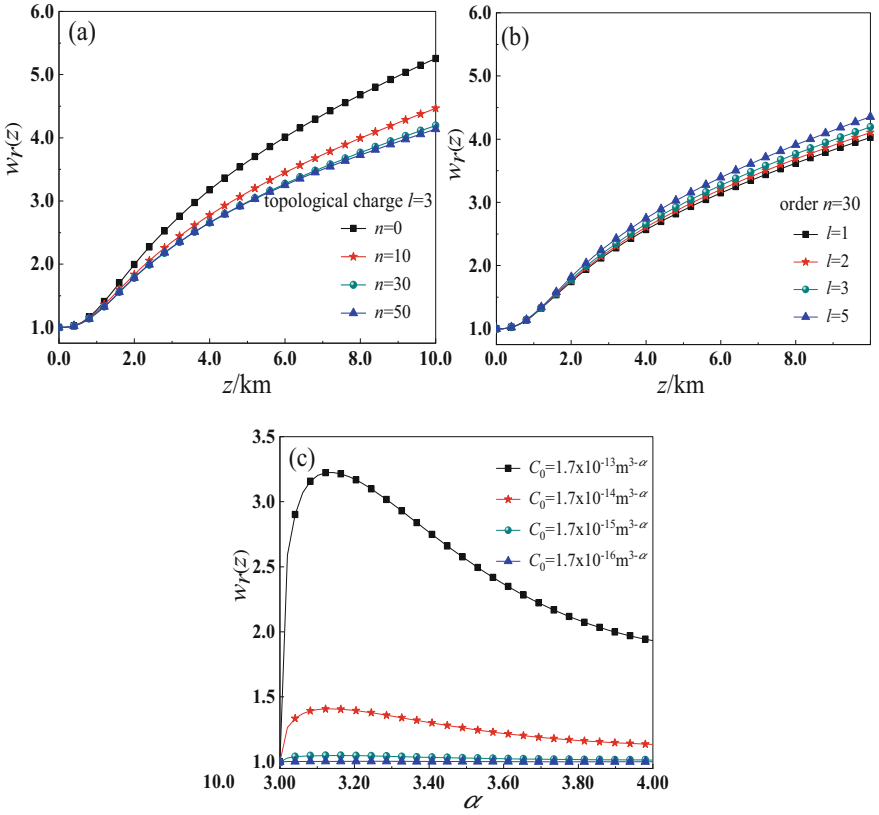

Fig. 48.23 Relative beam width of LGSMV beams after non-Kolmogorov turbulence with varying propagation distances. (**a**) Different orders n; (**b**) different topological charges l; (**c**) different turbulence intensities [184]

light wavelengths, and turbulence intensities, respectively. It can be observed that the larger the transmission distance, the stronger the turbulence intensity, and the smaller the signal light wavelength, the smaller the detection probability of the OAM state $|l_1; l_2 = l_p - l_1\rangle$. The joint detection probability of the two-photon OAM state $|l_1; l_2 \neq l_p - l_1\rangle$ then increases, and the entangled photon pair is more influenced by turbulence.

Figure 48.31 shows some transmission characteristic curves of photonic OAM. The curve in Fig. 48.31a illustrates that the nonmetallic ore affects the average per single-photon OAM to a lesser extent than metallic iron. Figure 48.31b–d show the effects of a tilt aberration, coma aberration, and astigmatism aberration on the photon OAM detection probability in turbulence, respectively. It is observed that the effect of the turbulent tilt aberration is the largest, followed by the coma aberration, and the smallest is astigmatism.

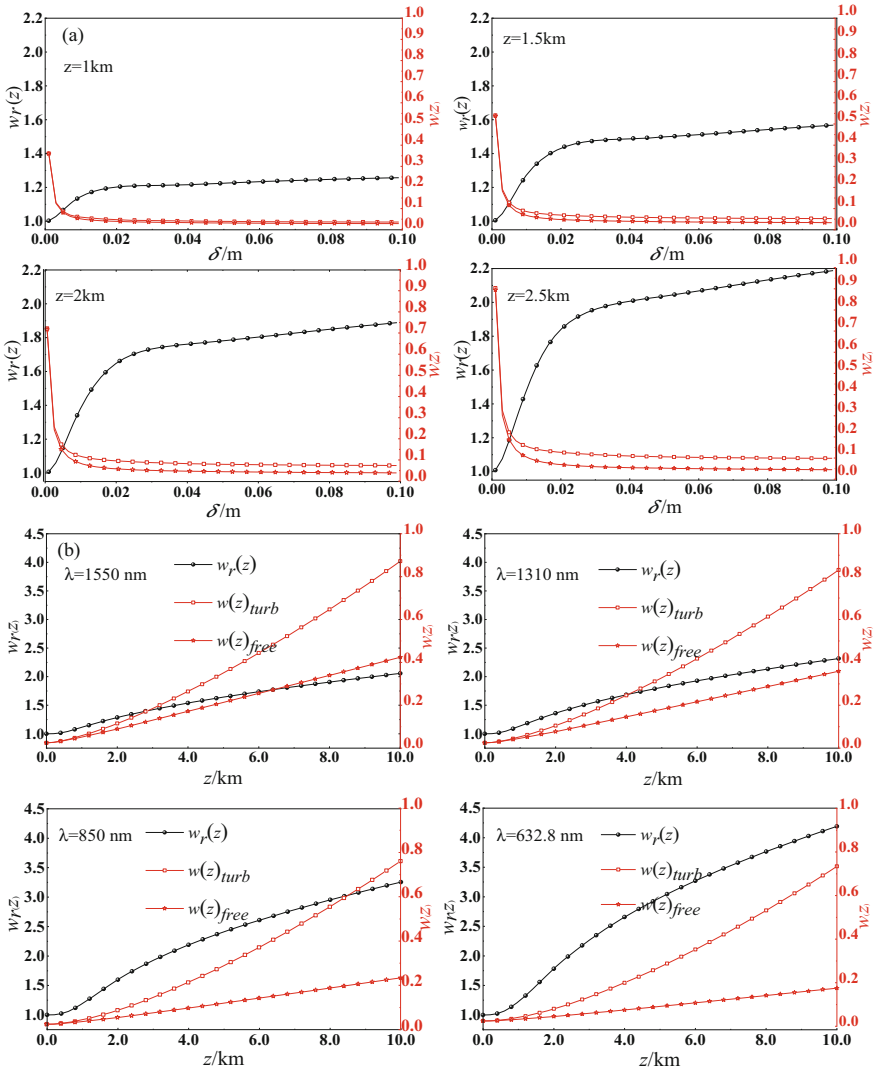

Fig. 48.24 Relative beam width curves of LGSMV beams after non-Kolmogorov turbulence with different parameters. (**a**) Wavelength; (**b**) transmission distance [184]

Finally, crosstalk suppression in an OAM-MIMO multiplexing system is studied. Figure 48.32a, b show a comparison of the constellation diagrams before and after equalization, using the cross-correlation function–multimode blind equalization (CC-MCMA) and multiuser kurtosis–multimode blind equalization (MUK-MCMA) algorithms, respectively. The MUK-MCMA algorithm restored the signal better than the CC-MCMA algorithm did.

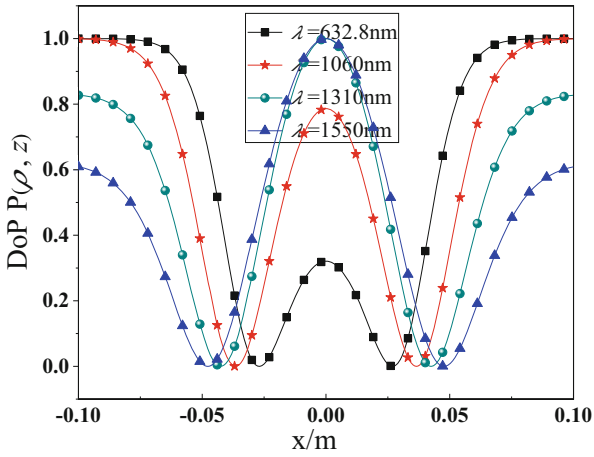

Fig. 48.25 DoP distribution curves of EGSMV beams transmitted by turbulence at different wavelengths [159]

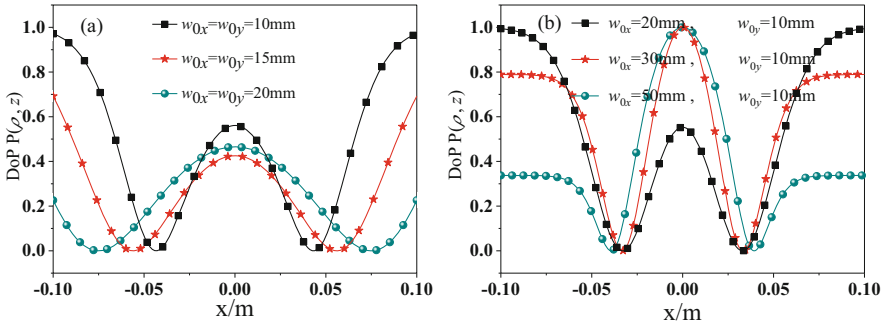

Fig. 48.26 DoP distribution curves of EGSMV beams with different waist radii after turbulent transmissions. (**a**) $w_{0x} = w_{0y}$; (**b**) $w_{0x} \neq w_{0y}$ [184]

Figure 48.33a, b show the variation curves of the average bit error rate (ABER) of the OAM-multiplexed communication system with the atmospheric turbulence intensity and the signal-to-noise ratio in the atmospheric turbulence channel, respectively. As shown in Fig. 48.33a, the MUK-MCMA algorithm can reduce the system ABER by 1–3.5 orders of magnitude and 0.4–1 orders of magnitude under either strong or weak turbulence, respectively.

In Fig. 48.33b, when the signal-to-noise ratio is approximately 20 dB, the MUK-MCMA algorithm improves the ABER equalization effect by one order of magnitude, compared with the CC-MCMA algorithm; therefore, the MUK-MCMA algorithm has the best equalization effect on the OAM multiplexing system.

Adaptive Optical Wavefront Correction

A vortex beam experiences wavefront phase distortion after atmospheric turbulence, and adaptive optical correction techniques are required to recover as much light

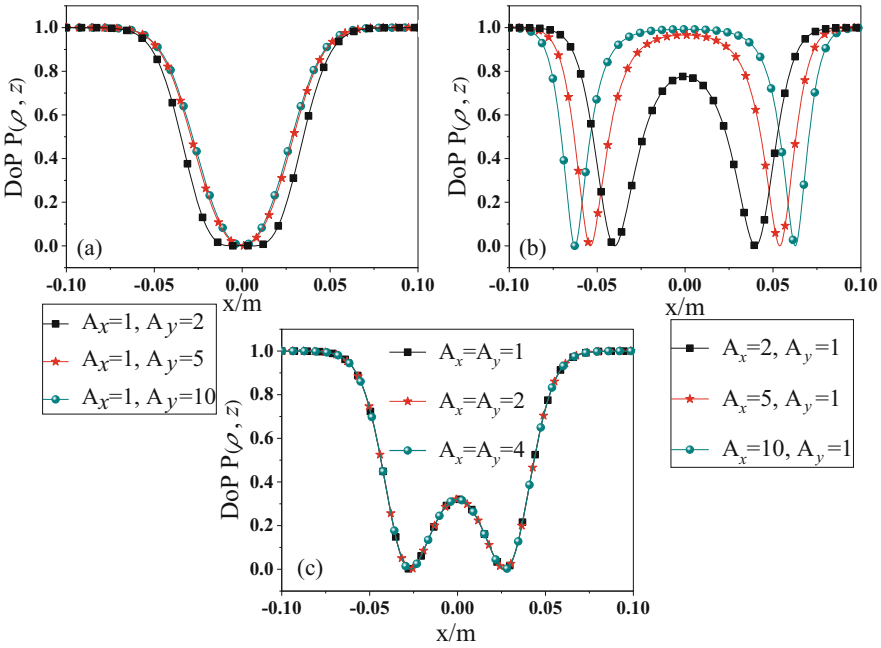

Fig. 48.27 DoP distribution curves of EGSMV beams transmitted through atmospheric turbulence with different amplitudes. (**a**) $Ax = Ay$; (**b**) $Ax < Ay$; (**c**) $Ax > Ay$ [184]

intensity phase information of the beam as possible. Here, adaptive optical correction techniques for wavefront-free measurements, based on the GS phase-retrieval algorithm, SPGD algorithm, and PD algorithm, are studied and analyzed.

The GS algorithm recovers the desired phase information by collecting the light intensity information in both the input and output planes, iterating cyclically under certain conditions to obtain the distorted phase information, and then loading the phase grayscale diagram onto a corrector, such as an SLM, by taking the conjugate.

Figure 48.34 shows the light intensity distribution of the single-mode and multimode vortex beams before and after correction by the GS algorithm. Figure 48.34 (a1)–(d1) are the spots without turbulence, Fig. 48.34(a2)–(d2) are the distorted spots after turbulence, and the corrected spots are Fig. 48.34(a3)–(d3). This shows that the singularity of the beam no longer wanders and is more uniformly distributed. The petal-like spot in the multimode case is also more complete.

The SPGD algorithm calculates the optimal voltage value of the deformation mirror corresponding to the maximum value of the light intensity correlation coefficient, based on the change in the light intensity correlation function in the iterative algorithm, which, in turn, drives a new deformation of the deformation-mirror surface. Thus, the beam reflected from the deformation mirror changes the optical-path difference, thus correcting the wavefront distortion [189].

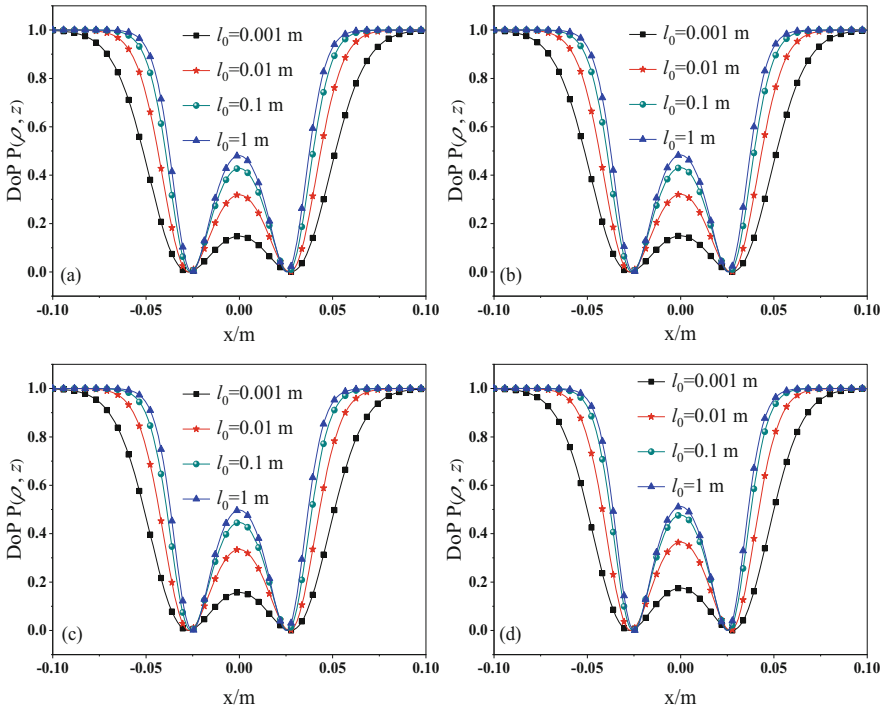

Fig. 48.28 DoP distribution curve of EGSMV beams with $l = 1$ transmitted through turbulence at different internal and external scales. (**a**) $L_0 = 200$ m; (**b**) $L_0 = 100$ m; (**c**) $L_0 = 10$ m; (**d**) $L_0 = 1$ m [184]

Figure 48.35 shows the light intensity distribution of single-mode and multimode vortex beams before and after correction using the SPGD algorithm. Figure 48.35 (a1)–(d1) show the light spots without turbulence; Fig. 48.35(a2)–(d2) show the distorted light spots after turbulence; and Fig. 48.35(a3)–(d3) show the corrected light spots. It can be seen that after correction by the SPGD algorithm, the vortex light intensity distribution becomes uniform and the spot shape becomes more regular. The correction effect is better for single-mode vortex beams than multimode beams.

The phase difference method is a phase recovery and image restoration technique. The algorithm collects the beam or image information in the focal and defocus planes, solves the optimized objective function using maximum-likelihood estimation, and obtains the phase distortion error by taking the difference between the obtained distorted phase and the ideal vortex phase. It finally recovers the original wavefront phase or image using the conjugate gray diagram of the phase distortion error.

Figure 48.36(a1)–(c1) show the beam distribution without turbulence; Fig. 48.36 (a2)–(c2) and (a3)–(c3) are the focal and defocused distorted spots after turbulence; and the corrected spots are Fig. 48.36(a4)–(c4). It can be seen that the light intensity

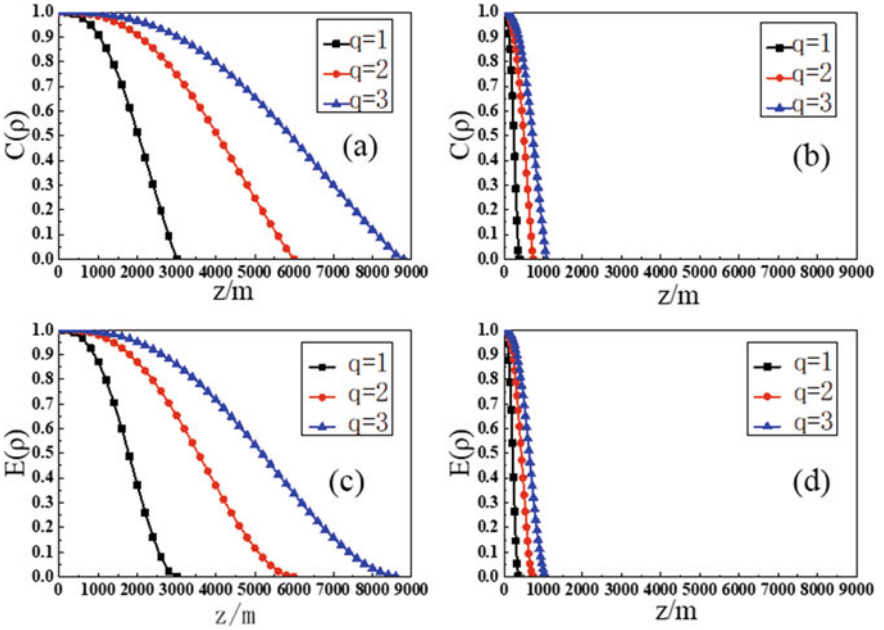

Fig. 48.29 Two-photon variation curves of different OAM entanglements. (**a–b**) Concurrence entanglement degree; (**c–d**) entanglement degrees [185]

distribution of Fig. 48.36(a2–c2) and (a3–c3) has decayed and distorted, and after correction by the phase difference method, the energy is recovered and the degree of distortion becomes lighter (Table 48.6).

Others

In addition to the above studies on transmission characteristics, there are also analyses of OAM beams passing through single-sphere particle scattering and through optical aperture systems. Figure 48.37 shows a model of OAM beam single-sphere particle scattering and the variation curve. The total scattering intensity is weaker than that of plane waves, as seen in Fig. 48.37a, and the scattering cross section increases as the beam width increases, as seen in Fig. 48.37b, c. The scattering cross section of particles is larger for plane waves than for Gaussian waves.

Figure 48.38a, b show the physical model of the LG beam passing through two aperture systems. Figure 48.39 shows the results after passing through the two optical systems. It can be found that the system obscuration ratio affects the beam intensity but does not affect the beam width, and the larger the wavelength, the greater the effect of the obscuration ratio on the beam transmission. In addition, in the near-field receiving range, as the spacing between the lens and aperture increases, the effect of the aperture and beam obscuration ratio on the beam transmission increases.

