Preface

Optical Communication: From Wired to Wireless

Transportation, energy, and communication are the three basic structures of human society. Transportation is the transfer of people and materials, energy is the transmission of energy, and communication is the transmission of information. All three greatly affect China's national economy.

The relationship between China's transportation, economic, and social development is undergoing tremendous changes, promoted by the application of modern information technology and innovative business models. The trend of integration, interaction, and mutual promotion is obvious. It also profoundly changes the traditional production, life, and organization of transactions, and has become an important force to drive the economic growth and social development of old and new systems.

Modern energy systems are based on a multi-energy structure that combines renewable energy with gaseous energy. Relying on smart energy technology coupled with clean energy and the Internet, the traditional energy system has gradually evolved to a new energy system, which is a necessary stage for future energy systems.

The deep integration and interdependence of transportation, energy, and information technology is a historical necessity. The tide of informationization, featuring digitization, networking, and intellectualization, is in the ascendant. Information technology is thriving daily and is fully integrated into the production and lives of human society. It is constantly interfusing with various industries, and is affecting the world's economic, cultural, security, and competition patterns.

Optical communication includes both wired and wireless methods. Cable optical communication requires a fixed medium. Optical wireless communication does not require a fixed medium and includes space laser, ultraviolet (UV), visible, and underwater blue-green communication, among others.

Fiber Communication

Optical fiber is the cornerstone of our digital society. Optical communication is a huge system, and optical transmission networks are the basis of the entire digital society. Following are some future development trends of optical communication technology.

1. The main task of optical communication is to transmit data and continuously expand bandwidth and capacity. In addition to improving its single-wave capacity, it should further expand its spectrum bandwidth.
2. Light is an energy-saving technology. The higher the optical-domain proportion in a transmission network, the lower the overall energy consumption. Operators should consider the top energy issues, such as reducing the overall network energy consumption, reducing the complexity of the network operation and maintenance, and reducing the amount of human intervention. From the optical-communication perspective, the transmission-energy consumption per unit bit kilometer and unit-bit switching-energy consumption should be further improved.
3. The changing role of metropolitan area networks should also be considered. A metropolitan all-optical network contains three layers: the metropolitan core, convergence, and access. A metropolitan all-optical network and the cloud network are closely related to each other. The metropolitan network not only intersects with data centers, but also enables operators with handheld devices to enter cloud business relations with government and enterprise customers. For example, operators can match private-line cloud services by providing optical broadband access.
4. Intelligent operation and maintenance are also necessary. After management is centralized, operators can intelligently operate the entire transmission network by introducing artificial intelligence (AI) and big-data technologies.

Optical Wireless Communication

Optical wireless communication does not require a fixed medium. Moreover, it is expected to become the main communication mode of satellite Internet, because of its high bandwidth, high security, and small device size. The main technical bottlenecks of optical wireless communication are narrow-beam long-distance divergence and atmospheric attenuation. The main technologies are automatic target acquisition and tracking, communication transceivers, atmospheric-turbulence compensation, integrated optical-electromechanical design, tethered-balloon relays, and stratospheric-airship relays.

Optical wireless communication also belongs to the field of applied optics, which combines optical, precision mechanical, electronic, material, computer, and other technologies to solve a variety of engineering application problems. It focuses on the acquisition, transmission, processing, storage, and display of light information and

the application of laser technology. It is directed toward multi-frequency bands, such as ultraviolet, visible, infrared, intensity, spectrum, polarization, and phase, as well as other dimensions, such as detection, imaging, and ranging. New communication and other multi-functional technologies are being developed.

Light has a much higher frequency than microwaves do, and as a communication carrier, it has a wider utilization band. At present, the working-frequency band of optical wireless communication is mainly 365 THz–326 THz (the corresponding wavelength range is more than 820 nm–920 nm), and there is no radio-frequency interference between devices. Waves, as information carriers, can transmit data rates up to 10 Gbit/s, and methods using wavelength-division multiplexing (WDM) technology can further improve this.

Optical wireless communication technology combines the advantages of radio and optical communication, and uses light as the communication carrier. Optical wireless communication technology has the advantages of a strong anti-jamming ability, high security, high communication rate, fast transmission speed, convenient band selection, and large information capacity. It has a small size, light weight, low power consumption, simple construction, and good flexibility and mobility. It has great strategic and application value in military and civil fields. In addition, the laser's advantages of a short wavelength, strong penetration, good directionality, and energy concentration also reduce the aperture of the receiving telescope, and eliminate the huge dish antenna of the radio communication system. The receiving system can also be made smaller and lighter. Thus, the construction and maintenance of laser communication-related systems and equipment are relatively inexpensive.