Vortex Beam Separation and Detection

Vortex Beam Detection

At present, there are several methods for detecting OAM modes:

1. Vortex beam and plane wave to detect spherical wave interference
2. Vortex beam diffraction after passing through a slit or type of aperture

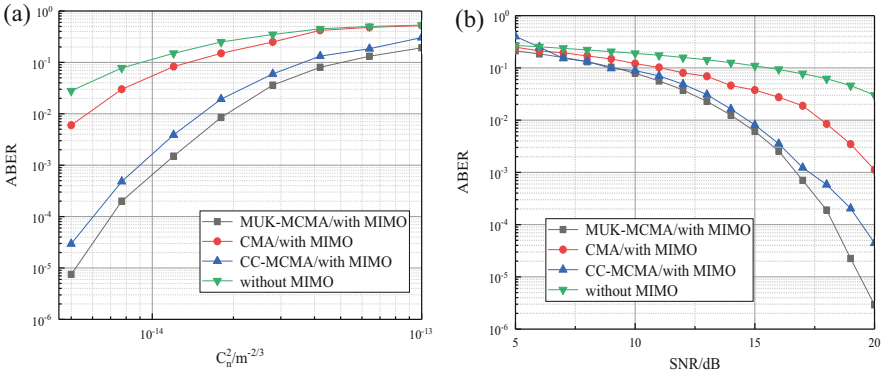

Fig. 48.33 Variation curves of the average bit error rate of an OAM-multiplexed communication system in an atmospheric turbulence channel. (**a**) Turbulence intensity; (**b**) signal-to-noise ratio (SNR) [188]

Vortex Beam Interference Detection Method

Vortex beam interference detection involves using vortex light and plane light for interference superposition by analyzing the generated interference fringes to detect the topological charge of the vortex light. Figure 48.40 shows that the number of bifurcations is 1, regardless of the simulation or experiment, and the bifurcations face upward at $l = 1$ and downward at $l = -1$.

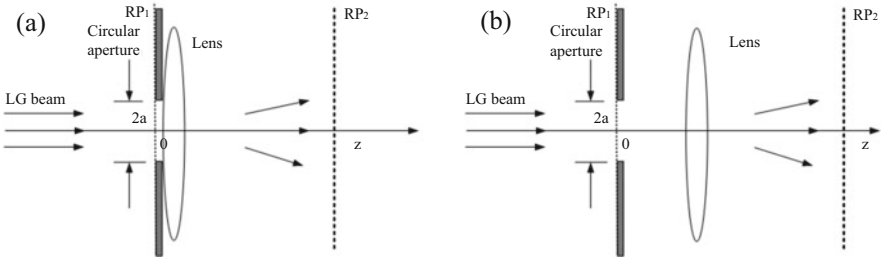

Fig. 48.38 Physical model of an optical system with a single aperture. (**a**) Lens adjacent to the aperture; (**b**) lens separated from diaphragm [142, 191]

Aperture-Detection Method

Figure 48.41 shows the diagrams of circular, square, and triangular apertures, as well as single and double slits. After passing through these apertures, the diagrams of the vortex beam can detect the OAM mode.

As shown in Fig. 48.42, the experimental results for a vortex beam diffracted by different apertures are shown. The positive and negative topological charges can be determined from the twisting direction of the diffracted spots, whereas the degree of twisting, number of array spots, and number of stripes can determine the size of the topological charge.

Table 48.7 presents a comparison of the detection effects of the five diffractive optical elements. Except for the circular aperture, which can only detect the topological charge of the incident vortex beam, the square, triangular, single, and double slits can detect the topological charge of the incident vortex beam, as well as the sign.

Grating Detection Method

The diffracted optical field of the vortex beam after passing through the gradually changing-period grating and annular grating can also be detected in the OAM mode. Figure 48.43 shows the ab-type gradually changing-period amplitude grating, ab-type gradually changing-period phase grating, annular amplitude, annular phase grating, phase correction, and fan-out phase diagram.

The light field distribution of various grating diffractions, improved by phase-correction and fan-out phase diagrams, were obtained according to the calculation and analysis of the Fresnel diffraction theory, as shown in Fig. 48.44. The topological charge magnitude and sign of the incident vortex beam can be detected by determining the number of diffraction stripes and their orientations.

The diffracted light intensity of the annular phase grating was the best, with clear stripes and the largest light intensity value. After phase correction, the maximum detectable topological charge was up to ± 20 orders for the gradually changing-period grating (GCPG) and up to ± 30 orders for the annular grating (AG).

Phase Singularity Evolution

Figure 48.45 shows the phase singularity evolution in the far field after the transmission of LGSMV beams with different topological charges and orders. With an

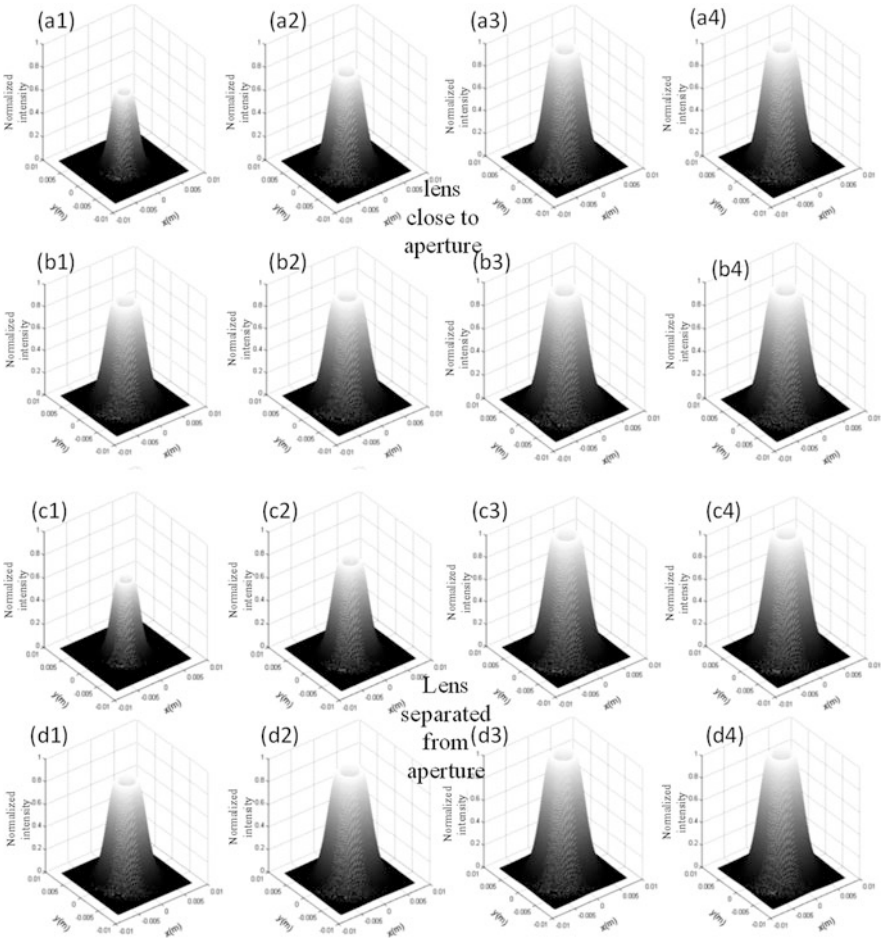

Fig. 48.39 Light intensity distribution of LG_0^1 under different obscuration ratios a/w_0 and wavelengths. (a1–a4) Obscuration ratio for $\lambda = 632.8$nm is $a/w_0 = 1.2, 1.6, 1.8, 2.0$; (b1–b4) obscuration ratio for $\lambda = 1060$nm is $a/w_0 = 1.6, 1.8, 2.6, 3.5$; (c1–c4) obscuration ratio for $\lambda = 632.8$nm is $a/w_0 = 1.6, 1.8, 2.2, 3.5$; (d1–d4) obscuration ratio for $\lambda = 1060$nm is $a/w_0 = 1.5, 2, 3.4, 6$ [142, 191]

increase in the transmission distance, the LGSMV light intensity distribution gradually expands, the central dark region splits, and the total number of phase singularities is equal to the original topological charge.

Orientation Angle of Polarization

The orientation angle of polarization (OAoP), which characterizes the direction of polarization of a vector vortex beam, can also be used to detect the topological

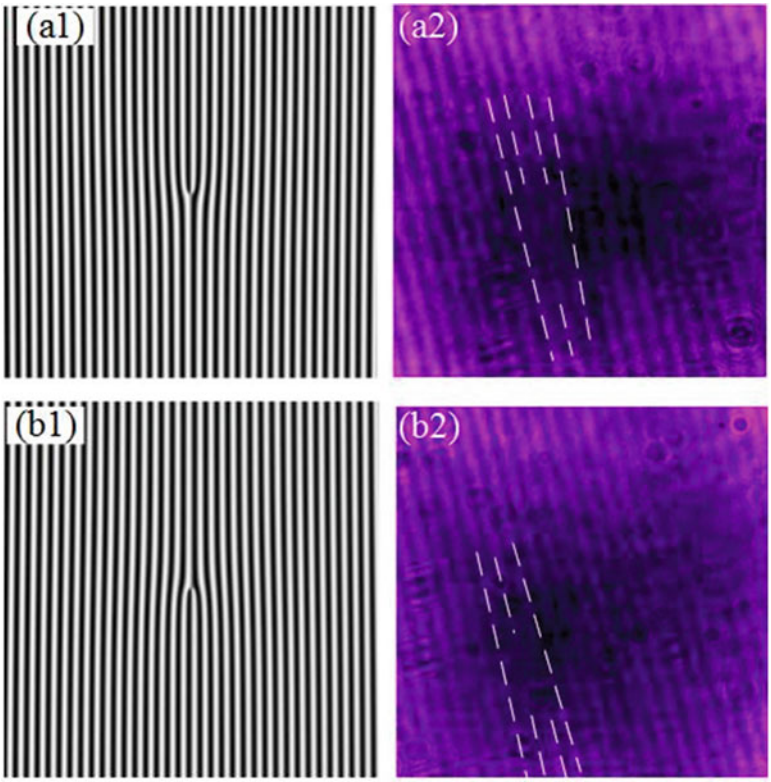

Fig. 48.40 Interference patterns of two vortex beams. (a1–a2) Vortex interference pattern with $l = 1$; (b1–b2) vortex interference pattern with $l = -1$ [145]

Vortex Beam OAM Separation and Detection

Figure 48.47 shows the diffracted light field distributions of $l = 1, 3$, $l = 1, 5$, and $l = 1, 7$ after a coordinate transformation. The coordinate-transformed light spot is horizontally laterally distributed in the form of bright stripes (Table 48.8).

Vortex Beam OAM Applications

Vortex Beam OAM Coding and Decoding

In OAM multiplexing communication, the additional degrees of freedom of the vortex beam can be used to realize multibit data coding and decoding for higher speed and capacity communication. Here, the phase coding is based on the eight-stage structure of an SPP, that is, each eight-stage structure can encode 24 bits of information after encoding by equal length, and the value and ordering of these eight characters represent phase coding.

The spiral spectrum is measured, and the value of the spiral spectrum is stored with the encoded information of the QSS through the correspondence of the step encoding and spiral spectrum to decode the information. The spiral spectrum has symmetric and asymmetric structures, as shown in Fig. 48.48a, b, respectively.

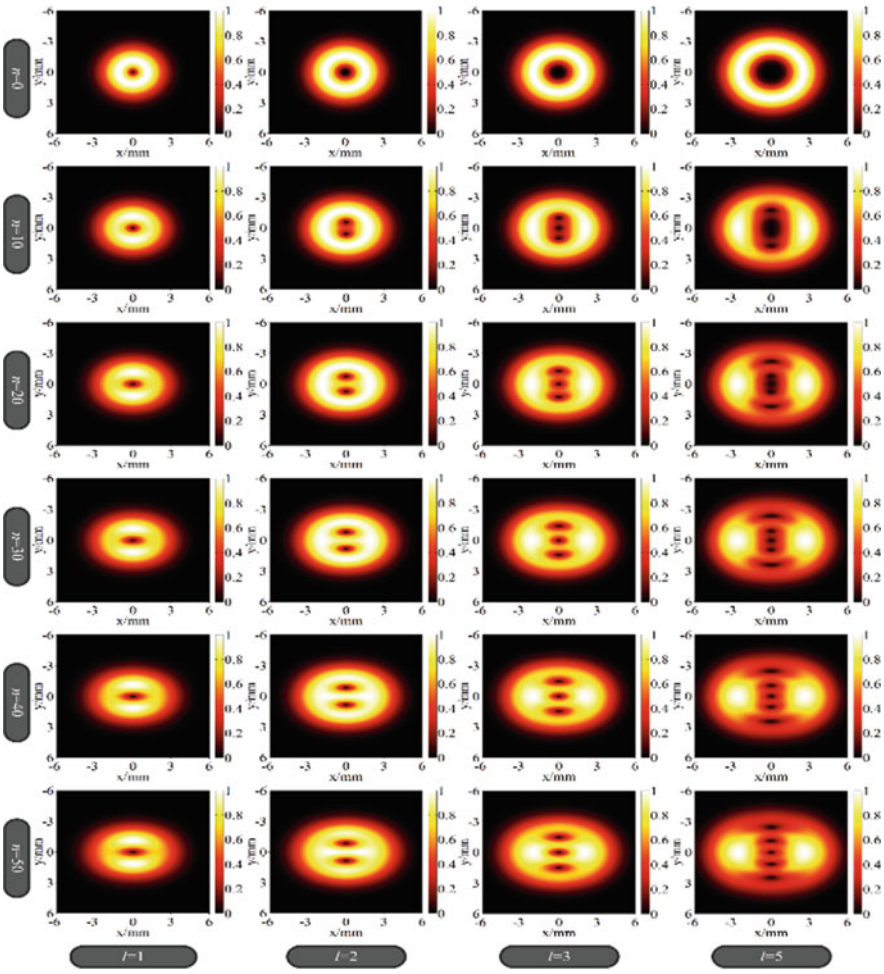

Fig. 48.45 Phase singularity evolution of LGSMV beams with different topological charges and orders [184]

The conical lens is used as a mode converter to convert the LG beam into a higher-order Bessel diffraction-free beam for spatial light information-transmission encoding, and then the array grating is used for decoding. Figure 48.49 shows the schematic diagram of the coding and decoding system.

The optical communication implementation method is based on orthogonal OAM state information encoding using a high-order Bessel function. A single photon can carry a determined OAM state, which can increase the key transmission rate of the protocol and provide a solution to simultaneously increase the optical communication distance. Figure 48.50 shows the high-order Bessel beam optical quantum communication codec system.

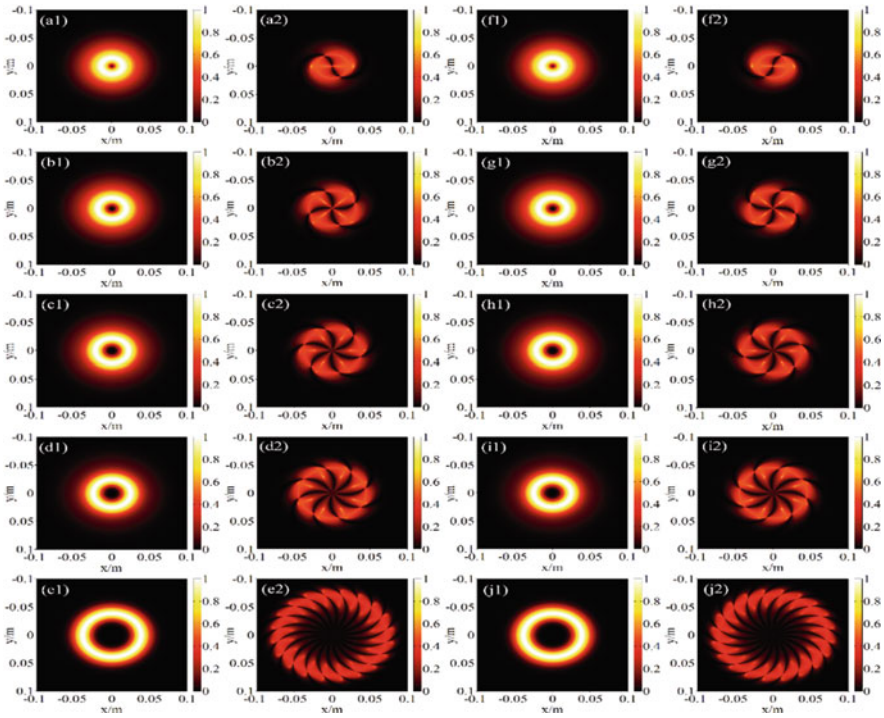

Fig. 48.46 Far-field diffraction patterns of EGSMV beams with different topological charges [184]

Vortex Beam OAM Information Exchange

OAM multiplexing communication systems exchange different data streams with different OAM modes. The topological load conversion of different OAM beams can increase the data processing flexibility and management in the communication link and realize a reconfigurable optical network based on OAM.

Figure 48.51 shows a schematic diagram of the OAM beam information exchange principle, which enables the OAM mode to exchange information by loading the spiral phase diagram on the SLM. Figure 48.52 shows the experimental results of different OAM beam information exchanges at different carrier frequencies. It can be clearly seen that the signal waveforms at different frequencies are switched, and the information of the two OAM beams is exchanged.

Vortex Beam OAM Through Maca-Antenna Emission-Efficiency Analysis

Maksutov–Cassegrain antennas (Maca-antennas) have the advantages of lower spherical aberrations, chromatic aberrations, and a long focal length, which can improve the resolution of the antenna system. Therefore, they are widely used in satellite remote sensing and LIDAR systems. Here, it is proposed that using a spirally distributed

Research Outlook of OAM Technology for Optical Wireless Communication Systems

With an in-depth study of a structured optical field carrying OAM, the traditional modulation parameters (amplitude, phase, frequency, and polarization state) can no longer meet the demand. The emergence of OAM provides a new type of space-dimensional resource, which opens up new avenues for the development of optical communication.

First, the domestic and foreign development status of OAM-related technologies was outlined, and the advantages and disadvantages were summarized and compared. In addition, the relevant research work of Xi'an University of Technology was introduced, including single-mode and multimode OAM beam generation, partial coherence, vector OAM beam transmission characteristics, crosstalk analysis, wavefront correction, grating aperture detection, separation and detection based on

the coordinate-transformation method in OAM-multiplexed communication systems, and practical applications.

With the advent of global communication integration, the establishment of 6G technology-based land, sea, air, sky, and micro-communication networks and their cross-scene intelligent optical communication networks is a major trend in communication development. Future OAM-related technologies for optical wireless communication systems can progress in the following areas.

1. Generate new OAM beam arrays and study their transmission characteristics to improve the beam energy at the transmitting end, thus enhancing the transmission efficiency of optical wireless communication systems.
2. Develop a geometric coordinate transformation of optical OAM toward compactness and miniaturization and combine it with improved iterative algorithms to improve the resolution and efficiency of the light spot, after separation at the receiving end.
3. Combine MIMO equalization and channel-coding techniques with OAM techniques, which can further mitigate the effect of turbulence on the beam.
4. Establish a multilayer phase diffraction optical neural network to realize a device that integrates the generation, multiplexing, demultiplexing, and detection of OAM beams, then, add iterative algorithms and error functions for optimization and evaluation. Thus, the integrated application of OAM technology in optical wireless communication can be advanced more quickly.

Abstract

Aircraft relay can quickly build end-to-end communication networks, enhance the coverage and transmission capability of communication systems, strengthen signal strength and increase data transmission speed, and improve the reliability of communication systems. This chapter summarizes the current research status of UAV relay in optical wireless communication at home and abroad and introduces the basic principles and key technologies of UAV relay in optical wireless communication. Finally, it outlooks the application and development direction of UAV relay in optical wireless communication.

Introduction

Optical wireless communication uses light waves to transmit data, typically using visible light, infrared, and other light waves for communication [1]. It transmits digital information by modulating the intensity and frequency of light, among other parameters [2]. It has a high transmission rate and unregulated operating frequency bands [3].

In the optical wireless communication process, the transmission distance and signal quality are affected by factors, such as terrain, buildings, and weather [4]. Therefore, when the signal source and target are far apart or obstacles are present, relaying is required to ensure that the signal can reach the target. Relaying can forward the signal to a greater distance and extend the signal coverage, thus improving the communication efficiency and reliability [5].

With the advancement of unmanned aerial vehicle (UAV) technology and the reduction of its production cost [6], using UAVs as relays for optical communication has become a new communication method [7]. Signals are transmitted from the ground to a high-altitude UAV, and then the UAV relay transmits the signals to the target location, thus enhancing and extending the signal [8–10].

When UAVs communicate via radio frequency (RF), they can interfere with existing ground-based wireless networks, which makes it challenging to implement airborne RF links [11]. Optical wireless communication links can provide higher bandwidth and security than traditional RF links [12], and their application in UAV relaying has been the subject of extensive attention and research. UAV-relaying technology can also enhance the coverage and bandwidth of free-space optical (FSO) communication networks, which is of great importance for optical wireless communication.

This chapter introduces the status of domestic and foreign research on UAV relays in optical wireless communication, describes the principles of the UAV relay system, including relay forwarding strategies, relay system models, protocols used in optical UAV relays, and an evaluation index of system performance. It also focuses on key UAV relay technologies in optical communication, such as channel characteristics, acquisition, pointing, and tracking (APT) technology, modulation and demodulation technology, and lightweight system designs. Finally, the application and development trends of UAV relays in optical wireless communication are foreseen.

Overview of UAV Relay Optical Communication Systems

UAV Relays

Nowadays, the UAV industry is developing rapidly and increasing numbers of UAVs are available. Commonly used relay vehicles [13] are fixed-wing UAVs, rotary-wing UAVs, tethered UAVs, and high-altitude platforms [14]. As shown in Fig. 49.1, fixed-wing UAVs have the advantages of long flight time, fast flight speed, long

distance, and a large load; thus, they are chosen for long-range and high-load relay communication. Multi-rotor UAVs have become the first choice for UAV applications, owing to their ability to hover at any time and their lower production costs.

Tethered UAVs have low environmental requirements for takeoff and landing and long working hours and are flexible and easy to deploy. They are widely used as relays for communication in harsh environments or in the event of natural disasters. High-altitude platforms, also known as quasi-static vehicles, are unmanned aerial systems (UAS) in a broad sense, with ultra-high payloads and power. They are often used as relay nodes between satellites and the ground, as a way to reduce the burden of satellite communications.

The four types of UAVs mentioned above are widely used in relay communications. Compared with other high-altitude vehicles, UAVs have the advantages of flexibility and speed and can provide communication support in areas that cannot be covered by ground communication networks. Moreover, UAVs can adjust their position and altitude at any time to achieve the best relaying effect. Therefore, an effective optical communication link can be established between air–ground and air–air by using UAVs as relays.

Figure 49.2 shows the model of a UAV relay communication system, where the UAV relays between two nodes. The data link between the UAVs is divided into an uplink and a downlink. The uplink sends command information from ground console 1 to the UAV to the telemetry link, and the downlink sends telemetry information from the UAV to the ground console to the telemetry link [15].

Because the UAV flies at a higher altitude, the communication link with the ground control terminal can be approximated as a direct vision communication, which meets the optical wireless communication requirements.

Relay Collaboration Technology

In UAV relay collaboration technology, the signals sent by the source node are processed and forwarded by the relay node and finally delivered to the destination node. The relay node forwarding extends the communication distance. Different relay selection techniques and relay location adjustments can obtain better channel environments, and different relay communication protocols can meet the needs of different application scenarios. The system performance should be evaluated after

Fig. 49.1 Main types of relay aircraft [12]. (**a**) Fixed-wing UAV, (**b**) rotor UAV, (**c**) tethered UAV, and (**d**) high-altitude platform

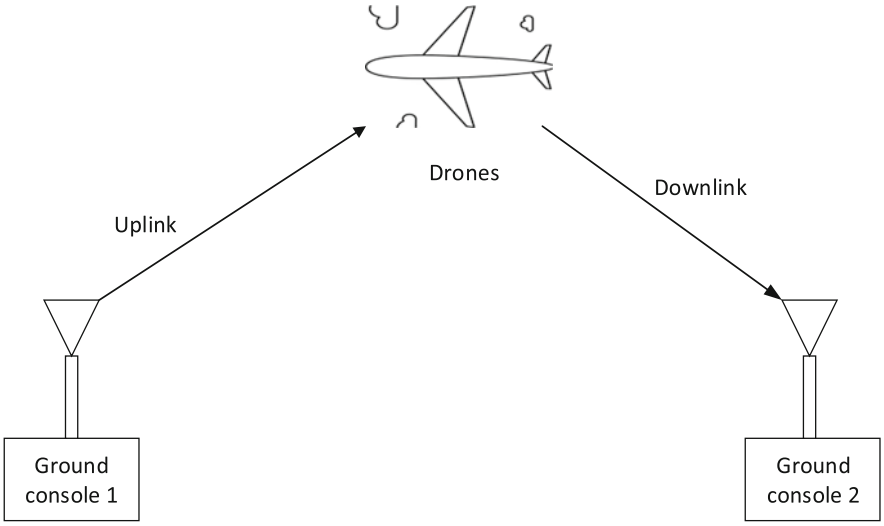

Fig. 49.2 Model of a UAV relay communication system [15]

the UAV completes the relay forwarding. Several relay forwarding strategies, relay system models, communication protocols, and performance evaluation indexes are analyzed below.

Relay Forwarding Strategy

In traditional wireless communication, a relay is used to extend the communication range and increase the line-of-sight transmission. There are three types of relay node forwarding protocols [16]: amplified forwarding, decoded forwarding, and coded forwarding. Figure 49.3 shows a schematic diagram of amplified forwarding, which is a double-hop relay. The double hops are independent of each other and there is no interference. It is better to use amplified forwarding in the case of a high signal-to-noise ratio.

The transmission rates of the UAV relay system under the amplify-and-forward protocol are shown below [17]:

$$R = \log\left(1 + \frac{\mathrm{SNR}_S \mathrm{SNR}_D}{1 + \mathrm{SNR}_S + \mathrm{SNR}_D}\right) \tag{49.1}$$

where SNR_S denotes the signal-to-noise ratio from the source node to the relay node and SNR_D denotes the signal-to-noise ratio from the relay node to the destination node.

Figure 49.4 shows a schematic diagram of decoding and forwarding. The principle is that the signal is demodulated at the relay node and the received signal is checked to determine whether its decoding is correct. If it is correct, it is recoded and forwarded; if not, the relay node will no longer function.

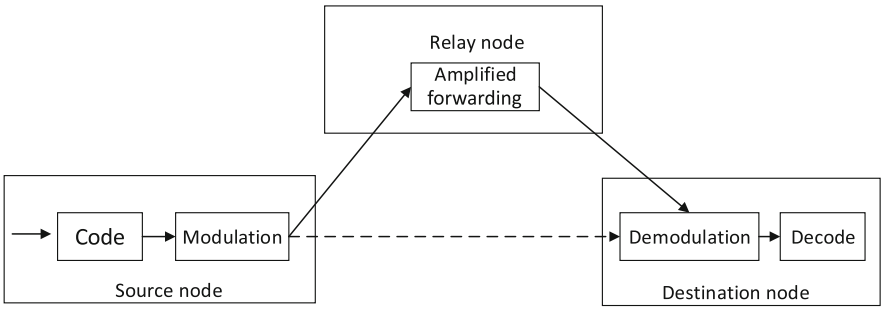

Fig. 49.3 Amplified forwarding schematic [16]

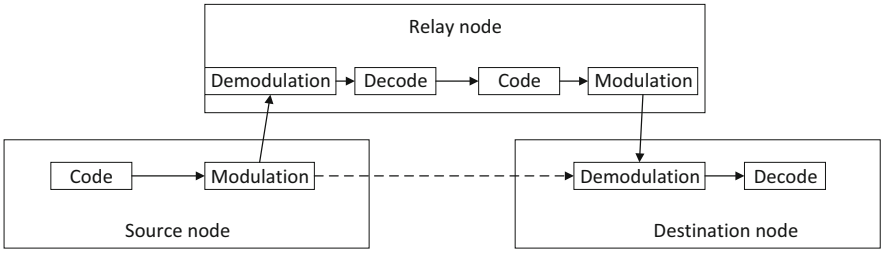

Fig. 49.4 Schematic diagram of decoding and forwarding [16]

The transmission rate of the communication system in a UAV relay system using a decode-and-forward protocol can be described as follows [17]:

$$R = \min\{\log(1 + \mathrm{SNR}_D), \log(1 + \mathrm{SNR}_S)\} \tag{49.2}$$

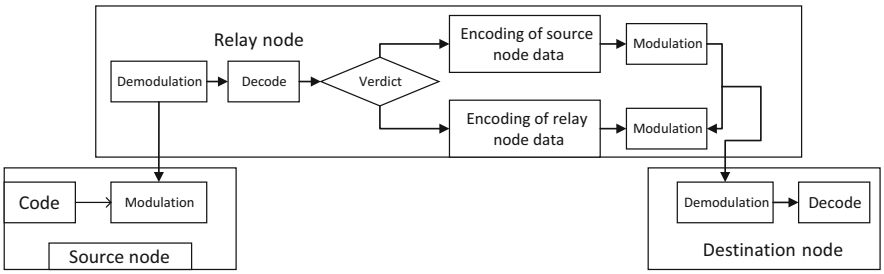
where SNR_S denotes the signal-to-noise ratio from the source node to the relay node, and SNR_D denotes the signal-to-noise ratio from the relay node to the destination node.

Figure 49.5 shows the schematic diagram of coded forwarding. The principle of this method is similar to decoded forwarding; the difference is that when the decoding result is judged to be wrong, the relay node will encode the incorrect information for forwarding. This method can improve the overall system performance; however, the method is very complicated.

Different relay forwarding strategies have advantages and disadvantages, and they are compared in Table 49.1.

Relay System Models

According to the number of relays forwarded, system models can be divided into single-relay and multi-relay communication, while according to the different relay nodes, relays can be divided into double-hop single-relay and multi-hop multi-relay. Figure 49.6 shows a double-hop single relay. When the communication path from the source node to the destination node is blocked, the relay node can be used for



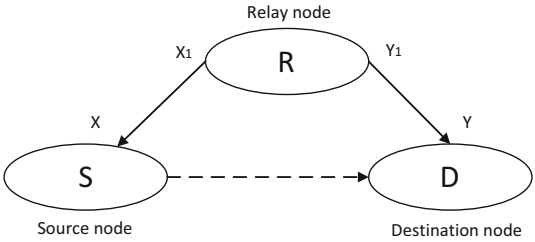


Fig. 49.5 Schematic diagram of coded forwarding [16]

Table 49.1 Comparison of advantages and disadvantages of relay forwarding strategies

Forwarding strategy	Advantages	Disadvantages
Amplify forwarding	More easily improves the signal strength	Unable to handle noise and interference in the signal; the signal quality is easily affected
Decoding and forwarding	Can handle signal noise and interference and perform error correction and error control	The presence of check digits in the checksum makes the transmission less valid and more computationally intensive
Coded forwarding	Encoding and decoding Operations can be performed to optimize signal transmission quality	High complexity and computational effort; less application in practical scenarios

Fig. 49.6 Double-hop single relay [18]

auxiliary communication to expand the communication coverage and improve the performance of the communication system.

S is the source node, D is the destination node, and R is the relay node. The specific process follows. When the S side sends a signal X to the R side, the R side receives signal X_1. The R side executes the prescribed protocol to process certain information on X_1 and sends signal Y_1 to the D side, and the D side receives signal Y. Therefore, the R side plays a crucial role in the communication quality for the entire communication system.

Figure 49.7 shows a multi-hop multi-relay, which adds multiple relay nodes to a two-hop single-relay, further extends the communication coverage, and forwards the

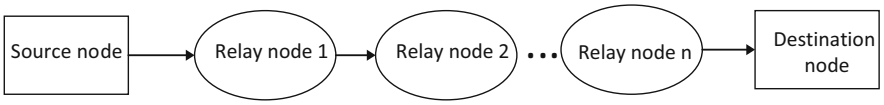

Fig. 49.7 Multi-hop multi-relay [18]

signal multiple times. The disadvantage is that the security rate decreases and the complexity of the entire relay network increases. The communication delay and energy consumption increase exponentially.

Compared with traditional wireless communication networks, relay collaborative communication transmissions have become a trend. Users can choose different relaying methods and forwarding protocols to carry out relay communication, and reasonably selecting a relay node has become the focus of attention. In a UAV relay communication system, the rationality of the selected relay forwarding method and relay node selection are measured by calculating from the interruption probability, signal-to-noise ratio threshold, bit error rate, and channel state information [19].

Relay Communication Protocol

A UAV relay needs to support a variety of communication protocols, including the Transmission Control Protocol/Internet Protocol (TCP/IP) and User Datagram Protocol (UDP) to meet the needs of different application scenarios.

1. TCP/IP protocol: The TCP/IP protocol is a connection-oriented protocol. TCP can provide reliable data transmissions in an IP environment; it can ensure the reliability and integrity of data transmissions and is suitable for scenarios where UAV relays transmit large amounts of data in optical wireless communication.
2. UDP protocol: The UDP protocol is a simple message-oriented transport layer protocol. It is a connectionless protocol with a fast transmission speed but does not guarantee the reliability or integrity of data transmissions. It is suitable for scenarios in which a UAV relay transmits real-time data in optical wireless communication.

Relay Performance Evaluation Metrics

The data transmission capability of UAV relays in optical wireless communication is reflected in the throughput and interruption performance [20], while the reliability and interference immunity of the system are reflected in the average bit error rate, signal-to-noise ratio, and channel capacity.

Interruption Probability

In wireless communication channels, the probability of disruption is generally chosen to reflect the performance of the overall communication system. When the link fades too much, compared to the source, it causes the output instantaneous signal-to-noise ratio of the destination node to be much smaller than the specified signal-to-noise ratio threshold, which in turn causes the signal to be interrupted.

Therefore, the probability that the output instantaneous signal-to-noise ratio of the link is below the threshold is defined as the interruption probability [21]. The expression for the interruption probability can be written as

$$P_{\text{out}} = \Pr(\gamma \leq \gamma_{\text{th}}) \tag{49.3}$$

where γ denotes the instantaneous signal-to-noise ratio of the system, γ_{th} denotes the threshold value, and Pr(•) denotes the probability of an event occurring.

Average Bit Error Rate

The average BER is the ratio of the number of erroneous bits occurring during a transmission to the total number of bits, which reflects the accuracy of the data transmitted by the communication system in a certain period of time. In optical wireless communication systems, the BER is affected by various factors, such as environmental factors, optical parameters, and modulation methods, and is usually measured using experiments or simulations. The lower the average BER, the higher the accuracy of the received data.

Assuming that the system signal is coherently detected and binary phase shift keyed, the BER of the optical wireless communication system is [22]

$$P_e = \int_0^{\infty} \frac{1}{\sqrt{\pi}\sigma^2} \exp\left[-\frac{(i_d + 0.5RIA\zeta)}{\sigma^2}\right] di_d \tag{49.4}$$

where σ^2 denotes the noise variance, i_d denotes the baseband signal strength, R denotes the response coefficient of the photodetector, I denotes half of the peak light intensity, A denotes the carrier amplitude, and ζ denotes the modulation index.

Signal-to-Noise Ratio

The signal-to-noise ratio is the ratio between the signal and the noise power. In an optical wireless communication system, the signal-to-noise ratio directly affects the signal quality and distance. The signal-to-noise ratio of the system can be improved by increasing the transmitting power, optimizing the receiver sensitivity, and reducing the environmental interference. The higher the signal-to-noise ratio, the higher the reliability of the data transmission.

The S/N ratio expression of a UAV relay optical wireless communication system is as follows [22]:

$$\text{SNR} = \frac{(IRA\zeta)^2 P_m}{\sigma^2} \tag{49.5}$$

where σ^2 denotes the noise variance, I denotes half of the peak light intensity, A denotes the carrier amplitude, ζ denotes the modulation index, and P_m denotes the subcarrier signal power.

Channel Capacity

The channel capacity refers to the maximum amount of information transmitted per unit of time and is related to the transmitting power, receiver sensitivity, and transmission distance. In optical wireless communication, it will be affected by fading, noise interference, and other factors. Assuming that the optical signal is affected by atmospheric turbulence factors, the average channel capacity in the optical wireless communication system is

$$C = \int_0^\infty B \log_2(1 + \mathrm{SNR}) P(I) dI \tag{49.6}$$

where B denotes the channel bandwidth, SNR denotes the signal-to-noise ratio, and $P(I)$ denotes the probability density function of the optical signal under atmospheric turbulence.

Relay System Throughput

The throughput refers to the number of packets received per unit time by a target node. This metric is often used to indicate the network's ability to transmit packets. The smaller the throughput value, the worse the transmission performance of the network. In communication systems, the system throughput is defined as the amount of data that is correctly transmitted between the sending node and the destination node within a unit of time [16].

Research Status of UAV Relays

UAV relay optical communication combines the high capacity of optical wireless communication and the high mobility of UAVs, which is of great significance to the further development and improvement of UAV relay optical communication technology.

Status of Foreign Research

The application of optical wireless communication technology in aircraft relaying has attracted widespread attention, and countries worldwide are studying its theory and key technologies. They have also achieved different results.

In 2013, Park et al. [23] investigated an asymmetric amplify-and-forward UAV-relaying approach, using a subcarrier intensity modulation scheme to convert the received RF signal into an optical signal. Under the assumption that the RF and optical wireless channels would experience Rayleigh fading and gamma–gamma fading, respectively, they developed an asymmetric radio frequency/free-space optical (RF/FSO) dual-hop relay system where the average error probability was derived. Its results showed that the average error probability of the asymmetric

RF/FSO UAV relay system was lower than that of the RF/RF relay system under a low signal-to-noise ratio, and better system performance could be obtained.

In 2014, Kaadan et al. [24] investigated the effect of instability of hovering multi-rotor UAVs on the system performance in an optical wireless communication link. It was modeled to measure the power characteristics of fiber optic transceivers at different wavelengths and transmission ranges, enabling for the first time, a short-range optical wireless communication link between two multi-rotor UAVs.

In 2018, Dabiri [25] performed the first stochastic analysis of the channel characteristics of a UAV relay all-optical communication link, assuming that the channel underwent gamma–gamma fading. Statistical models for ground-to-UAV, UAV-to-UAV, and UAV-to-ground links were derived, and the outage probability of each link was derived.

In 2018, Alzenad et al. [26] analyzed the drone characteristics of optical wireless communication under different weather conditions. A point-to-point optical wireless communication link was established between the core network and a terrestrial access point for transmitting data traffic using drone relays to improve the system stability. The research results showed that the backhaul link based on optical wireless communication had a higher transmission rate when the base stations were more densely clustered.

In 2018, Fawaz et al. [27] proposed to apply UAV relaying to optical wireless communication by installing an optical wireless communication transceiver and its optical device on a UAV and using this UAV as a removable relay node with caching capability. It was shown that the effects of atmospheric turbulence and fading losses on the optical wireless communication system could be reduced by setting multiple UAV-assisted relays in harsh environments with longer transmission distances.

In 2018, Dong et al. [28] applied the edge computing method to an unmanned aircraft relay optical wireless communication network to support a wireless network architecture to complement the ground infrastructure. Optical wireless communication receivers were carried on both the forward and return links for a rapid response to unexpected events and flexible deployment.

In 2019, Lee [29] investigated a two-hop FSO/RF heterogeneous system based on UAV relaying and used a time-discrete and continuous-convex approximation method to obtain a suboptimal solution for the UAV trajectory, with the maximum throughput rate as the optimization objective. Based on this, a UAV trajectory optimization method based on dichotomous and sequential programming methods was proposed to maximize the flight time.

In 2019, Lee et al. [30] studied the trajectory optimization of fixed-wing UAV relaying in optical wireless communication and used the dichotomous and sequential planning methods to maximize the service time of a vertical wireless backhaul network, based on optical wireless communication.

In 2019, Wu et al. [31] studied UAV-relay-assisted mobile access networks under optical wireless communication. They designed a user quality of service (QoS)-aware algorithm to maximize the number of served mobile users by using UAV-base station and mobile-user association strategies to jointly optimize UAV base-station deployment, mobile-user association, and bandwidth allocation.

In 2019, Safi et al. [32] studied the effect of pointing errors on the link, owing to UAV fluctuations in a UAV relay optical wireless communication system. Because the fluctuations of hovering UAVs caused beam drift and angle-of-arrival undulations, the beam was tracked using quadrant detectors to find the optimal detector size that minimized the tracking error. Closed expressions for the tracking error and BER were derived, and Monte Carlo simulations were performed to verify the accuracy of the expressions.

In 2020, Usman et al. [33] proposed a hybrid backhaul for mobile base station-assisted cellular networks and derived expressions for the BER of RF, free-space optical, and hybrid backhaul communication. In the hybrid connection, optical wireless communication was selected when the UAV relay was in a fixed position, and RF communication was selected when the UAV relay was flying from one position to another. It was also demonstrated that this hybrid backhaul network outperformed the single optical wireless communication and single RF communication scenarios.

In 2020, Ansari [34] used a hovering UAV as a relay for optical wireless communication between a ground base station and a user. To increase the hovering time of the UAV, an optical wireless communication receiver was placed on the UAV, along with a solar panel. The optical wireless receiver received a portion of the beam from the ground base station and demodulated the data carried by the beam. The solar panel received the remaining beam and absorbed the energy carried by the beam. The results of the study showed that the method effectively increased the hover time and data transmission rate.