Optical wireless communication faces a dilemma. The reliability of light transmissions is challenged by such factors as atmospheric absorption and scattering, atmospheric turbulence, and background light. The main factors affecting satellite–ground light communication are atmospheric absorption and scattering, atmospheric turbulence, background light, clouds, rain, etc.

Atmospheric laser absorption is mainly due to the interaction between atmospheric molecules and a laser of a specific wavelength. Atmospheric scattering is also related to the wavelength, and can be described by the Beer–Lambert law. Atmospheric turbulence is caused by changes in atmospheric temperature and pressure, which redistribute the signal strength and phase, i.e., wavefront distortion. It is usually described using a gamma–gamma distribution or a more accurate two-parameter Weibull distribution. The influence of background light comes from the sun, other stars, and scattered light. Clouds and rain affect laser communication mainly from the angles of absorption and scattering.

Trends in Optical Wireless Communication

The technological trends of optical wireless communication are developing toward high speeds, networks, multipurpose applications, and integration. All-in-one systems, full photoluminescence, and multispectral communication are also discussed.

High Data Rates

With the rapid development of high-speed modem and transmission technology for space laser communications, future satellite-to-Earth optical wireless communication link rates are expected to reach 100 Gbit/s. High-speed laser communication uses high-order modulation methods, such as orthogonal phase-shift keying, orthogonal amplitude modulation, and multiplexing, such as wavelength-division, time-division, and orbital-angular-momentum multiplexing. Short-distance rates can reach Tbit/s magnitudes.

Networks

With the development of globalization and information technology, there is an urgent need to build spatial networks that do not depend on ground networks, with seamless global coverage, high bandwidth, and high performance. Therefore, space-based broadband-transmission networks are an important trend in the future.

Optical wireless communication technology is gradually moving from point-to-point modes to relay-forwarding and building optical wireless networks. The main difficulties when constructing laser networks are the small laser divergence angle, dynamic access of optical signals, and large impact of a space environment. Consequently, it is necessary to break through the one-to-many problem of laser-communication technology, study dynamic routing to solve the access scheme, and search for a joint laser–microwave communication system. Because of its simple optical principle, using a rotating parabolic structure to design one-to-many point optical antennas for laser-communication networking between multiple satellites is a major breakthrough in exploring and solving this difficult problem.

Multipurpose Applications

With the maturing of optical wireless communication technology, its advantages of a high modulation rate, long transmission distance, and low energy consumption have become increasingly prominent. At present, optical wireless communication technology has been widely used in the broadband data transmissions of inter-satellite, sky, space, and ground links, and has gradually expanded to deep-space detection, underwater and ground-access communications, etc.

Deep-space exploration involves the exploration of the moon, distant objects, or space. It is an inevitable step in understanding the solar system and the universe, discovering the origin and evolution of the universe, and expanding the living space of human beings. The implementation of a lunar-exploration project opened the curtain of deep-space exploration in China, and was followed by a Mars-exploration project.

Underwater optical wireless communication has the advantages of a large capacity, high bandwidth, good confidentiality, and strong anti-jamming ability. It has

become an important communication technology developed by the world's major powers. In addition, space laser communication technology can play an irreplaceable role in applications where optical cables cannot be laid, such as between islands, urban buildings, complex field environments, etc.

Optical wireless transmission technology using visible light for data communication combines the functions of lighting, communication, and control positioning. It is easy to integrate with existing basic lighting facilities, and conforms to national energy-saving and emission-reduction strategies. It is expected to gradually become the main broadband transmission method for ultra–high speed universal optical networking in the future intelligent era.

Integration

Because of the advantages of lasers in high-speed communication and accurate ranging, the integration of laser ranging and communication technology has received increasing attention in recent years. Integrated designs of laser ranging and communication are based on high-speed communication and enables precision ranging. The same laser beam and hardware platform are used for ranging and information transmissions, thus achieving the dual functions of ranging and communication with the same set of devices.