In 2021, Lee [35] investigated the throughput maximization of FSO/RF-hybrid UAV-assisted mobile relaying and designed effective trajectories for UAV relaying under different weather conditions, considering buffering and delay. The throughput maximization problem under buffer constraints was divided into delay-limited and delay-tolerant transmissions, and its effective trajectory was obtained by convex quadratic constraint planning to find the optimal buffer size and delay time requirements. It resulted in a significant increase in throughput compared with the conventional static relaying scheme.

In 2021, Dabiri et al. [36] studied the source-node-to-relay and relay-to-destination-node channel models for UAV-assisted optical wireless communication relay links and derived the optimal three-dimensional coordinates and optimal beam pattern for the UAV relay to minimize the disruption probability. Moreover, physical parameters that affected the optimal UAV relay positioning were investigated, such as the UAV directional fluctuation intensity, obstacle height, and location.

In 2021, Safi [37] investigated a multi-rotor hovering UAV in a ground-space free-space optical link. The UAV used a four-quadrant photodetector array. This method was able to increase the field of view at the receiving end, thus effectively reducing the effects of fluctuations. A variable focal length lens was used to adjust the beam size and reduce the impact of angle-of-arrival jitter and aiming error on the system performance.

In 2021, Wang et al. [38] used a UAV relay-assisted optical wireless communication system to mitigate the limiting effect of turbulence-induced atmospheric

scintillation. A serial optical wireless communication decode-and-forward system based on a hovering UAV was investigated to reveal the effects of different factors, such as atmospheric turbulence, pointing errors, and angle-of-arrival undulations, on the system. The beamwidth, field of view, and UAV position were also optimized, and the results showed that the proposed method could significantly improve the system performance.

In 2021, Dabiri et al. [39] investigated the application of UAV relaying to optical wireless communication amplify-and-forward systems. They derived the statistical probability of the end-to-end signal-to-noise ratio under the influence of the directional and positional fluctuations of the UAV relay, position of the UAV relative to the source and target nodes, beamwidth, and turbulence intensity of the source-to-repeater and relay-to-target links, as well as the BER and interruption probability expressions. The results showed that the optimal UAV height for the minimum interruption probability was determined by the beamwidth at the target, and the optimal value of the source-to-relay node link length increased when the beamwidth at the destination decreased.

In 2022, Wang et al. [40] analyzed the performance of a UAV-assisted dual-hop optical wireless communication relay system, considering the effects of the pointing error, fading loss, and atmospheric turbulence on the source-to-relay and relay-to-destination links. The source-to-relay and relay-to-destination links were assumed to satisfy the Malaga and gamma–gamma distributions, respectively, from which expressions for the probability density function, cumulative distribution function, end-to-end outage probability of the relay system, and average BER were derived. The results showed that in the weak turbulence case, the system performance mainly depended on the turbulent environment, while in the strong turbulence case, the system performance was more sensitive to the position offset.

In 2022, Janji et al. [41] used a UAV relay optical communication system for small cell (SC) backhaul links, in which UAVs with optical wireless communication devices were used as backhaul relay nodes. They proposed to use the visible map algorithm and shortest-path method to find the location of the UAV relay station to ensure direct-view communication between consecutive hops. The final results showed that this method could effectively improve the system gain.

In 2022, Qu et al. [42] studied an integrated air–air, air–ground network in an UAV-assisted free-space optical communication system. Assuming that the RF communication and optical wireless communication followed the shadowing and Malaga fading distributions, respectively, the outage probability, average BER, and traversal capacity for different modulation methods were derived. The simulation results indicated that the system performance was severely degraded when the turbulence conditions or pointing error became large. Moreover, the system with outlier detection performed better than the system with intensity modulation.

In 2023, Lee [43] proposed an FSO/RF satellite–UAV integrated hybrid for nonterrestrial networks using deep reinforcement learning methods to maximize the total end-to-end throughput, while minimizing the UAV energy consumption. Their simulation results indicated that the method could significantly increase the

throughput compared to fixed terrestrial relaying; however, the energy consumption increased.

In 2023, Singh et al. [44] investigated the performance of an optical wireless communication system during decode-and-forward for a hovering UAV relay, considering the effects of path loss, atmospheric turbulence, aiming error, and angle-of-arrival undulation. Using direct detection techniques, a closed-form expression for the point-to-point channel gain was derived, and the interruption performance of a serial multi-hop system was analyzed on this basis.

The development of UAV relaying in optical wireless communication has evolved from individual UAVs to UAV clusters, from fixed-wing UAVs to rotary-wing UAVs, from air–ground links to air–air links, and from FSO/FSO links to FSO/RF links, and the research has evolved from theoretical derivations to simulations to practical applications. The system performance of UAV relay optical communication systems is studied by considering different relay forwarding methods and different fading losses, which significantly improve the system throughput, energy consumption, and other aspects (Table 49.2).

Status of Domestic Research

In the 1990s, China began to study optical wireless communication and at the beginning of the twenty-first century began to develop UAV relay technology. Only in recent years UAV relay and optical wireless communication technology have been combined; however, they were rapidly fully developed and researched, and research results were achieved.

In 2017, An et al. [45] studied the communication condition of a UAV air–ground optical wireless communication system in different weather, in terms of the maximum received power, maximum power variation range, Ethernet packet loss rate, and stability of transmitting high-definition video at a fixed distance and time. Field experiments showed that when the weather temperature rose, the turbulence affected the communication-power variation range. In rainy weather, the power variation range was smaller, and the smaller the power variation, the lower the Ethernet packet-loss rate and the better the communication quality. It provided experience for air–ground long-distance information transmissions by UAV relays in optical wireless communication systems.

In 2018, Xu et al. [46] designed a UAV airborne laser communication device because of the demand for high-precision equipment for UAV-relayed optical wireless communication. It had small aperture reception, adaptive adjustment of the light-range divergence angle, coaxial-signal optical transceiver, and omnidirectional automatic scanning capture tracking. The results showed that the device had the advantages of a small size, low power consumption, high scanning and capturing tracking efficiency, shortened communication link establishment time, and stable data transmissions. This provided a high-precision device for the development of optical wireless communication in UAV relays.

Table 49.2 Foreign research results

Year	Researcher	Research results
2013	Park	Asymmetric amplify-and-forward RF/FSO UAV relay system outperformed an RF/RF UAV relay.
2014	Kaadan	Short-range optical wireless communication between two multi-rotor UAVs achieved for the first time
2018	Dabiri	First stochastic analysis of channel characteristics of all-optical communication links for UAVs
2018	Dong	Applied edge computing to optical wireless communication networks for UAV relays
2019	Lee	Study of a two-hop FSO/RF heterogeneous system to obtain a suboptimal solution for UAV trajectories
2019	Lee	Maximized flight time obtained by trajectory optimization of fixed-wing UAVs
2019	Wu	Designed user quality-of-service perception algorithm to maximize the number of mobile users of the service
2019	Safi	Found the optimal detector size to minimize tracking errors, based on the impact of the pointing error on a ground-to-UAV optical wireless communication link
2020	Usman	By comparing the BER of a single RF link, a single optical wireless communication link, and a hybrid link, it was concluded that the performance of the hybrid link was better.
2020	Ansari	Effectively increased the hovering time of a hovering drone by placing solar panels and optical wireless communication receivers on it
2021	Dabiri	Modeled the channel from the source node to the relay node and the relay node to the destination node to derive the optimal three-dimensional coordinates
2021	Safi	Used a four-quadrant photodetector array to increase the field of view at the receiver and variable focal-length lens to adjust the beam size
2021	Wang	Optimized beamwidth and field of view by analyzing the UAV relay optical communication system under decode-and-forward, considering the effects of atmospheric turbulence, pointing error, and arrival angle undulation on the system
2021	Dabiri	Developed expressions for the interruption probability and BER of a UAV relay optical communication system under amplification-and-forwarding, where the beam width at the target could determine the optimal UAV altitude
2022	Wang	By analyzing the UAV relay optical communication system under decode-and-forward, the outage probability and average BER were derived by considering the effects of fading loss, atmospheric turbulence, and pointing error on the system
2022	Janji	Used UAV relays equipped with optical wireless communication devices for cellular networks to determine the location of UAVs using visible map algorithms and the shortest path method to ensure direct vision communication
2023	Lee	A deep learning-based UAV relay–optimization algorithm was proposed to maximize the throughput when using UAVs as relays between satellites and the ground

In 2018, Xu et al. [47] studied UAV relay optical wireless communication under an amplify-and-forward protocol to maximize the end-to-end throughput of a UAV relay system by power allocation, as well as UAV trajectory. An iterative algorithm was proposed for optimizing the power allocation and UAV trajectory at the source and relay nodes. The results of the study showed that the method could significantly improve the system throughput.

In 2019, Yuan [48] studied the channel characteristics of a two-hop optical communication system with a UAV relay and a multi-hop hybrid RF/optical communication system and derived the probability density functions of the alignment errors from the ground end to UAV and UAV to UAV during the communication process. Because of the maneuverability of UAVs, their coverage and path loss were considered, from which the optimal flight altitude of UAVs with a minimum disruption probability and the effects of different alignment error coefficients on the system performance were derived.

In 2019, Yang et al. [49] studied a multi-hop hybrid RF/FSO communication system, where two UAVs were selected as relays. The outage probability of the system and the optimal UAV altitude were derived by considering the pointing error and path loss. The results showed that the UAV flight altitude had a significant impact on the system performance.

In 2019, Gu [50] studied link load balancing and minimum network delays for UAV-relayed free-space optical communication. The network topology was modeled considering power, link reliability, and link capacity, so that the network capacity could be maximized with a minimum number of UAVs. By jointly optimizing the location and resource allocation of UAV relays, the network latency was effectively reduced.

In 2020, Lei et al. [51] investigated a nonorthogonal multiple access communication system based on UAV hybrid RF/FSO, where the data to be transmitted were converted into an optical signal at the transmitter side after modulation and sent to the UAV. The received data were decoded at the UAV relay and the signal was sent to the user, thereby deriving a closed expression for the interruption probability. The results showed that the UAV flight altitude and alignment error, as well as atmospheric turbulence, affected the system performance.

In 2020, Hu [52] studied the influence of external environmental constraints on the performance of UAV relay optical wireless communication and analyzed the influence of the atmospheric channel and transmitter side on the beam transmission. They detected the UAV transmission link length, stability, channel quality, and other indicators, as well as adjusting in real time the transmitting optical power and beam dispersion angle by designing each UAV module. The results showed that the method could improve the link security and reduce the bit-error rate of the UAV downlink and reduce the optical detector saturation and data transmission interruptions.

In 2020, Ma et al. [53] studied a free-space optical serial multi-hop decode-and-forward relay system based on hovering UAVs. They derived the interruption probability expressions for each link from the ground to UAV, UAV to UAV, and UAV to ground, considering the effects of atmospheric attenuation, atmospheric

loss, pointing error, and arrival angle undulation, focusing on optimizing the effect of arrival angle undulation on the field of view of the UAV receiver. The results showed that the derived expressions could accurately assess the system interruption performance and significantly improve the field-of-view performance.

In 2021, Lu et al. [54] investigated the secrecy performance of UAV-assisted FSO communication systems by modeling the channel, considering the effects of path loss, atmospheric turbulence, pointing error, and reach-angle fluctuations. They derived theoretical expressions for the secrecy interruption probability that could be easily handled.

In 2021, Liang [55] studied automatic beam tracking in UAV optical communications. The performance states of different servo motors in the APT system were compared, and a four-quadrant detector offset calculation method under different energy distribution models and the centering algorithm of the through-hole four-quadrant detector were investigated to capture, align, and track the beam signal using the principle of spot detection. A lightweight and rapidly deployable APT system was designed, using a stepper motor, reflector, and four-quadrant detector instruments, which solved the problem of the limited load of a UAV relay for optical wireless communication systems.

In 2022, Xu [21] studied an optical wireless communication system using an unmanned aircraft as a relay. Atmospheric turbulence, aiming error, angle-of-arrival undulation, and receiver-side noise were analyzed, including the performance of the optical wireless communication system under different noise and turbulence intensities; moreover, expressions for the average bit error rate under atmospheric turbulence and noise were given. The interruption performance of the two-hop relay system was then investigated, and performance metrics for the interruption system were derived. The signal-to-noise ratio of the ground-to-UAV link was derived by considering the fading loss when studying the effect of the link between the ground and the UAV.

In 2022, Xu et al. [56] studied UAV relay communication based on a hybrid optoelectronic architecture, using free-space optical technology between the base station and the UAV relay and RF communication technology between the UAV and the user. This meant that the user information collected by the RF link was forwarded to the base station through an optical wireless communication link. An expression for the interruption probability at a high signal-to-noise ratio was derived, considering the effects of the pointing error and atmospheric turbulence. It was concluded that the beamforming scheme could improve the system diversity and enhance the system performance.

In 2022, Ma [57] studied an optical wireless communication system based on a UAV relay, considering the joint effects of atmospheric turbulence, pointing error, angle-of-arrival jitter, etc. On this basis, the interruption performance of a serial multi-hop relay system was analyzed, and the UAV hovering position, link-reception beamwidth, and field-of-view angle were optimized in turn. UAV relay heterogeneous energy efficiency optimization was also studied, and an iterative algorithm was used to obtain the UAV operation trajectory. The results showed that this type of

algorithm could avoid relay-cache overflow and optimize the energy efficiency of the system.

In 2022, Long [58] studied the physical layer security system for a UAV-relayed optical wireless communication system in amplify-and-forward mode. The wireless channel was modeled under direct and nondirect vision conditions, and the outage security probability and security capacity were derived, considering the distance between the UAV relay and the ground, as well as the path loss. Moreover, a new energy harvesting technique was designed to recollect the direct current component that should be filtered out during optical wireless communication, which improved the energy utilization of the system and effectively enhanced the range of the UAV.

In 2022, Ma [59] studied the use of UAVs as relays between satellites and the ground for resource scheduling and constructed a communication model between UAVs and satellites, based on optical wireless communication under the proportional fairness scheduling algorithm. It selected users with better channel conditions for data transmission at each resource scheduling, which significantly improved the throughput of the system. The communication model between the UAV and users based on RF communication was constructed in decode-and-forward mode, and the signal-to-noise ratios of RF communication and optical wireless communication were derived. The research results showed that the method could significantly improve the fairness of resource allocation for users.

In 2022, Han et al. [60] studied air–ground UAV oblique-range laser communication under the influence of atmospheric turbulence, using a multiple-input single-output technique in the uplink and a single-input multiple-output technique in the downlink. They derived BER expressions for the uplink and downlink and investigated the influence of the zenith angle and pointing error on the system. The results showed that the multiple-input single-output and single-input multiple-output techniques both reduced the power and improved the effect of atmospheric turbulence on the system as well as the communication quality. The light-intensity flicker index varied with the zenith angle and should be controlled within 30 degrees. When the ratio of the pointing error to receiver aperture varied, the BER also varied with the beam dispersion angle; consequently, there exists an optimal beam dispersion angle to optimize the BER performance.

In 2023, Li et al. [61] studied the dynamic switching of optical wireless communication and RF communication based on rate matching. They used a satellite as the source node, a high-altitude platform as a relay, and a UAV as the destination node, using optical wireless communication between the satellite and high-altitude platform. The Radar and Algorithm Display System (RADS) was used for dynamic selection between the high-altitude platform and the UAV, which gave preference to optical wireless communication; when the link's instantaneous signal-to-noise ratio was lower than the threshold value, the RF communication was switched. The research results showed that the algorithm reduced the interruption probability and improved the transmission rate.

Domestic development on designing and optimizing UAV relay optical communication systems has been rapid, mainly from optimizing UAV navigation paths,

improving signal processing algorithms and data transmission protocols, and investigating the hardware equipment needed for UAV relays, such as communication modules, control systems, etc. Then, we considered the factors that affected the channel model when UAV relay optical communication was transmitted in the atmosphere, such as atmospheric turbulence, atmospheric attenuation, pointing error, etc., to optimize the system performance (Table 49.3).

The comprehensive domestic and foreign research status indicated that research on optical wireless communication in UAV relays mainly focused on the following aspects:

1. Research on channel influence factors, such as atmospheric turbulence, fading loss, etc.
2. Research on the rapid establishment of data links, such as rapid beam alignment, etc.
3. Optimization of communication equipment, such as structure design, optical path design, etc.
4. Research on transmission technology, such as relay forwarding methods, modulation and demodulation types, etc.

Research on optical wireless communication in UAV relay systems has made some progress in theory and application; however, there are limitations and shortcomings, and they should be studied in depth.

Key Technologies for UAV Relay Optical Communication

UAV relay optical wireless communication is a relay transmission technology based on UAVs carrying optical wireless communication equipment, such as lasers, to communicate with ground targets. It has the advantages of a high transmission rate, long distance, and anti-interference. To build a stable and efficient system, the following key technologies are focused on.

Channel-Influencing Factors and Their Suppression Techniques

Channel Model

Both UAV optical communication systems and RF systems cannot be kept completely open in arbitrary weather conditions or complex environments. The FSO/RF channel has the advantages of both optical and RF communication and can improve link utilization. Therefore, FSO/RF hybrid transmission technology is still a current research hotspot, and the FSO/RF channel is introduced here.

Because of the high transmission rate of optical wireless communication, it is used between the source node and the relay UAV. RF communication is used

Table 49.3 Domestic research results

Year	Researcher	Research results
2017	An	Designed an optical wireless communication system suitable for small UAVs to achieve high-speed long-distance data transmissions to users
2018	Xu	Designed UAV-airborne laser communication equipment, with the advantages of small size, low power consumption, high scanning and capturing tracking efficiency, short communication-link establishment time, stable data transmissions, etc.
2019	Yuan	Used the channel characteristics of double-hop and multi-hop UAV relay optical communications to obtain the optimal flight altitude for UAVs with a minimum outage probability
2019	Yang	Selected two UAVs as relays to obtain the optimal height of the UAV
2019	Gu	Modeled the network topology to obtain the maximum network capacity with the minimum number of drones
2020	Hu	Adjusted the UAV modules, as well as the emitted optical power and emitted beam dispersion angle, to improve the link security and reduce the optical detector saturation
2020	Ma	Optimized the effect of angle-of-arrival undulation on the UAV receiving field-of-view angle, significantly improving the field-of-view performance
2021	Liang	A lightweight and rapidly deployable APT system was designed to solve the problem of limited UAV loads and an automatic tracking algorithm was designed.
2022	Lu	An expression was derived for the secrecy outage probability that could accurately evaluate the physical layer secrecy performance of the system.
2022	Xu	Considering the effect of noise at the receiver side, an expression for the average BER was derived for different noises and turbulence intensities.
2022	Xu	A new beamforming scheme was derived to improve the diversity of the system by studying the UAV relay communication with a hybrid optoelectronic architecture.
2022	Ma	Considering the optimization of UAV relay heterogeneous energy efficiency, an iterative algorithm was used to optimize the system energy.
2022	Long	New energy-harvesting technology was proposed to improve the energy utilization of the system by collecting the DC component that should be filtered out in optical wireless communication through an energy-harvesting device.
2022	Ma	UAVs were used as relays between satellites and the ground for resource scheduling, optical wireless communication was used between UAVs and satellites, and RF communication was used between UAVs and users to improve the fairness of user-resource allocation.
2023	Tang	Multi-input single-output and single-input multi-output technologies for uplink and downlink, respectively, improved the quality of optical wireless communication.
2023	Li	A high-altitude platform was used as a relay between the satellite and the ground, and the RADS algorithm was used to dynamically select the communication link.

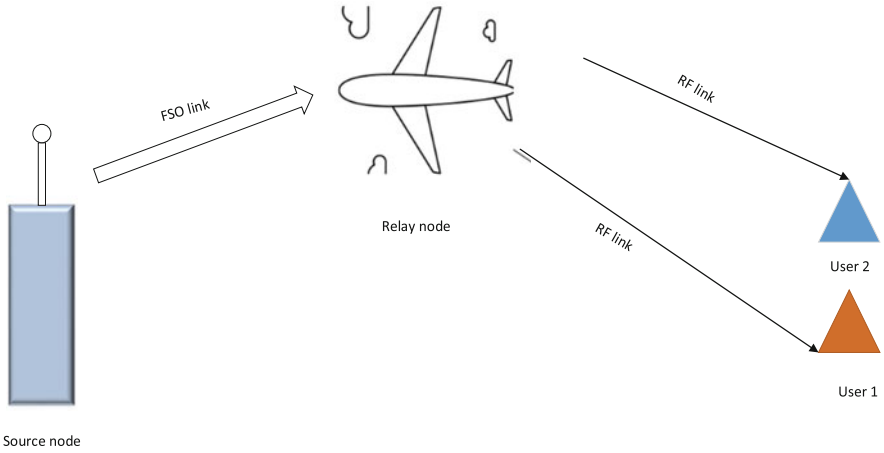

Fig. 49.8 Model of an RF/FSO communication system based on a UAV relay [51]

between the relay UAV and the destination node because of the uncertainty of the user's location and building occlusion [51]. A model of an FSO/RF system based on a UAV relay is shown in Fig. 49.8; it consists of source and relay nodes and users 1 and 2. Optical wireless communication is used between the source node and the relay UAV, and RF communication is used between the relay UAV and the user.