In 2013, the United States National Aeronautics and Space Administration's (NASA's) liquid-crystal display (LCD) system successfully implemented on-track demonstration verification of monthly high-speed laser communications and high-precision ranging, with the ranging accuracy reaching 3 cm. In 2006, scientists at Pennsylvania State University conducted an evaluation study of a laser/microwave hybrid transmission. It was found that the laser link was strongly affected by clouds, mainly due to the attenuation and scattering of cloud particles; however, the availability of the overall link can be greatly improved by introducing microwave links.

Usually, in a laser/microwave hybrid transmission mode, the laser link can pass through the laser transmission; however, the microwave link cannot be used to transfer the data. This method not only inefficiently uses the overall channel bandwidth, but also causes unnecessary transmission interruptions when switching between laser and microwave links.

All-in-One Systems

Space laser communication and ranging have many similarities; for example, they both require pointing, acquisition, and tracking (PAT) units, pulse-timing detection, and have advantages of high-speed communication and precision ranging. Therefore, they can be combined to form a composite communication and ranging system by sending and receiving a single laser beam, i.e., integrated laser communication and ranging.

For example, NASA's lunar laser-communication demonstration system has been successfully implemented to verify lunar–terrestrial high-speed laser communication and high-precision ranging in orbit. The Beijing Institute of Telemetry Technology has also completed an integrated high-speed communication and ranging design, based on coherent communication.

Integrating laser communication and ranging produces a single device with multiple functions, thus reducing the size and power-consumption requirements. However, it has disadvantages, such as poor anti-jamming capability and weak ranging optical energy. Fortunately, these can be solved by adopting technologies, such as common ranging and communication wavelengths, dual modulation systems, and pseudocode and communication-signal conversion.

Full Photoluminescence

At present, a satellite laser-communication relay node adopts an "electric relay" mode, which converts the weak received optical signal into an electric signal. It then amplifies the signal, recovers the clock, and filters and denoises the signal in the electric domain before modulating it to the laser carrier and transmitting it out. Thus, there is a process of light to electricity/electronics to light for this signal. The "electric relay" mode mainly suffers from a complex system structure (back-to-back transmitters and receivers are required), electronic bottlenecks (the electronic chip rate is limited to Gbit/s), etc.

The European Space Agency's (ESA's) high-throughput optical network plan proposes to build a high-throughput all-optical network by planning two satellites, GEO and LEO, to be used as all-optical link nodes for in-orbit demonstrations and user data-collection validation and distribution. The all-optical network is a broadband network that replaces traditional electrical nodes with optical nodes and connects them into a network with laser links; this enables information to be transmitted and processed entirely in the optical domain. The all-optical network uses advanced all-optical technologies, such as transmission, amplification, regeneration, and switching. To realize an all-optical laser-communication network, it is necessary to break through in key technologies, such as on-star all-optical relay-regeneration and switching technologies.

Multispectral Communication

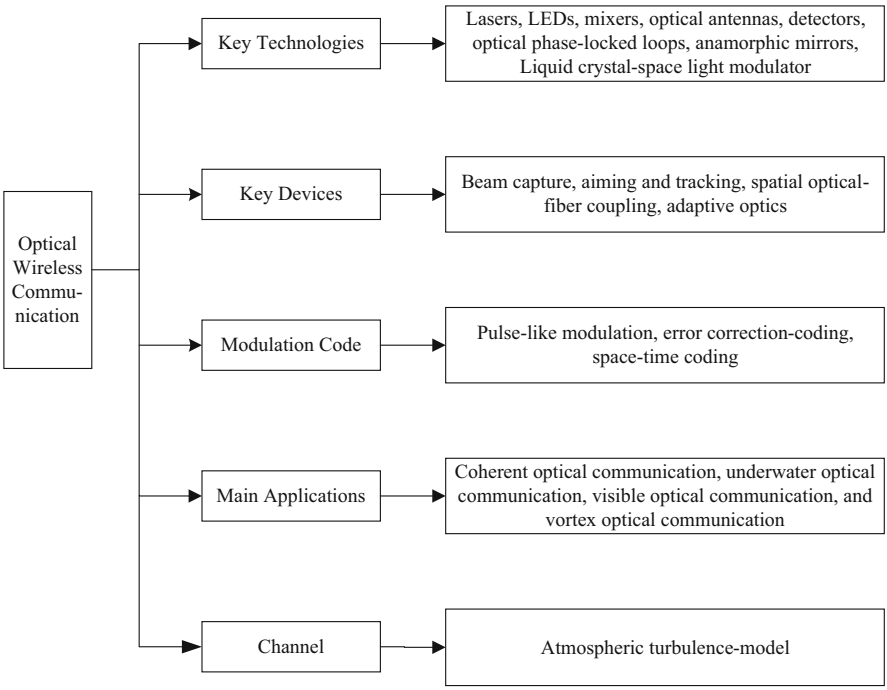
Laser technology can be applied to a variety of spectral bands, from ultraviolet to infrared, and even terahertz. For example, NASA has begun to apply a terabit-class infrared-transmission payload to perform SpaceX's Transporter-5 carpool mission.