Optical Wireless Communication Link

Suppose users 1 and 2 have a small packet transmission communication service. When the information is sent from the source to the relay drone, the electrical signal can be expressed as $(\alpha_1 s_1 + \alpha_2 s_2)$. s_1 and s_2 denote the packets delivered to the user, α_1 and α_2 are their respective distribution coefficients, and $\alpha_1 + \alpha_2 = 1$. Then, after modulation, the signal is sent to the drone relay, where the direct current signal is removed. After demodulation, the relay can be expressed as

$$y_1 = I\sqrt{p_1}\xi\eta(\alpha_1 s_1 + \alpha_2 s_2) + n_1 \tag{49.7}$$

where $I = h_a h_p$ denotes the optical wireless communication channel coefficient [21], h_a denotes the atmospheric turbulence coefficient, and h_p denotes the pointing error. p_1 denotes the transmit power at the source node, n_1 denotes Gaussian white noise, ξ denotes the conversion efficiency from optical to electrical signals, and η denotes the photoelectric conversion coefficient, whose value is between 0 and 1.

The signal-to-noise ratio of user 1 is

$$\gamma_1 = \frac{p_1(I\xi\eta\alpha_1)^2}{p_1(I\xi\eta\alpha_2)^2 + N_0} \tag{49.8}$$

The signal-to-noise ratio of user 2 is

$$\gamma_2 = \frac{p_1 (I\xi\eta\alpha_2)^2}{N_0} \tag{49.9}$$

RF Communication Link

As can be seen from Eq. 49.7, the signal sent by the UAV relay is y_1. This signal will be sent out as an RF signal by decoding and forwarding; and then the signals received by the users are

$$\gamma_1 = \sqrt{\tau_1}\sqrt{p_2}h_1(\alpha_1 s_1 + \alpha_2 s_2) + n_1 \tag{49.10}$$

$$\gamma_2 = \sqrt{\tau_2}\sqrt{p_2}h_2(\alpha_1 s_1 + \alpha_2 s_2) + n_2 \tag{49.11}$$

where h_1 denotes the channel gain of the RF link between user 1 and the relay, h_2 denotes the channel gain of the RF link between user 2 and the relay, and $h_1 h_2$ follows the Rice distribution. p_2 denotes the transmit power of the relay UAV, n_1 and n_2 denote the Gaussian white noise in the user channel, and τ denotes the path loss attenuation factor.

The signal-to-noise ratios at the user side are the following:

$$\gamma_3 = \frac{\tau_1 p_2 (h_1\alpha_2)^2}{\tau_2 p_2 (h_1\alpha_2)^2 + N_0} \tag{49.12}$$

$$\gamma_4 = \frac{\tau_2 p_2 (h_2\alpha_2)^2}{\tau_2 p_2 (h_2\alpha_1)^2 + N_0} \tag{49.13}$$

where N_0 denotes the power spectral density, γ_3 denotes the signal-to-noise ratio of user 1, and γ_4 denotes the signal-to-noise ratio of user 2.

Channel Characteristics

When a drone is used as a relay for optical communication, the free-space optical signal in the system is affected by atmospheric refraction, absorption, and scattering, degrading the system performance [18]. Several factors affecting the communication system and their suppression methods are described below.

Path Loss

The path loss refers to the decrease in signal strength during signal propagation. It is mainly due to the effects of scattering, reflection, and refraction when the signal is propagating in air, resulting in a gradual weakening of the signal energy. Under the free-space model, the path loss of the signal is [62]

$$L_P = 20\log\left(\frac{4\pi d}{\lambda_c}\right)^2 = 20\log\left(\frac{4\pi d f_c}{c}\right)^2 \tag{49.14}$$

where d denotes the distance between the source and destination nodes, λ_c denotes the wavelength of the transmitted signal, f_c denotes the signal frequency, and c denotes the speed of light. From the above equation, we can see that the energy loss of the signal is proportional to the signal frequency and transmission distance; an excessively high signal frequency or excessively far transmission distance will lead to excessive signal energy loss. UAVs fly at lower altitudes and have smaller energy loss and lower time delays than high-orbiting satellite communication systems.

Doppler Effect

The Doppler effect is caused by the motion of the transmitting and receiving ends. Because there is relative motion between the two when the UAV and ground terminal communicate, it causes the phase and frequency of the received signal to be out of phase with the expected path. The Doppler effect can be expressed as [62]

$$f = \frac{v_c}{\lambda}\cos\beta(t) = f_c\frac{v(t)}{c}\beta(t) \tag{49.15}$$

where f denotes the Doppler shift, $v(t)$ denotes the velocity of the moving object, $\beta(t)$ denotes the angle between the UAV and the direction of ground motion, and f_c is the frequency of the transmitted signal.

Multipath Effect

Owing to the complex wireless propagation environment, the signal in the transmission process often follows more than one transmission path, so the receiver receives the signal at different times. The phases of these signals will also superimpose each other to form interference, resulting in signal distortion. Multipath propagation also causes time delay expansion, so that the signal pulse width of the received signal will appear to broaden, resulting in intersymbol interference.

Atmospheric Turbulence

Atmospheric turbulence may cause the laser pulse signal to spread in time and space and reduce the received optical power. This leads to a reduction of the average signal-to-noise ratio of the communication system and an increase of the communication bit error rate and the number of transient communication interruptions, which have a great impact on the stability and reliability of the communication [63].

Aiming Error

The aiming error is mainly caused by phenomena, such as the photodetector offset and building shaking [62], which mainly include the position offset error and angular tilt error. The aiming error causes the axis between the optical signal transmission and receiving ends to deviate, which reduces the received optical power and limits

the performance of the optical wireless communication system. Therefore, the effect of the aiming error should be considered in a long-range optical wireless signal transmission with UAVs as relays.

When a Gaussian beam is emitted from the transmitter, the aiming error coefficient for the receiver incidence angle is [64]

$$h_{p|\theta_d} = \int_{\pi r^2} I(r - r_1, z)\cos(\theta_d)dr \tag{49.16}$$

where $I(r, z)$ denotes the normalized light intensity distribution, z denotes the transmission distance, and θ_d denotes the incidence angle of the UAV receiver.

Arrival Angle Undulation

The angle-of-arrival undulation is due to the nonstop change in the orientation of the UAV while hovering, the instability of the signal power received by the target node, the jitter in the focusing plane, etc., which leads to a serious decrease in the reliability of the optical wireless communication system.

Assuming that the angle of incidence at the UAV receiver with a smaller viewing angle is θ_d, the θ_d approximation follows the Rayleigh distribution with a probability density function of [65]

$$f_{\theta_d}(\theta_d) = \frac{\theta_d}{\sigma_0^2}\exp\left(-\frac{\theta_d}{2\sigma_0^2}\right) \tag{49.17}$$

where σ_0^2 denotes the link variance.

Table 49.4 summarizes the causes of the abovementioned UAV relay optical wireless communication channel impact factors, their effects on the system, and the suppression techniques.

High-Precision Capture, Alignment, and Tracking Technology

Through analyzing the UAV relay channel model, it is clear that to build a stable and reliable system for effective information transmission between the ground and UAV, the accuracy of the capture, alignment, and tracking technology must be high. Moreover, owing to their small size and lightweight, UAVs are more influenced by airflow, which will affect the flight attitude; hence, fast and accurate beam alignment is the core of UAV airborne laser communication.

To effectively transmit large amounts of information and efficiently reconstruct the wireless laser communication system for stable acquisition, pointing, and tracking (APT), the APT system is critical. APT is divided into three main stages [55].

1. Capture. To connect the UAV to the optical communication link at the ground end, when the optical receiver has not yet captured the beacon light, the loop is

Table 49.4 Channel-influencing factors and their suppression techniques

Influencing factors	Causes	Causes' impact	Suppression technology
Path loss	The signal is scattered, reflected, and refracted when propagating in air.	Gradual weakening of signal energy	Increase transmitting power and optimize antenna design
Doppler effect	Relative motion exists when the UAV and ground terminal are communicating.	Affects the phase and frequency of the received signal	Signal preprocessing, adaptive filtering, or optical path compensation
Multipath effect	The signal has multiple transmission paths in the transmission process, causing the receiving end to receive the signal at different times. The phases superimposed on each other form interference.	Causes signal distortion, time-delay expansion, and pulse spreading	Diversity reception or channel equalization
Atmospheric turbulence	Random changes in the atmospheric temperature and humidity cause changes in the refractive index.	The pulse spreads, received optical power decreases, average signal-to-noise ratio decreases, and communication BER increases	Adaptive optic technology compensates for signal wavefront distortion. Increase optical antenna aperture to suppress optical signal flicker.
Aiming error	This is caused by phenomena, such as photodetector deflection and building shaking.	Reduced received optical power	Build more accurate target models, higher-precision optical sensors, and attitude control systems.
Arrival-angle undulation	This is caused by constant changes in the drone orientation while hovering, instability of the signal power received by the target node, geometric link loss, and jitter in the focus plane.	Reduced reliability of optical wireless communication system	Adaptive modulation technology and adaptive optical path compensation

opened to scan the entire uncertain area information. The scanning stops once the signal light has been detected in the field of view, to complete the capture and lay the foundation for subsequent alignment and tracking [19].

2. Alignment. The UAV optical receiver is aligned with the laser transmitter at the ground end to ensure that the transmitting, as well as tracking related, view axes have high-precision coaxiality. In the process of realizing long-range laser communication, the transmitting end must be overaligned when high-speed relative motion occurs between the transmitting and receiving sides [3].

3. Tracking. The optical signals are tracked and adjusted in real time in the laser-communication link between the UAV and the ground after the alignment is completed. Real-time tracking technology can circumvent the vibration residuals of the platform and the dynamic lag error caused by the relative motion between the two communicating parties [19].

The UAV relay laser communication terminal is divided into the APT system, laser transmitter, and laser receiver, in terms of system function. The working principle of the APT system [67] is shown in Fig. 49.9. The coarse tracking servo ring is composed of a charge-coupled device (CCD), coarse tracking servo controller, and coarse tracking turntable, which completes the initial pointing of the view axis, open-loop capture, and dynamic coarse tracking.

The larger the tracking field of view of the coarse-tracking ring, the smaller the capture time will be; however, with the increase of the tracking field of view, the spatial resolution of the CCD decreases, affecting the final tracking accuracy and bandwidth of the tracking system. Thus, the tracking and field-of-view accuracy must be optimized.

The fine-tracking servo ring is composed of two-dimensional piezoelectric transducer (PZT) mirrors, high bandwidth spot measurement unit, servo control unit, etc. It has the advantages of a small field of view, high servo bandwidth, and high tracking accuracy and can effectively control the dynamic hysteresis bias and platform residuals, so that the accuracy of the APT system meets the standard communication requirements.

To meet the high accuracy laser link alignment and fast automatic establishment of the communication link in UAV relay optical communication, bidirectional data transmissions are realized at the ground and UAV ends [67].

First, the inertial navigation system is used to accurately measure the current information of the carrier to achieve automatic initial pointing. Then, the scanning and capturing technology is used to guide the signal into the tracking phase with the fiducial light and position detector to drive the gyro-servo turntable to guide the laser into the detector-position field of view. Then, the laser-communication link is established. The gyro-servo turntable can reduce the high-frequency vibration of the UAV carrier due to flight, enabling the system to automatically track in the field of view. Figure 49.10 shows the workflow of the APT system in a UAV relay laser communication transmission.

Modulation and Demodulation Techniques

The intensity modulation method is commonly used in UAV relay optical wireless communication. Intensity modulation transmits information by changing the output power of the laser light source. Intensity modulation can be divided into baseband signal intensity modulation and subcarrier intensity modulation.

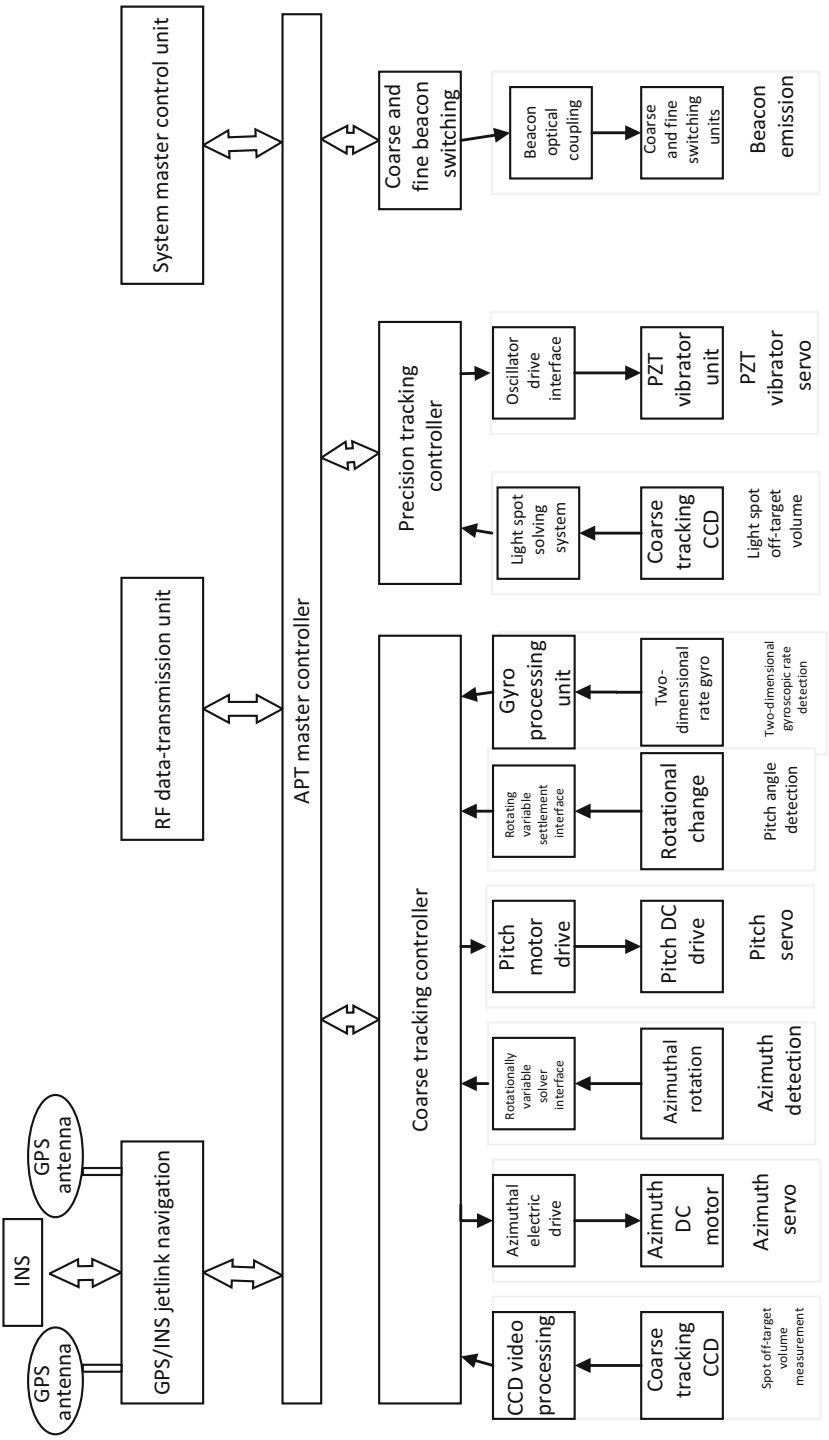

Fig. 49.9 Diagram of the composition of the APT system for laser communication [66]

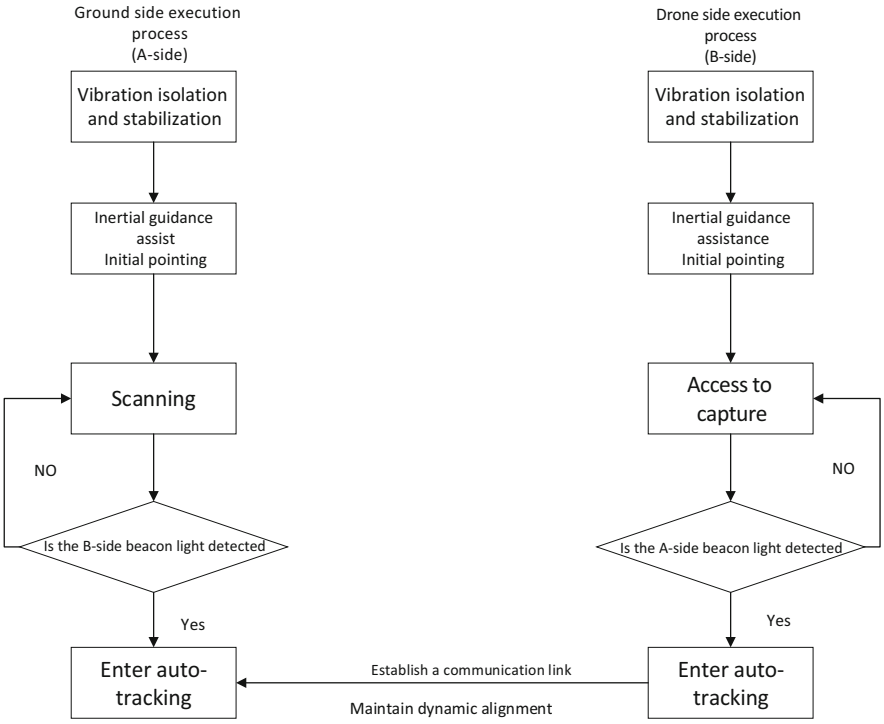

Fig. 49.10 APT system workflow [67]

The most commonly used method in baseband signal intensity modulation is switch keying, which sends light pulses of a given duration when the information bit is 1 and does not send light pulses when the information bit is 0 [48]. The subcarrier intensity modulation technique is also widely used in UAV relay optical wireless communication. It mainly includes phase-shift keying, differential phase-shift keying, and orthogonal phase-shift keying [21].

In terms of signal demodulation, the system needs to demodulate the received signal to extract the valid information. The two demodulation methods commonly used in optical communication are coherent detection and direct detection.

Figure 49.11 shows the block diagram of a coherent detection system. The photodetector accepts the received signal, together with the coherent carrier wave generated by the local oscillator, amplifies and processes it, and finally converts it to the required information signal. Coherent detection has high sensitivity and good noise immunity [47]. Direct detection, on the other hand, directly detects the envelope and converts the intensity-modulated optical signals to electrical signals, which are then amplified [21]. The direct detection technique has the advantages of simplicity and low cost.

Different modulation and demodulation methods have their own advantages and disadvantages, as shown in Table 49.5.

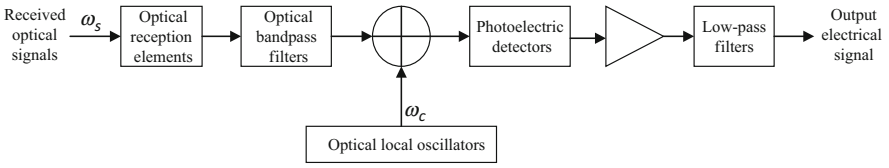

Fig. 49.11 Block diagram of the coherent detection communication system [47]

Table 49.5 Comparison of advantages and disadvantages of modulation and demodulation methods

Method		Advantages	Disadvantages
Modulation	Switch keying	High bandwidth utilization and simple implementation	Poor noise immunity and limited modulation-frequency range
	Subcarrier intensity modulation	Modulated signals have a wide frequency range, allowing transmissions at higher data rates	Requires complex modulation and demodulation circuitry
Demodulation	Correlation testing	Strong anti-interference ability, can achieve higher-precision demodulation	Requires the use of complex circuits and algorithms, with high requirements for signal phase and frequency
	Direct detection	Simple structure, easy to integrate, can increase the transmission rate to complete high-capacity transmissions	Poor anti-jamming capability, low band utilization, and reception sensitivity

Lightweight and Miniaturization Design Technology

While ensuring the speed and stability of the UAV, minimizing its load volume and weight is a key technology in the field of UAV relay optical wireless communication. The smaller the load weight of the UAV, the more flexible and convenient it will be when flying, enabling it to carry more weight. Lightweight miniaturized UAVs can be designed from the following aspects:

1. Use integrated features: By optimizing the selection and layout of components, such as lasers, mirrors, and optical fibers, we can reduce the size of the entire optical-transmission system and integrate the communication equipment with other sensors and navigation systems, thus reducing the number and weight of devices [68].
2. Adopt low-power electronic components: We select low-power electronic components, including power amplifiers, optical receivers, and control circuits, to reduce the energy consumption and required power capacity of the equipment.
3. Adopt efficient optical technology: By adopting efficient optical technology, such as adaptive optics and multi-beam technology, the optical communication

performance can be improved, while reducing the weight and power consumption of the optical communication equipment.

The abovementioned aspects can be used to create lightweight and miniaturized equipment and improve the adaptability and comprehensive performance of UAV relays.

Non-Co-axial Aircraft-Relay Technology

Non-co-axial communication refers to a optical wireless communication process in which the transmitter and receiver cannot be directly aligned. Hence, the antennas of the signal transmitter and receiver must be adjusted so that the transmitter and receiver can be aligned to complete the communication process.

Figure 49.12 shows a schematic diagram of non-co-axial communication [70], in which two-dimensional reflector alignment is used. In the coarse-alignment calibration system from the transmitting antenna to the two-dimensional reflectors, a calibration camera is used to position the calibration, and the transmitting antenna is adjusted according to the feedback image. In a two-dimensional reflectors-to-receiver antenna short-axis fine-alignment system, the two-dimensional reflectors are adjusted according to the feedback from detector 2 for non-co-axial communication.

Non-co-axial laser communication can be well implemented using reflectors, as shown in Fig. 49.13, for the application of non-co-axial communication in UAV relays. A two-dimensional motor turntable and other optical-receiving devices are mounted on the UAV to capture, align, and track the laser signal from the ground

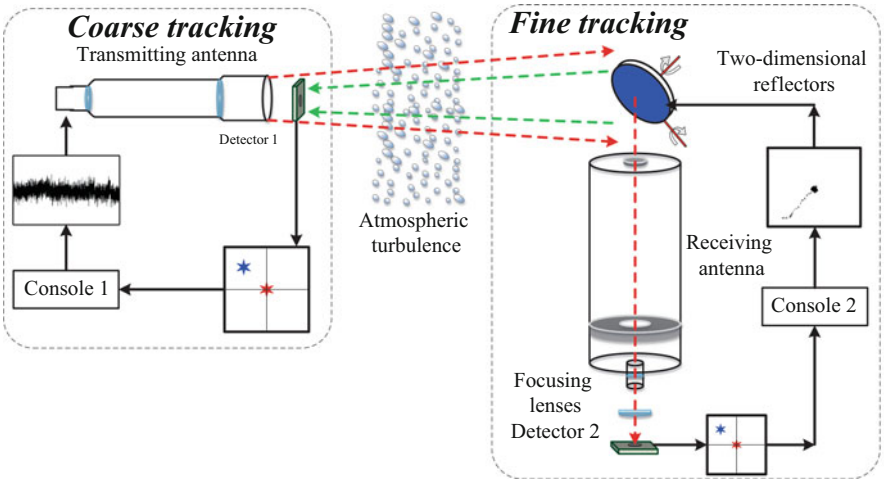

Fig. 49.12 Principle of non-co-axial communication [70]

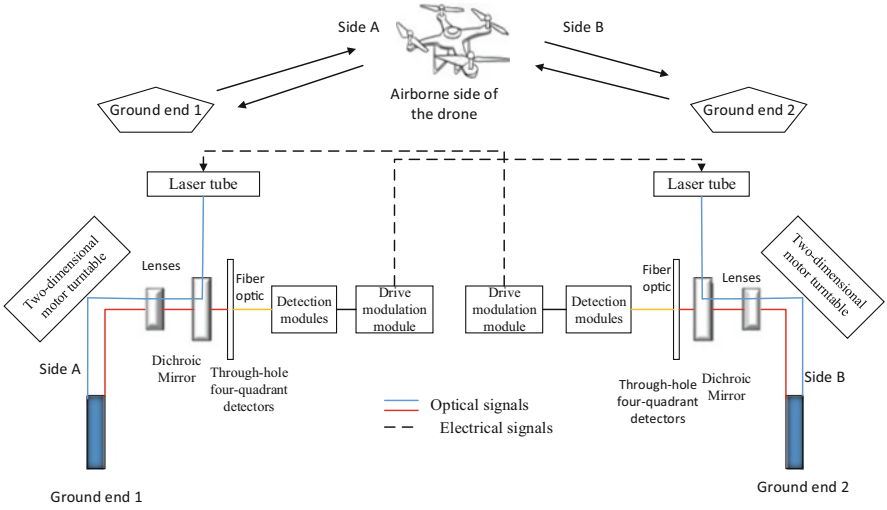

Fig. 49.13 Schematic diagram of a transceiver-integrated UAV relay APT system [54]

end, allowing two ground terminals to form a communication link through the UAV relay communication system [54].

The transmitting end (ground end 1) emits a laser beam signal to the A end of the UAV. It is reflected by the reflector in the two-dimensional motor turntable carried by the relay UAV and then coupled through the lens and the four-quadrant through-hole detector. Then, it enters the optical fiber and is reemitted through the detection module, drive modulation module, and laser tube. Among them, optical fiber is a fiber made of glass and plastic, which acts as a conduction tool for light. Finally, the laser signal is transmitted back to ground end 2 through the dichroic mirror, lens, and two-dimensional motor turntable with the reflector, that is, from the B end to ground end 2. When ground end 1 is the transmitting end, ground end 2 is the receiving end and vice versa.

This method solves the problem of time-consuming beam alignment in conventional optical wireless communication. The method facilitates the establishment of communication links in non-co-axial free space and can help rapidly align laser beams in optical wireless communication using aircraft relays.

Application of Optical Wireless Communication to UAV Relaying

1. Intelligent transportation applications [71]: The UAV relay is used in telematic systems. In recent years, vehicular networking has developed rapidly, which enabled vehicle-to-vehicle, vehicle-to-pedestrian, vehicle-to-infrastructure, and vehicle-to-base station communications. While traffic congestion and obstacles can interfere with the communication links between vehicles and reduce the throughput, using UAVs as relays to assist communication can effectively reduce the problems of network communication, content caching, and security privacy in telematic systems.

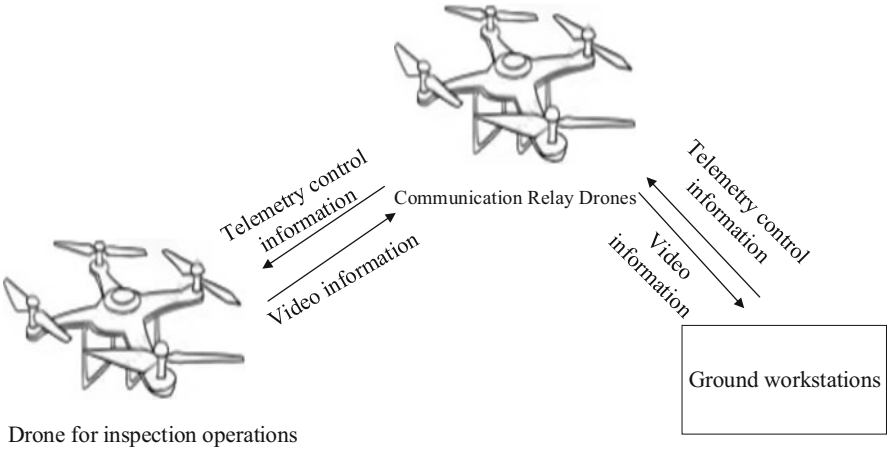

Fig. 49.14 Principle diagram of UAV relay power inspection [73]

2. Environmental-monitoring applications [72]: In response to the forest fires in Australia, domestic scholars built a fire monitoring model based on the interplay of a system safety assessment (SSA) UAV, relay UAV, and emergency operations center. Among them, the SSA UAV cruises to monitor the fire, the relay UAV transmits the data, and the emergency operations center directs firefighters to extinguish the fire. The artificial fish swarm algorithm (AFSA) is used to make specific deployments to the specific location of the emergency operations center, which can minimize economic costs.
3. Electrical power applications [73]: The UAV relay is applied to electric power inspection, and a relay communication system is used to transmit stable signals over long distances. Two small multi-rotor UAVs are selected, one of which carries an infrared HD camera, data transmission, image sending, and other equipment, and the other carries communication-relay equipment.

The overall system setup should consider the aerodynamic shape of the vehicle setup, the communication signal, and the setup of the inspection system. Figure 49.14 shows the schematic diagram of a UAV relay power inspection. The UAV relay achieves over-the-horizon wide-range flight, which expands the communication system coverage and promotes the development of UAV relays in the power industry.

Summary

UAV relays can not only provide long-distance communication but also act as collectors for sending and receiving information. Optical wireless communication has a high transmission rate and good confidentiality and can solve the problem of RF communication congestion. Therefore, combining RF and optical wireless

communication can take advantage of the high mobility of UAVs and improve the stability of existing mobile communication networks.

This chapter introduced the optical wireless communication and UAV relay systems. The research status of UAV relays in optical wireless communication was presented, and the relay-related technologies of UAV relay optical communication systems were introduced. In addition, a brief overview was given of the key technologies of UAV relays in optical wireless communication, such as channel characteristic compensation, APT, modulation and demodulation, lightweight and miniaturized design, etc. Finally, the applications of UAV relays in optical wireless communication are introduced. The future development trends will be mainly in the following areas:

1. UAV relay communication systems will develop in the RF/FSO heterogeneous direction: RF communication is susceptible to interference and cannot communicate efficiently but has a strong ability to penetrate clouds and fog; while free-space optical communication has a strong anti-interference ability, it is easily affected by the atmosphere. Therefore, to maximize the advantages of the different spectrum communication systems, constructing RF/FSO heterogeneous systems for UAV relay communication provides efficient data connections and improves the spectrum utilization and data transmission rate to achieve more efficient, safe, and reliable communication services [74].
2. UAV relay optical communication systems will develop in the direction of artificial intelligence and automation: Nowadays, machine learning and artificial intelligence are developing rapidly. When machine learning is applied to UAV relay optical communication systems [74], it can help to quickly establish communication links, improve the data transmission rate and anti-interference capability, and also enable UAVs to independently select the best relay path. Hence, combining UAV relay optical communication with machine learning and artificial intelligence is a hot spot for future development.
3. The energy consumption of UAV relay optical communication will develop in the direction of energy-saving and green technology: UAV relays can collect energy through solar panels, fuel cells, and other energy collection technologies to ensure their long operation. For example, lithium-polymer batteries are light in weight and have low voltage when the battery is discharged and no memory effect. Lithium-iron-phosphate battery packs are lighter in weight and safer to use and have a greater operating temperature range, allowing ultrasmall and micro-UAVs to have better flight times and payload quality than lithium-polymer batteries.

   Modern composite materials, using glass and carbon fibers and reinforced epoxy resins, have good potential for extending flight time, reducing the weight of UAVs, and increasing their service life. Moreover, UAV relays can be used to ensure the normal equipment operation by distributing the collected energy to optical wireless communication devices and other sensor devices.
4. The relay synergy mechanism of UAV relay optical communication will develop in a more efficient direction: An efficient synergy mechanism should be established between a UAV relay and ground optical communication equipment

to ensure the communication quality and service reliability. The UAV relay optical wireless communication can work in concert with other communication systems, such as satellite and mobile communication, to form a complete communication system. To further improve communication reliability and coverage, future research will enhance the exploration and study of such synergistic mechanisms to improve the performance and efficiency of the entire system

In summary, UAV relay optical wireless communication is an important trend in the future development of communication technology and has broad application prospects in the Internet of Things, intelligent manufacturing, and smart cities.

industrial manufacturing. This chapter firstly introduces the relevant applications of optical wireless communication under the background of industrial Internet; summarizes the research status at home and abroad in recent years; summarizes the typical research progress; expounds the channel model and key technologies of optical wireless communication system; and introduces the RF/visible light heterogeneous technology used to ensure the reliable transmission of the uplink and downlink of the communication system. Finally, the chapter summarizes the current problems faced by optical wireless communication in the industrial Internet, and looks forward to the future development trend, which can provide certain reference and reference for the future research and development of optical wireless in this field.

Industrial Internet · Optical wireless communication · Visible light communication · Data transmission · Visible light positioning

Introduction

Optical wireless communication uses light as a carrier to transmit information in free space. It has the advantages of rich spectrum resources, strong security, anti-electromagnetic interference, free spectrum authorization, and can easily monitor the rapid access of intelligent devices to Internet platforms.

Since the twenty-first century, with the continuous innovation in industrial production and industrial communication services, the industrial Internet has been gradually developing toward information and networks [1]. Traditional wired communication has high deployment costs and low transmission rates. The industry has proposed introducing a range of wireless-communication technologies into factories for data transmission, such as radio frequency identification (RFID), wireless LAN, and wireless sensor devices. However, these technologies face the problems of signal fading and multipath interference [2].

Optical wireless communication has been widely studied as an important supplement to radio frequency (RF) technology. Optical wireless communication under the industrial Internet is a subject worthy of further study and has practical significance.

This chapter introduces the application of optical wireless communication to the industrial Internet and summarizes and discusses the key technologies and research progress at home and abroad. Finally, the challenges of optical wireless communication in the industrial Internet are analyzed, and its future is examined.

Optical Wireless Communication and the Industrial Internet

In recent years, the industrial Internet has become an important support for China's development of a manufacturing power 2025 strategy. To enhance the safe and reliable interconnection between production factors and reduce costs, there is an

urgent need to replace traditional wired communication with wireless communication. Today's common RF wireless communication is vulnerable to electromagnetic interference from factory equipment and its spectrum is limited.

Visible light communication (VLC) combines lighting and communication through a high-density layout of light-emitting diodes (LEDs) to achieve a wide communication coverage range of factory equipment; not only can it transmit data to equipment and support indoor equipment positioning, but its spectrum resources are rich, more than 10,000 times [3] the existing RF spectrum. Hence, it can become a strong supplement to today's wireless communication technology. VLC and RF communication features are compared, as shown in Table 50.1.

VLC is an optical wireless communication technology [4] that transmits information in free space using 380–780 nm light waves as information carriers. A block diagram of the VLC system is shown in Fig. 50.1. It is mainly composed of three parts: a transmission module, wireless channel, and receiving module.

The transmission module is responsible for encoding and modulating the data to be transmitted to the corresponding electrical signal. The electrical signal passes through the LED drive circuit and becomes an optical signal. The LED transmits a flashing signal, which the human eye cannot recognize, to the receiving end [5] through a wireless channel. The receiving end primarily uses a photodetector or

Table 50.1 Comparison of VLC and RF communication characteristics [3]

Characteristic	VLC	RF
Bandwidth	428 THz–750 THz	300 MHz–10 GHz
Electromagnetic radiation	No	Yes
Multipath interference	Low	High
Noise interference	Large	Small
Power dissipation	Less	Relatively more
Facility	LEDs, no additional infrastructure is needed	Hot spots, infrastructure must be increased
System complexity	Low	High
Security	High	Low
Flexibility	Low	Relatively high

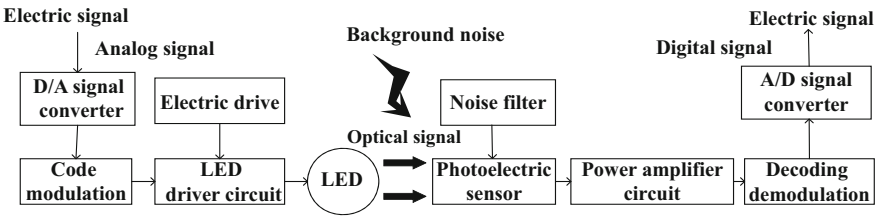

Fig. 50.1 VLC system block diagram [6]

image sensor to achieve the optical-to-electrical conversion, and the electrical signal is transmitted to the decoder and demodulation circuit to recover the original data.

Related Applications of Optical Wireless Communication in Industrial Scenarios

Data Transmission

Light fidelity (LiFi) extends the concept of VLC to enable two-way fully networked wireless communications [7]. Figure 50.2 presents an application block diagram for data transmissions in a factory. LED lights communicate through power-line communication (PLC). The upper computer loads the information on the power line and transmits it to intelligent devices in the factory through LED lights on the ceiling. The feedback information from the device is transmitted to the receiving end through the WiFi uplink and then transmitted to the host computer through PLC.

PLC can simplify the connection of equipment in a factory. There is no need to establish a new communication network as long as there are cables that can carry transmissions, to achieve low-cost and cost-effective broadband data delivery. Because LED lights require a power supply, power-line communication is a very attractive technology for LiFi backbone networks.

Indoor Positioning

With the development of intelligent factories, goods identification and positioning technologies are gradually being demanded. The wavelength of a light signal is short

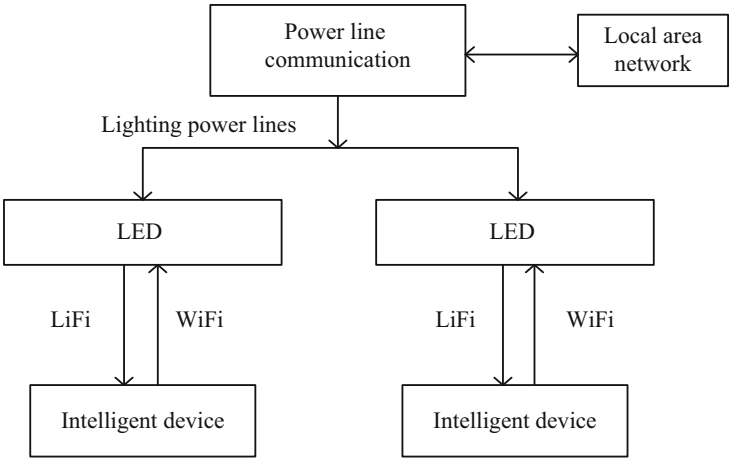

Fig. 50.2 Block diagram of factory data transmission [8]

and it propagates in a straight line, which makes visible light positioning (VLP) technology more accurate than RF positioning.

At the sending end of the optical signal line coding, the lamp is equipped with a modulator. Each LED is given a unique identifier that serves as a code word suitable for VLC transmission. The corresponding drive circuit opens the key control modulation mode to drive the LED lamp to achieve an electric-optical conversion. After the optical signal is received, it is decoded and processed; the position coordinates are then calculated using the corresponding positioning algorithm. The machine control module calculates [9] the direction information according to the positioning results, and inspects and navigates the factory equipment.

According to the receiving method, VLP can be divided into non-imaging-positioning technology based on a photodetector (PD) and imaging-positioning technology [10] based on an image sensor (IS). The positioning algorithms are classified as shown in Fig. 50.3.

Positioning technology with an IS as the receiver mainly uses an image-processing algorithm and optical-imaging principle to locate the measuring point. First, the camera captures the VLP signal and processes the received image. The position information [12] of the undetermined point is then calculated according to the optical-geometry relationship. Acceleration sensors commonly integrated into factory equipment can provide angle correction for images captured by this technology, thereby improving the positioning accuracy of the VLP.

Positioning technology with a PD as the receiver uses the PD's light sensitivity to receive visible light signals, combined with the time of arrival (TOA), time difference of arrival (TDOA), received signal strength (RSS), angle of arrival (AOA), scene analysis, and other positioning algorithms to achieve indoor positioning [13].

TOA and TDOA convert the time or time difference into a distance to measure it, and then use the trilateral positioning method to estimate the location. The RSS estimates the position according to the light signal strength from the anchor point to the LED. The AOA estimates the position by receiving visible light signals from multiple LEDs, according to the angle at which each LED signal reaches the PD receiver.

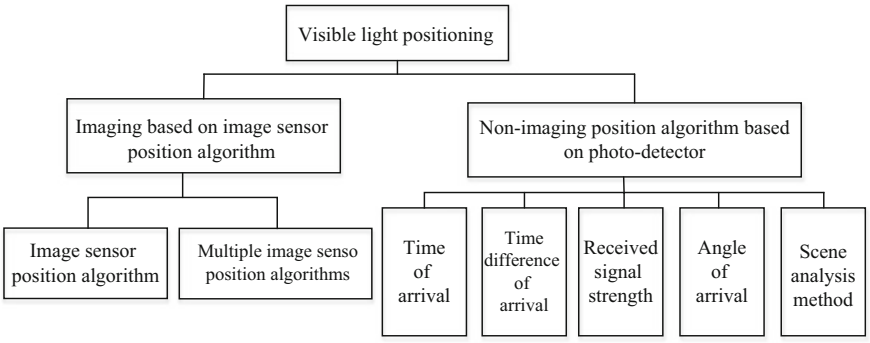

Fig. 50.3 VLP algorithm classification [11]

The scene analysis method first establishes the light intensity information of the environmental sampling point and records it in a database. After receiving the light intensity information, the receiver matches it with the database to estimate the location of the fixed point.