Each spectrum has different cloud-penetration abilities and suffers different levels of anti-electromagnetic interference. For example, the ultraviolet and visible-light bands have poor cloud-penetration and high anti-electromagnetic interference abilities. The terahertz spectrum has a strong cloud-penetration ability, second only to

radio, but its anti-interference ability is better than radio. The infrared light band's cloud-penetration ability is worse than terahertz, but its anti-electromagnetic interference ability is stronger.

Therefore, future space–laser communication will vigorously develop the UV, visible light, mid-infrared, terahertz, and other multispectral communication-mode combinations to take advantage of the different strengths of the spectral communication systems. Moreover, in-depth research on multispectral communication will be emphasized, with a view to achieving uninterrupted and barrier-free communication under different environmental conditions, through the joint application of multiple spectra.

Beaconless Light



An optical wireless communication system typically uses two wavelengths of light: one wavelength to maintain alignment between the two terminals, and another wavelength for the transmission of information. Two lasers have different transmit power, modulation rate, and light dispersion angle, increasing the complexity of the system design. The direction of future development is not to beacon light, directly using the signal light for alignment.

Non-Co-Optical Axis

The transmitter and receiver of Optical wireless communication require a common visual axis. However, when the communication distance is far away, due to the disturbance of the wireless channel, the light beam will produce off-target, resulting in communication interruption. By adopting the non-co-axial technique, the transmitter and receiver are adjusted individually, which suppresses the effect of the disturbance of the wireless channel on the communication system and also reduces the requirement for ATP technology.

Structure of This Book

The figure in the following page shows a structural block diagram of the main contents of this book. This book analyzes and discusses the key technologies of optical wireless communication, including beam capture, aiming and tracking, spatial optical-fiber coupling, and adaptive optics. It also discusses the research progress and control algorithms of key devices used in optical communication systems, such as lasers, LEDs, mixers, optical antennas, detectors, optical phase-locked loops, deformation mirrors, and liquid-crystal spatial light modulators. The research progress of modulation and error coding in optical wireless communication

Block diagram of the main contents of the book

is summarized, and several typical optical wireless communication methods are introduced, such as coherent optical communication, underwater optical communication, visible optical communication, and vortex optical communication. The atmospheric-turbulence model of an optical wireless communication channel is introduced. Research progress and development trends are also discussed.

About the Author

Xizheng Ke is Doctor of Science, Second-Level Professor, Foreign academician of the Russian Academy of Natural Sciences, Head of the Department of Information and Communication Systems at Xi'an University of Technology, and Deputy Director of the Key Laboratory of Military-Civilian Joint Construction of Intelligent Cooperative Networks in Shaanxi Province. He is a famous teacher in Shaanxi Province, Fellow of Chinese Institute of Electronics, Director of Chinese Optical Engineering Society, Executive Director of Shaanxi Optical Society. He received a Bachelor's degree from Shaanxi Institute of Technology in 1983 and a Doctor of Science degree from the University of Chinese Academy of Sciences in 1996. From 1997 to 2002, he conducted post-doctoral research at Xidian University and the Second Artillery Engineering College. Dr Xizheng Ke is a member of the editorial board of *Journal of Electronics*, *Infrared and Laser Engineering*, *Journal of Electronic Measurement and Instrument*, *Laser Technology*, *Applied Optics*, *Journal of Xi'an University of Technology*, *Journal of Time and Frequency*, and *Journal of Atmospheric Science Research*. He is the national expert for reviewing science and technology awards and a member of the disciplinary review group of the Shaanxi Academic Degrees Committee. In 2000, Dr Xizheng Ke won the Outstanding Young Scholar Award of the Chinese Academy of Sciences. In 2009, he was awarded the title of "Outstanding Science and Technology Commissioner of Guangdong Province" by the Ministry of Science and Technology. In 2015, he was awarded the title of "A Golden Phoenix on Green Poplar" in Yangzhou City. In 2018, he won the China Industry-University-Research Innovation Award,

and in 2019, he won the China Industry-University-Research Innovation Achievement Award. Since 2001, he has won 16 provincial and ministerial science and technology awards, including 1 first prize and 5 second prizes. He has obtained more than 20 nationally approved invention patents, published 9 monographs in Science Press, and published more than 400 academic papers in domestic and foreign journals. More than 30 PhD students have been trained under his direction.