Environmental Monitoring

Some industrial sites such as chemical plants, mines, etc., are more sensitive to indoor environmental parameters and electromagnetic interference, such as gas concentration, indoor temperature, and air pressure in the current environment. In these cases, VLC can be combined with indoor environmental-monitoring technology, using the dual-use characteristics of LED communication lighting. The data collected by the sensor are sent to the background server through a VLC transceiver module to monitor the indoor environment in real time.

Figure 50.4 shows a block diagram of the VLC environmental-monitoring system in an industrial environment. The advanced RISC machine (ARM) processor is responsible for collecting environmental parameters, including temperature, humidity, air pressure, etc., and then sends the data information to the VLC sending module in the defined data frame format. The LED light is sent out in the form of visible light. The VLC receiving module converts the optical signal into a current signal, modifies it into a certain data frame format, and sends it to the server. The server is responsible for analyzing the received environmental data.

Foreign and Domestic Research Progress

As early as 1990, foreign scholars have proposed optical wireless communication (OWC) as an important means of indoor communication. At that time, there was great interest in the potential of free-space optical systems to provide portable data communication, especially with the congestion of the radio spectrum. Ultra-bandwidth frequency allocation was difficult to obtain, and microwave or millimeter-wave systems could not be used for higher bandwidth services, owing to technical limitations. Consequently, scholars in this field shifted their focus to

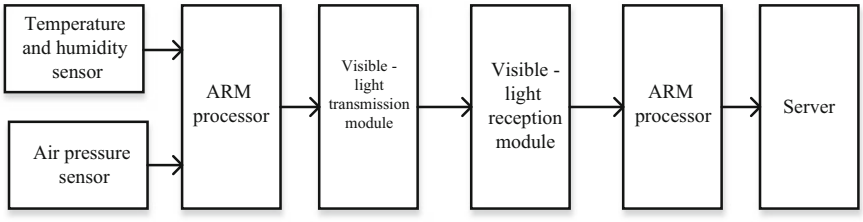

Fig. 50.4 Block diagram of a VLC environmental-monitoring system [14]

optical wireless communication technology, which was rich in spectral resources, security, and environmental protection.

In 2009, Paraskevopoulos et al. [15] proposed to apply OWC to short- and medium-distance industrial applications in the future. Orthogonal frequency-division multiplexing (OFDM) was proposed in combination with adaptive signal processing. Experiments showed that the transmission rate could be dynamically adjusted according to the current link quality. A reliable optical wireless link in the range of 100–200 Mbit/s achieved a high throughput.

In 2015, Goroshko et al. [16] studied the time-synchronization scheme of a VLC system based on OFDM. The system improved the transmission rate between machines in a factory, as well as the robustness and low-latency characteristics of the communication process, and could make future factory-manufacturing units more flexible.

In 2015, Shao et al. [17] proposed two heterogeneous WiFi–VLC systems. The first system used a one-way VLC channel as the downlink and retained the WiFi reverse channel as an uplink, which addressed the optical-uplink challenge. The second system used both WiFi and VLC parallel aggregation as a downlink. Studies showed that both hybrid systems had a high throughput, outperforming single WiFi systems, and that the aggregated system performed better when considering the blocking duration and distance between the access point and user device.

In 2017, Niu et al. [18] proposed a new intelligent lighting control system based on VLC, which combined with virtual reality technology can realize the information location of items in factories, the analysis of pipeline detection data, and the transmission speed is higher than the traditional intelligent lighting control system.

In 2018, Kim et al [19] proposed a VLC-based industrial Internet device management and data transmission scheme. Research showed that under this scheme, the VLC-packet exchange time was 590 ms, and the switching time between VLC transmitters was approximately 210 ms.

In 2018, Berenguer et al [20] studied channel measurement for robotic distributed 8×6 multi-input multi-output (MIMO) VLC systems in industrial manufacturing cells. The results showed that the link was available with a sufficient signal-to-noise ratio. However, because the direct-view link was blocked by the movement of the robot arm, the signal level suddenly dropped by 10–20 dB, which affected the link availability. An antenna diversity scheme was proposed to solve the link-blocking problem.

In 2018, Li Hao [21] proposed to use VLP as the indoor addressing mode of automatic guided vehicles in the factory, modulate the light source by using single-chip microcomputer cross-25 codes to improve transmission efficiency, use CMOS sensors to capture image information and process the image at the receiving end, and propose a dual-lamp positioning algorithm to realize automatic addressing of the car. The verification results showed that the system could satisfy the automatic addressing function; the positioning error was approximately 3.6 cm, and the positioning delay was approximately 37 ms.

In 2019, Berenguer et al. [22] proposed to increase the drive signal power in industrial OWC process by using a nonlinear equalizer, which can improve the

3.5 dB signal-to-noise ratio, and verified that the antenna diversity scheme in MIMO technology can significantly improve the reliability of the physical layer in the communication process.

In 2019, Almadani et al [23] proposed to combine VLP with UAVs to study the coverage area of UAVs in industrial environments. The results showed that when the divergence angle of the transmitter and the field-of-view angle of the receiver were set, the signal could be accurately received by the UAV outside a certain angle range.

In 2019, Lam et al. [24] proposed a new VLP ray-surface location method, which uses steerable lasers (rays) and LEDs to locate devices with active receivers. Studies showed that this technology could provide real-time tracking of devices within an operating area, add additional light sources for redundancy, scale to larger spaces, solve occlusion problems, provide capacity for more mobile devices, and be used as a low-cost positioning system for Industry 4.0.

In 2019, Liu et al. [25] proposed an indoor self-powered VLC system, which is able to collect energy from electromagnetic interference signals in factories to power VLC for IoT devices. An evaluation and analysis of the system proved its feasibility. It can be used as a supplementary technology in the hostile radio environment of the industrial Internet of Things.

In 2019, Yang et al. [26] proposed a heterogeneous RF/VLC industrial network architecture, which can simultaneously meet the high reliability, low latency, and high data transmission rate in industrial wireless networks, and proposed a new deep learning algorithm to realize intelligent resource management. Simulation results verified the effectiveness of the RF/VLC industrial network, and the proposed learning algorithm was superior to other existing algorithms.

In 2020, Bechadergue et al. [27] proposed that LiFi could provide a stable framework for the mass production of factory-specific chips based on the current market feedback of LiFi in the industrial field, laying a key foundation for the integration of LiFi technology into smart phones and other devices.

In 2020, Jungnickel et al. [28] proposed a new LiFi system concept for industrial wireless applications. It adopted a distributed multi-user MIMO architecture, which provided sufficient network capacity, moved seamlessly in large indoor areas, achieved reliable low-latency communication, and could be centralized into 5G core networks, such as WiFi.

In 2020, Muller [29] proposed a system architecture that combined 5G and LiFi in intelligent manufacturing scenarios using the industrial Internet. Research showed that this system provided reliable network communication and indoor positioning, making the integration of mobile devices in factories more flexible.

In 2020, Alturjman et al. [30] proposed to use subtle changes in the radiation intensity of LED lights to generate binary data streams, which are sensed by photodiodes and converted into electrical signals for wireless control of robots in factories, overcoming the need for wires. The results showed that the system improved the throughput and reliability for both direct and nondirect viewing links.

In 2020, Sun [31] introduced a LiFI-based IoT device access point architecture, which can meet the application scenarios of most IoT devices and realize energy

independence, providing a new idea for the future research of LiFi technology in the direction of IoT.

In 2021, Zhang et al. [32] proposed the diffuse reflection focusing technology and introduced the fast focusing transmission matrix algorithm, which was experimentally proved on the diffuse 25 cm free-space link. The experiment proved that a 40-Gbit/s non-line of sight beam could guide optical wireless links for communication, and the achieved function showed great potential in the Industry 4.0.

In 2021, Kouhini et al. [33] proposed a LiFi indoor positioning system based on time-of-flight measurements between multiple optical front ends deployed on the ceiling and devices moving within overlapping coverage areas. Studies showed that the system conformed to the recommended standard G.9991 of the International Telecommunication Standardization Department and achieved accurate indoor positioning with an average distance error of only a few centimeters. The LiFi positioning proposed in this study is a promising new feature that can be added to existing protocols to further enhance the functionality of intelligent lighting systems.

In 2021, Daniel et al. [34] conducted experimental research on the harsh environment of optical wireless channel transmission in factory conditions, proposed a new method to calculate the single spectral emission of superposition measurements, and built a model to quantify the impact of superposition measurements on communication. Research showed that the interference of the environment and artificial light sources affected the spectral and electrical-spectrum distributions. Therefore, the optical wireless communication system should be designed according to the actual factory environment.

In 2021, Koonen et al. [35] realized single wireless connection without interference of densely spaced devices in Industry 4.0 environment through narrow two-dimensional steerable infrared beams, capable of realizing self-calibration positioning of devices, and proposed a low-complexity wideband wide-field optical wireless receiver based on a photodiode matrix.

In 2021, Kang et al. [36] will design and optimize the optimal rotation angle receiver and aperture array receiver for complex dynamic scenes in the industrial Internet of Things to reduce noise interference and interference between adjacent channels during VLC transmission. Research showed that the design enabled robust data transmissions and improved the anti-interference ability.

In 2022, Ma et al. [37] evaluated the LiFi positioning system based on ITU-T G.9991 OWC standard in the factory environment, and the results showed that the three-dimensional positioning errors of the system were 7, 6 and 3 cm, respectively, and were further improved to about 3, 5, and 4 cm by introducing correction factors. Their research method demonstrated the possibility of further developing LiFi systems for product positioning and navigation vehicles in the future industrial Internet.

In 2022, Salvi et al. [38] proposed an optical camera communication system inspired by the Aztec model that could be applied in industrial scenarios in the future. The signal-to-noise ratio and intensity distribution of the system were evaluated, and the results showed that the method was superior to traditional

two-dimensional code recognition methods, in terms of power consumption and bit-error rate.

In 2022, Kouhini [39] proposed a real-time communication system for an all-optical fixed-wireless LiFi link with distributed MIMO. The operation of this link under spatial diversity and spatial multiplexing was analyzed, and the research showed that dynamically switching between spatial diversity and spatial multiplexing was feasible.

In 2022, Costa et al. [40] used artificial intelligence based on machine learning to predict the trajectory and channel performance of OWC links. Two industrial scenarios were considered as examples to evaluate the proposed scheme. The results showed that the algorithm could optimize the link parameters, predict the VLC channel gain, and effectively improve the power and spectral efficiency of the VLC system in industrial scenarios.

In 2022, Reguera et al. [41] proposed a VLC system based on multi-pulse position modulation (MPPM), which allows dimming control and can be used in resource-constrained devices. The results showed that the system had an efficient data transfer rate and lower energy consumption. The proposed new codec algorithm for MPPM significantly reduced the running time and could easily be embedded in the LED drivers and receivers of VLC for large-scale industrial deployment.

In 2022, Xue et al. [42] proposed a hybrid integrated system combining multi-access edge computing and visible light communication to solve the problem of unbalanced resource utilization caused by users moving in the dense coverage of VLC. The results showed that the system had a lower user drop rate, improved the resource utilization, reduced the overall delay, and met the requirements of low delay and high capacity in today's industrial IoT.

In 2022, Xue et al. [43] proposed a no-boundary dense networking VLC system, which cancels the multiple access technology of transmitter in traditional industrial scenes to improve transmission efficiency, and the receiving end can adaptively realize anti-noise reception in nonoverlapping areas and simultaneous recovery of two transmitted signals in overlapping areas. The results showed that the system had a lower bit-error rate and wider communication coverage.

In 2022, Xu [44] proposed four optical OFDM schemes based on discrete Hartley transform LED index modulation and subcarrier index modulation to reduce hardware costs and computational complexity. The results showed that the four proposed schemes obtained better peak-to-mean ratios and error performance, providing a reference for introducing efficient optical OFDM system schemes in industrial Internet scenarios.

In 2022, Yang [45] proposed three time-synchronization algorithms for DC-biased optical OFDM systems applied to VLC. Research showed that the proposed algorithms had a higher time-synchronization performance, reduced the impact of time-synchronization errors on the system performance, better complemented RF technology in industrial scenarios, and had a higher spectral efficiency and lower algorithm complexity.

In 2022, Ozyurt et al. [46] proposed an industrial LiFi network technology combining device-to-device communication and coordinated multi-point joint

transmission, and launched an analytical model of the coverage area of inter-device communication according to half illuminance and half angle. The simulation results agreed with the proposed theoretical model, which was valuable for practical industrial LiFi design and development.

In 2022, Yang [47] combined VLC and PLC technology, used the power-line transmission data as the uplink, selected their own adaptive OFDM technology on the two transmission channels, and built a PLC-VLC cascade communication system platform for testing. The results showed that the system could achieve stable upstream and downstream communication, and the transmission bit-error rate reached 10^{-4}, which opened a new idea for upstream and downstream communication links in industrial settings.

In 2023, Nguyen et al. [48] proposed a MIMO modulation system based on time-domain open key control modulation and light-emitting diode array. The results showed that compared with traditional region of interest signal detection, the deep learning for detection and tracking of the system has the advantage of low bit-error rate over a long communication distance, and can be widely used in smart factories.

In 2023, Wang et al. [49], based on the intelligent lighting system, proposed combining the visible light system with virtual reality technology to achieve positioning and automatic detection to meet the information requirements of smart factories.

In 2023, Du et al. [50] proposed a visible light positioning LED region recognition framework based on CMOS image sensor, which can realize mobile terminal positioning from the perspective of recognition without modulating the LED. Experiments showed that the model was highly robust and could be applied to various types of LED lights, which play an important role in the positioning of mobile terminals in industrial environments.

In 2023, Zhou et al. [51] suppressed cross talk in full-duplex VLC by reducing beam angle and field angle, power isolation, and ground plane segmentation. The results showed that, combined with the existing communication network, a full-duplex real-time VLC system based on Ethernet was realized, and the system could also be used as an optical wireless access system for the industrial Internet.

In 2023, Aboagye et al. [52] introduce the design of VLC system based on reconfigurable intelligent surface and integrate reconfigurable intelligence surface (RIS) with other emerging VLC technologies, so as to solve the problem of direct-view blocking in VLC system. Research showed that by selecting an appropriate RIS technology to adapt to VLC systems, the complexity of the RIS technology could be effectively reduced, and the data transmission rate could be improved. This design can provide useful guidance for wireless communication networks in the industrial Internet.

In 2023, Ozyurt et al. [53] analyzed the key performance indicators of device-to-device (D2D) communication in ultra-dense industrial LiFi networks, and deduced the coverage model of LiFi for D2D communication range and the expression of D2D residence time. Research showed that densely deployed access points led to a reduced D2D residence time and increased transition rate, which are of great value in practical industrial LiFi design.

Key Technologies of Optical Wireless Communication in the Industrial Internet

Visible Light Channel Model

The VLC system adopts a Lambert-type white LED at the transmitting end and a photoelectric sensor at the receiving end. The VLC linear baseband-transmission model is shown in Fig. 50.5.

The photocurrent signal received by the receiving end is represented as

$$Y(t) = R \cdot X(t) \otimes h(t) + N(t) \tag{50.1}$$

where $\otimes$ is a convolution, R is the photoelectric conversion efficiency, $X(t)$ is the transmitted light power of the LED, $h(t)$ is the impulse response of the channel, and $N(t)$ is the additive Gaussian white noise in the channel.

In a closed indoor VLC environment, an LED optical signal can be divided into two propagation paths to reach the receiving end. The path directly to the receiving end is called the line of sight (LOS), and the path to the receiving end after reflecting off an object in the propagation process is called the non-line of sight (NLOS) [55]. Owing to the presence of solid particles, such as smoke and dust, in some plants it is necessary to consider the effect of the particle-scattering characteristics on the light propagation, according to the actual situation in the channel analysis. The VLC link modes are shown in Fig. 50.6.

In the LOS link, the transmitting and receiving ends are aligned and have a high power utilization rate. However, if there are obstacles between the LED light source and the receiving end, the signal transmission will be hindered or communication will be interrupted. In the NLOS link, the receiving angle is large, and the requirements for the directions of the transmitting and receiving ends are low.

However, there is a difference in the time required for the reflected light signals of different objects to reach the receiving end, which may lead to intercode cross talk, thereby reducing the accuracy of the VLC system. Therefore, in actual factory applications, the two link modes should be selected according to the different requirements.

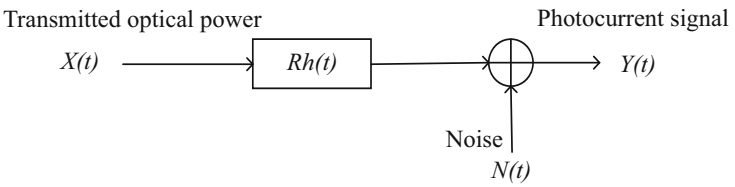

Fig. 50.5 Linear baseband-transmission model for VLC [54]

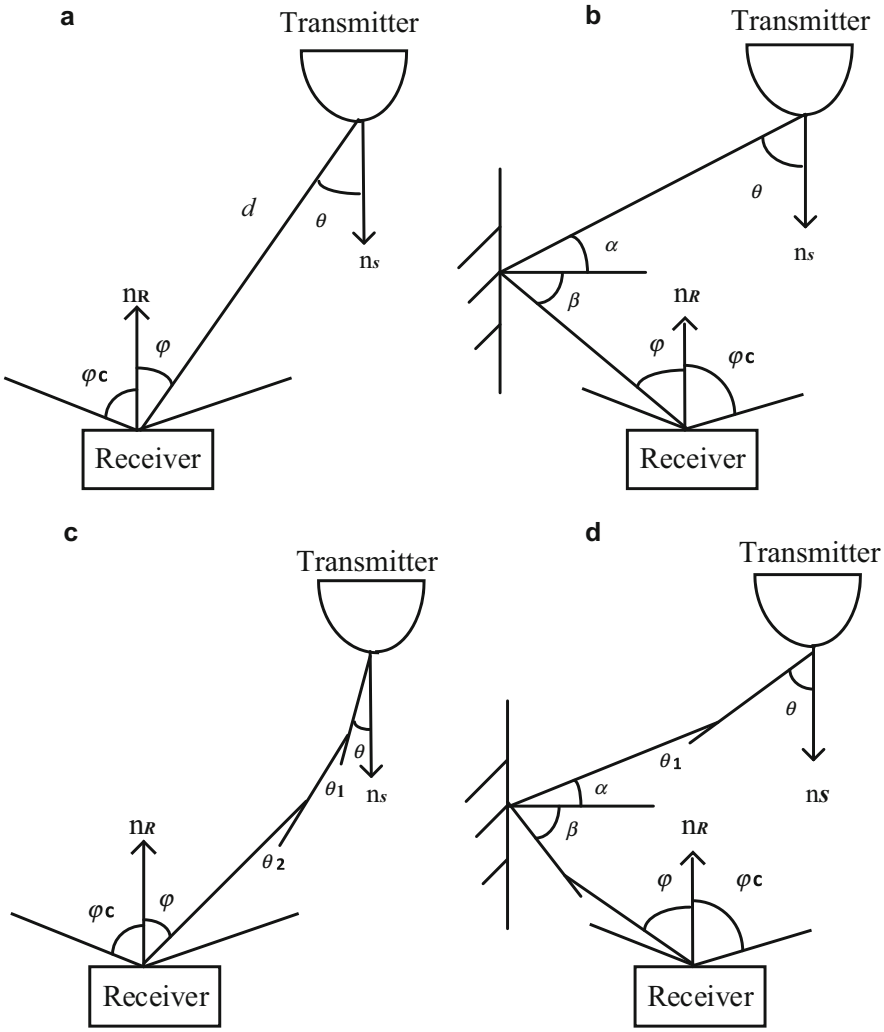

Fig. 50.6 VLC link modes [56]. (**a**) Line of sight; (**b**) non-line of sight; (**c**) LOS (with scattering); (**d**) NLOS (with scattering)

The power formula of the receiving device is

$$P_r = H(0) = H(0) \lim_{T \to \infty} \frac{1}{2T} \int_{-T}^{T} X(t) d(t) \tag{50.2}$$

where P_r denotes the mean value of the transmitted power; $H(0)$ denotes the DC channel gain; and $H_d(0)$ and $dH_r(0)$ are successively summed in the LOS and NLOS links, respectively. The formula is as follows:

$$H_d(0) = \begin{cases} 0 & ,\varphi > \varphi_c \\ \dfrac{(m+1)A}{2\pi d^2} \cos^m(\theta) T(\varphi) g(\varphi) \cos(\varphi), & 0 \le \varphi \le \varphi_c \end{cases} \tag{50.3}$$

$$dH_r(0) = \begin{cases} 0 & ,\varphi > \varphi_c \\ \dfrac{(\mathrm{m}+1)A}{2(\pi d_1 d_2)^2} \cdot dA_{\mathrm{wall}} \cdot \cos^{\mathrm{m}}(\theta) \cos(\alpha) \cos(\varphi) T(\varphi) g(\varphi) \cos(\varphi), & 0 \le \varphi \le \varphi_c \end{cases} \tag{50.4}$$

In Eqs. (50.3) and (50.4), A represents the receiving area of the sensor; θ represents the transmitting angle; φ represents the receiving angle; and φ_c represents the receiving range of the receiver. When the incident light exceeds the receiver range, the optical signal will not be received. m is the Lambert radiation coefficient; d represents the link distance; d_1 represents the distance from the LED sending array to the first reflection point; d_2 represents the distance between the first reflection point and the receiver; and dA_{wall} is the unit area of the reflecting surface. α and β are, respectively, the incident angle of light to the reflection point and the radiation angle of the reflection point to the receiver. $T(\varphi)$ represents the filter gain and $g(\varphi)$ represents the intensity of the concentrated energy of the receiver.