Abstract

Optical wireless communication is an emerging wireless communication technology, which has faster transmission speed, higher bandwidth, and lower power consumption compared with traditional communication technology. This chapter systematically summarizes the development status, system composition, and key technologies of optical wireless communication at home and abroad. The key technologies and technical difficulties are analyzed, and the future development trend of space laser communication is summarized, which points out the direction for the future research and development of space laser communication.

Introduction

Compared with traditional radio-frequency (RF) communication, optical wireless communication has the advantages of high capacity, good confidentiality, light weight, low power consumption, strong anti-interference ability, and abundant frequency resources. Compared with fiber-optic communication, optical wireless communication can transmit under special link conditions, such as interstellar, star–ground, and air–ground, and can save expensive fiber-optic laying and maintenance costs.

These advantages make space optical communication technology an important research direction for a new generation of information and communication technology. Space laser communication, ultraviolet (UV) nondirect vision communication, visible-light communication, and blue–green light underwater communication are all important application scenarios for optical wireless communication.

Optical wireless communication includes two systems: intensity modulation/direct detection, which can also be called direct detection, and higher-order modulation/coherent detection, which can also be called coherent optical communication. The higher-order detection uses a local oscillating light source at the receiver side to coherently demodulate the received signal.

In terms of modulation and demodulation, coherent optical communication systems have many advantages over direct-detection systems, such as high sensitivity, a longer communication distance, many different modulation/demodulation methods, and the abilities to filter out very strong background light, select different light wavelengths for communication without significant wavelength restrictions, and recover damaged signals through digital signal processing algorithms.

Although optical wireless communication technology has many advantages, its disadvantages somewhat limit its application prospects. In an optical wireless communication system, the atmospheric channel characteristics can seriously interfere with the propagation of a signal beam containing information. This can cause light-intensity flicker, spot drift, beam expansion, phase undulation, pulse spreading, beam bending, and drift. These seriously reduce the uniformity and stability of the received optical signal. In addition, scattering and absorption will weaken the beam energy.

With increased communication distance, a strong turbulence environment, large optical system aperture reception, and other conditions, the laser output power gradually increases, the laser-cavity mirror suffers from thermal deformation, and the beam wavefront undergoes phase distortion, which reduces the beam quality. This directly leads to an increased communication error rate, is not conducive to establishing a stable communication link, and in serious cases, will interrupt communications.

To reduce the abovementioned atmospheric effects on wireless coherent optical communication and improve the system performance, corresponding measures must be taken to suppress the atmospheric effects when designing the system, so that the optical wireless communication can adapt to the long-distance, high-speed, and low transmission bit-error rate (BER) requirements.

Research on atmospheric turbulence suppression and performance compensation techniques has been conducted, and various methods to suppress atmospheric turbulence effects on wireless coherent optical communication systems have been proposed. These include large-aperture reception, diversity transceivers, partially coherent optical transmissions, coding and modulation, time-domain and threshold optimization, and adaptive-optics techniques.

Optical Wireless Communication Development Status

Foreign Development Status

In 1880, Alexander Graham Bell, a famous American inventor, developed the "optical telephone," which was the first time light was used as a carrier to send information, using the atmosphere as a transmission medium. This is regarded as the beginning of modern optical wireless communication [1]. After the development of the first solid-state ruby laser, the spectrum, coherence, directionality, and other light-source characteristics were improved, and research on optical wireless communication gradually entered the experimental stage [2]. However, owing to the limitations of early device performance and external factors, such as atmospheric channels, research on optical wireless communication was stagnant for a long time, while fiber-optic communication technology flourished and was widely used.

In the 1970s, as technologies were updated, optical wireless communication again became the focus of worldwide attention, and various military organizations tried to apply it to their equipment. The military and aerospace institutions of Europe, the United States, and other advanced countries successfully conducted numerous experiments on optical wireless communication transmissions.

In the 1980s, optical wireless communication technology was combined with wavelength-division multiplexing (WDM) access, optical amplification, and adaptive optics, which greatly improved optical wireless communication in terms of the transmission distance, transmission capacity, reliability, etc. In the late 1980s, some manufacturers began to develop commercial optical wireless communication technology, solving a series of key problems, and further reducing the cost. By the 1990s, optical wireless communication technology was widely used in civilian products.

In the late twentieth century, early major twenty-first-century communications companies began to research and apply optical wireless communication technology on a large scale. In recent years, with the continuous development of erbium-doped fiber amplifiers, adaptive optics, coherent detection, and other technologies, the transmission distance and reliability of wireless laser communication have greatly improved and it has re-emerged as a hot research topic.

United States

The United States was the first country to study free-space optical communication technology. Since the 1960s, it has conducted numerous experiments on optical communication under various scenarios. As early as the mid-1980s, the

Massachusetts Institute of Technology's (MIT's) Lincoln Laboratory built an experimental interplanetary laser-outlier coherent detection communication system using frequency-shift keying modulation, with modulation rates up to 220 Mbit/s. The performance of each module of the system was tested in a space environment. However, the project failed to conduct actual flight tests and only completed demonstration experiments on the ground [3].

In 1981, the US Air Force conducted a demonstration experiment between ground stations and aircraft, using a frequency-doubled yttrium–aluminum–garnet (YAG) laser with a 532-nm wavelength. The communication distance and rate reached 100 km and 1 Gbit/s, respectively. They also successfully demonstrated wireless light detection and ranging (LIDAR) [4].

In 1998, NASA's Jet Propulsion Laboratory (JPL) conducted a terminal system-level assembly and performance test of an optical communication demonstrator using a laser communication terminal measurement station [5]. Ground-based optical-link experiments were conducted at a distance of 4 km. The ground terminal used for the demonstration experiments was the Optical Communications Telescope Laboratory (OCTL); its construction was completed by the JPL in 2000. This laboratory was used to study the performance of multiple laser transmissions in space, allowing optical communication with both low and synchronous orbit terminals [6].

In February 1998, Lucent Technologies, Inc. built an experimental system for optical wireless communication with a rate of 10 Gbit/s for inter-near-earth links. Because the signal-light transmission was in the atmosphere, the communication distance was limited by the atmosphere's complex environment; the thermal expansion and contraction of buildings also affected the collimation of the beam. The Astro Terra company added an automatic tracking system to correct the influence of buildings, thus maintaining the beam collimation. In August of the same year, Lucent and Astro Terra successfully tested a prototype of a optical wireless communication system with a 1.5-km link distance and 1.5-Gbit/s data rate [7].

In 2000, the Tri-Service Experiments 5 (TSX-5) satellite was successfully launched. It carried an on-board optical communication terminal; however, the position and attitude-control accuracy of the satellite was not considered in the design. Consequently, the on-board optical communication terminal was never able to capture and track the signal light emitted from the optical ground station, despite a dozen link attempts [8].

In 2008, the United States and the German Space Agency (DLR) initiated an international collaboration to explore the capability of high-rate coherent laser communication through the atmosphere, establish a communication link, and test the performance of terrestrial laser communication terminals. In the same year, NASA launched the Deep Space Optical Communications Program, which included the Lunar Laser Communications Demonstration. Its aim was to verify the feasibility of laser communications between Earth and the moon, using small, lightweight communication terminals [9].

By 2013, the MIT Lincoln Laboratory had developed an onboard optical communication terminal. On September 6, 2013, the successful liftoff of the terminal

aboard the Lunar Atmosphere and Dust Environment Explorer spacecraft marked the beginning of NASA's Lunar Laser-Communications Demonstration Validation Program in-orbit experiment. The program was designed to validate two-way laser communications between the on-board optical communication terminal and an optical ground station. This was the world's first laser communication program at a lunar–terrestrial distance.

Considering the weather, three optical ground stations communicated with the onboard optical communication terminal: one primary and two backups. These included the terrestrial optical communication terminal at White Sands, New Mexico, the Lunar Laser Communication Telescope Laboratory terminal at the Table Mountain Facility in California, and the Lunar Optical Ground System, the European optical ground system for laser communication at