The impulse response $h(t)$ is shown in Eq. (50.5):

$$h(t) = \frac{(\mathrm{m}+1)A}{2\pi d^2} \cos^{\mathrm{m}}(\theta) T(\varphi) g(\varphi) \cos(\varphi) \mathrm{rect}\left(\frac{\varphi}{\varphi_c}\right) \delta\left(t - \frac{d}{c}\right) \tag{50.5}$$

Multiple-Input Multiple-Output Technology

With the rapid increase in the number of devices on the industrial Internet, it is necessary to establish powerful communication networks to ensure reliable communication between devices. To support large-scale connections [57–59] in industrial networks, multiple-input multiple-output (MIMO) technology has been introduced into the VLC transmission process. This technology can effectively use space resources, realize multi-antenna parallel data transmissions, and greatly improve the transmission capacity [60] of the system without increasing the system transmission bandwidth.

Visible MIMO technology involves setting up a number of antennas at both ends of the transceiver. The transmitter is a multichannel serial signal modulated and encoded using visible-channel parallel transmissions. The receiving end of the signal demodulates, decodes, and restores the original signal [61]. A schematic of the visible MIMO system is shown in Fig. 50.7.

Visible MIMO technologies can be divided into two kinds [63]: spatial diversity and spatial multiplexing.

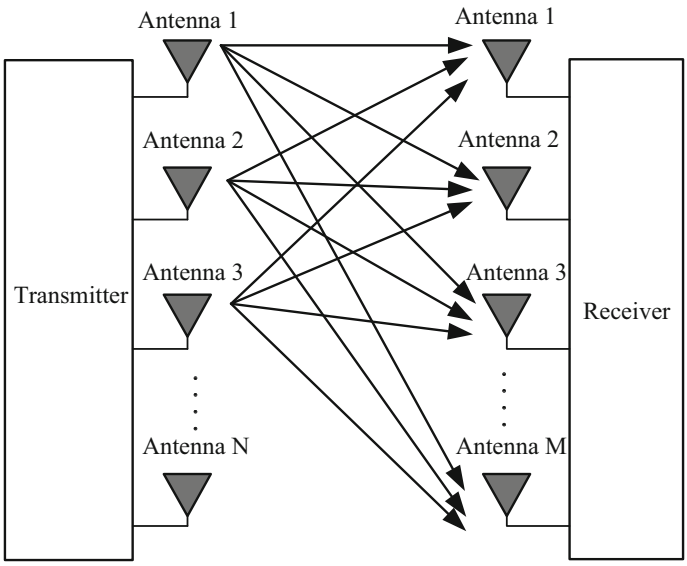

Fig. 50.7 Schematic diagram of a visible MIMO system [62]

Spatial Diversity

Spatial diversity uses multiple transmitting antennas to transmit the same data through different communication channels and multiple receiving antennas to receive information [64] at the receiving end. Because the signal attenuation differs in different channels, the receiver combines multiple signals, which can effectively reduce the bit-error rate of the system, weaken the influence of multipath fading in the channel, and improve the reliability of communication transmissions without increasing the transmission power and bandwidth.

Spatial Multiplexing

Spatial multiplexing uses multiple antennas at the sending end to transmit independent signals simultaneously. To achieve spatial multiplexing, it is necessary to ensure that the distance between the sending and receiving antennas is greater than the correlation distance to ensure that the subchannels at both ends of the transceiver are independent and unrelated. However, the adjacent channels may interfere with each other; therefore, it is necessary to adopt precoding technology to preprocess the signal at the transmitting end, or adopt anti-jamming technology, such as the zero-forcing, minimum mean-squared error, and maximum-likelihood algorithms, at the receiving end to reduce the bit-error rate [65] of the system.

Although spatial diversity is similar to spatial multiplexing, the two methods divide the data into several information streams and send them out through different transmitting antennas. However, the gain of spatial multiplexing is not as high as that of spatial diversity. The information flow of spatial diversity is used to send redundant information and improve the reliability of the communication

transmission, whereas spatial multiplexing can increase the transmission rate and improve the effectiveness of the communication transmission by sending different information flows.

MIMO technology is a compromise between the bit-error rate and data transmission rate of the system. While improving the spatial diversity gain, the spatial multiplexing gain is reduced [63], so it is necessary to select the appropriate technology according to the actual communication purpose in the factory.

Coding and Modulation Techniques

VLC systems usually adopt an intensity modulation/direct detection mode to transmit signals. The encoding mode mostly adopts binary open-key control or Manchester coding to improve the transmission speed. It also uses similar optical-group encoding forms, such as pulse position modulation; however, the system has higher requirements for clock synchronization in the decoding process. Binary on–off keying is relatively simple; however, the transmission speed is slow and the time-slot error rate is high. The Manchester coding bit-error rate is low, but the frequency-band bandwidth requirements are high, and the available modulation bandwidth of LEDs is very limited [66].

In VLC system modulation technology, the commonly used single-carrier modulation scheme causes a series of problems [67] such as LED front-end nonlinear signal distortion, and the data transmission rate is high in the industrial environment. In order to achieve high-speed transmission of information under the limited channel bandwidth, researchers at home and abroad consider introducing more efficient multi-carrier modulation technology into the industrial VLC systems.

Orthogonal frequency-division multiplexing (OFDM) technology has the advantages of high spectral efficiency and strong bandwidth expansibility, which can effectively reduce the frequency-selective fading caused by the indoor multipath effect. The basic concept is to divide the entire communication channel into multiple smaller subchannels, divide serial data into multiple parallel data streams, and transmit information on each subchannel after modulation.

The signal bandwidth on the subchannel is smaller than the relevant bandwidth of the entire channel, which can resist delay expansion and overcome the interference between signal symbols. The optical OFDM block diagram is shown in Fig. 50.8.

After the input data stream undergoes constellation modulation and series/parallel conversions, the frequency-domain signal is converted into a time-domain signal through an N-point Fourier inversion. To ensure the orthogonality between subchannels, a cyclic prefix is inserted, and a continuous analog signal is obtained after parallel/series and digital-mode conversions. Then, a DC bias is added to ensure that the signal is a positive real-value signal, and it is finally transmitted by the LED light source. After receiving the signal, the receiving end performs the inverse process of the transmitting end to restore the original data [68].

In the communication transmission process, each subcarrier adopts the same transmit power and simultaneously carries out the same modulation mode, which

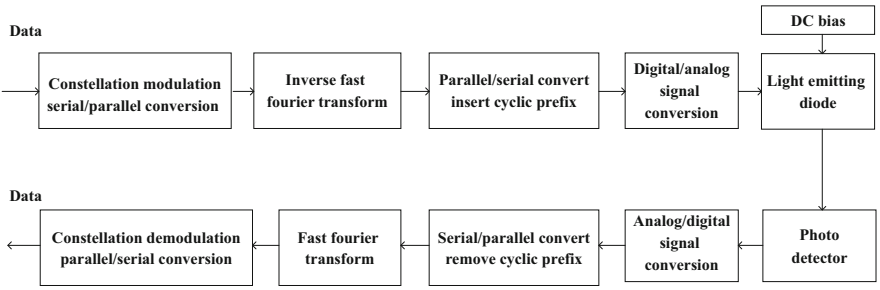

Fig. 50.8 Optical OFDM block diagram

may cause an increase in the bit-error rate among the subchannels and affect the system performance.

In 2009, Turkish Paraskevopoulos [15] proposed to introduce adaptive technology into an OFDM system. It achieved reliable communication links in the range of 100–200 Mbit/s and reduced the multipath effect of the system. Adaptive OFDM modulation can reasonably adjust the modulation mode and power, according to the transmission situation of each subchannel, to realize high system flexibility, maximize the utilization of channel resources, and improve the transmission efficiency [69] of the system.

Adjacent-Channel Interference Suppression Technology

Co-channel interference (CCI) [3] will be generated when the same transmission frequency is used. CCI schematic diagram is shown in Fig. 50.9. The emission mode of the LED light source has strong directivity, and most of the optical power radiated by the light source is located in the coverage area of the access point. Therefore, CCI will occur in the area between the edges of the coverage unit and the adjacent access point, where the optical emissions overlap. For high-density spatial multiplexing, CCI significantly affects the accuracy [70] of the communication transmission. The problem of CCI in adjacent units in visible optical communications can be effectively suppressed by adopting frequency-multiplexing technology.

A VLC system with multiple LED arrays is known as a cellular optical network. The basic idea of frequency-multiplexing technology is to divide the entire optical network into several cell clusters, and cells with the same frequency are separated by a certain distance. The number of units that use the same frequency in a cluster is called the frequency-multiplexing factor [71].

A schematic diagram of frequency multiplexing is shown in Fig. 50.10, where (a) is unified-frequency multiplexing and (b) is partial-frequency multiplexing with a frequency-multiplexing factor of two. All cells in unified-frequency multiplexing use the same frequency band, and all cells in partial-frequency multiplexing with a frequency-multiplexing factor of two share two frequency bands. Interference occurs

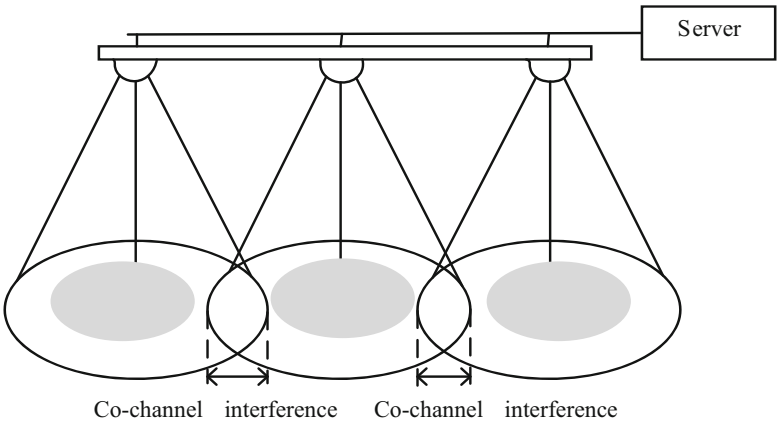

Fig. 50.9 Co-channel interference diagram

only in the overlapping areas of adjacent cells at the same frequency, thereby suppressing the CCI.

Multiple-Access Technology

In a factory, when multiple devices communicate simultaneously using the same resource (such as a shared channel), information collisions can result in communication failures. Multiple-access technology means that multiple devices can access the same communication network simultaneously. They use a specific channel-multiplexing technology in the same transmission channel, in which multiple devices can independently and reliably receive and demodulate data to share resources and improve channel utilization.

Table 50.2 Comparison of common multiple-access technologies

Multiple-access method	Principle	Advantages	Disadvantages
Time division	Different devices transmit information in different time slots	The average power efficiency is high and the realization difficulty is low	Requires equipment synchronization and has high overhead
Frequency division	Different devices transmit information in different frequency bands	Multiple signals are transmitted simultaneously without interfering with each other	The more frequency bands are divided, the slower the transmission rate on a single channel
Code division	Orthogonal codeword sequences are used to distinguish different terminal signals	Bandwidth communication has strong anti-fading and anti-jamming ability	When there are many users, the code word is too long
Space division	Free space is divided into different subchannels to transmit data	High spectrum utilization	High precoding complexity, interference from adjacent channels
Nonorthogonal	Different transmit powers are assigned to terminals according to the channel quality	Multiple signals are transmitted simultaneously, with a high transmission rate	High complexity

Currently, a variety of multiple-access technologies [72] have been developed for indoor VLC systems. Their principles, advantages, and disadvantages are listed in Table 50.2.

Heterogeneous RF/VLC Technology

Obstacles between the receiving and sending ends in a factory or changes in the position of the receiving equipment may lead to a reduction in VLC signal quality or communication interruptions. An effective method to address this challenge is to combine the advantages of RF wireless communication with those of VLC high-speed communication to form a heterogeneous RF/VLC network [73].

According to current research, the uplink of a communication system typically adopts RF wireless communication technology, and the downlink adopts heterogeneous RF/VLC technology. System models can be roughly divided into three types: double-hop, independent, and parallel-transmission [74].

Double-Hop RF/VLC System

As shown in Fig. 50.11, the double-hop RF/VLC system divides the link transmissions into two stages. The first stage is set as the VLC link, and the second stage is set as the RF link. Between the two hops, relay nodes, intelligent reflectors, and

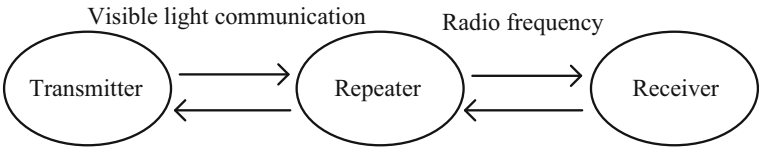

Fig. 50.11 Double-hop heterogeneous RF/VLC system

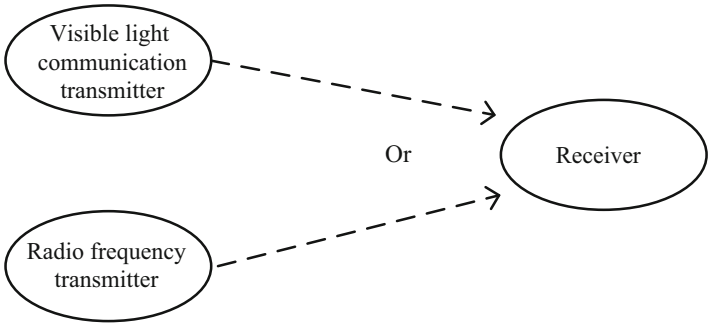

Fig. 50.12 Independent RF/VLC system

other devices are added to convert the VLC transmission signals into signals suitable for transmission in the RF link.

Conversely, the first hop can be set as an RF link and the second hop as a VLC link. This system can be applied to the receiving end but does not have the ability to receive VLC or RF system transmission signals; the direct link between the receiving and sending ends is unreachable.

Independent RF/VLC System

As shown in Fig. 50.12, an independent RF/VLC system implies that the receiver or central unit set by the system decides whether to use an independent VLC link or an independent RF link for information transmission. Typically, the receiver in the system does not have the ability to aggregate VLC and RF information.

The receiving end can freely choose the best network, according to the received signal-to-noise ratio, application requirements, device mobility, and other parameters, while the central unit set by the system can choose the network to provide services, according to the load balance and fairness of the network.

Parallel-Transmission RF/VLC System

As shown in Fig. 50.13, a parallel-transmission RF/VLC system implies that the RF and VLC systems simultaneously transmit information to the receiving end, and the receiving end uses aggregation technology to integrate the sent information. The real-time transmission performance of the heterogeneous system is good. When one link does not work, the other sends and receives information normally. However, the equipment complexity of this system is relatively high and difficult to realize.

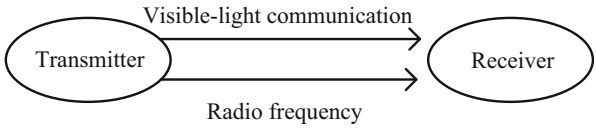

Fig. 50.13 Parallel-transmission heterogeneous RF/VLC system

Optical Wireless Communication Problems in the Industrial Internet

Although research on optical wireless communication technology in the industrial Internet has achieved some results, the actual application of these technologies in the industry is immature, and many challenges remain before widespread deployment. These include a long transmission range, indoor attenuation, multipath reflection, signal loss and blocking, and heterogeneous RF/VLC transmission theory.

Long Transmission Range

In larger places, such as warehouses and factories, the ceiling height leads to a longer link range, which causes multipath dispersion, resulting in higher path losses and lower data rates. In addition, the more light sources on the ceiling, the higher the level of interference between them, which affects the communication system performance [75].

Indoor Attenuation

The transmission medium for indoor applications is usually fresh air. Complex industrial environments may contain impurities, such as oil vapor, water mist, and industrial smoke, which affect light-wave transmissions and weaken the signal power [76].

Multipath Reflections

Highly reflective surfaces, such as metal devices and equipment, in industrial environments cause the multipath reflection of optical signals. The intersymbol interference generated by the multipath effect affects the quality of optical-signal transmissions. According to current research, OFDM can be used to improve the performance of VLC links, therefore different variants of OFDM have been introduced, such as DC-biased optical OFDM, asymmetric limiting optical OFDM, pulse–amplitude discrete multitone systems, etc.

Signal Loss and Blocking

VLC relies heavily on direct-vision propagation; therefore, there must be a clear and uninterrupted path between the sending and receiving ends. The random motion of a robot arm in a factory is likely to block light-wave propagation and cause signal loss. Foreign researchers have proposed an antenna diversity model [20] that places the receiving end near the manufacturing unit to ensure that there is always a direct-view link; the results showed that even if the robot arm moved a few centimeters, a signal attenuation of up to 20 dB could occur.

Theoretical Problems of Heterogeneous RF/VLC Transmissions

For heterogeneous VLC/RF networks, most existing studies assume that the input signal of the VLC is a Gaussian signal, but the visible signal is bounded and nonnegative; therefore, the traditional Shannon formula is not suitable for deriving the transmission rate. The closed-form expression of the transmission rate of heterogeneous RF/VLC systems and the optimal-transmission mechanism require further investigation.

In addition, the current design of optical wireless communication in the industrial-Internet environment is still limited to Lambert beam emitters, which do not fully use the non-Lambert beam-space characteristics of today's commercial LED light sources. Owing to the complexity of industrial environments, research in related fields must be evaluated and characterized to determine whether it meets the industrial-automation requirements to be placed into factories.

Summary

In recent years, researchers at home and abroad have demonstrated the industrial application potential of optical wireless communication through numerous experiments. Future research on optical wireless technology in the industrial field will focus on improving bandwidth, increasing transmission distance, and automatic direction alignment. Currently, it has the following potential applications in the industrial Internet environment.

Device Positioning and SIGNAL Transmission

Optical wireless communication is used for device positioning and signal transmission. A mobile vehicle in a factory can exchange data with the LED light and position itself using the power intensity emitted by the LED. The central controller can accurately locate the position of the mobile vehicle through the feedback signal conveyed by the LED. The device installed with the LED can transmit data

information and request the delivery of raw materials for production. A drone will respond immediately and execute the task after receiving the corresponding signal.

Integrated Wearable Security Devices

In some high-risk industrial places, workers must wear wearable safety devices in the form of helmets to cope with emergencies. VLC transceivers can be integrated into wearable safety devices to capture warnings emitted by the LEDs and broadcast them to other employees to improve workplace safety.

Underwater Industrial IoT

In marine environments, the underwater industrial Internet is used to transmit data throughout the ocean, enabling underwater sensor systems to communicate with each other and transmit data to ground networks. Because radio frequency signals cannot penetrate water, the data rate of acoustic signals in the transmission process is low and the cost is high; therefore, optical wireless communication is considered one of the communication technologies for the underwater industrial Internet.

Augmented-Reality Technology

Augmented reality is a technology that complements real-world experiences with the help of virtual information to provide guidance for machinery operation in factories. Augmented reality can be combined with wireless light to virtually label data for a machine, and employees can use dedicated devices to access this information, making it easier to work.
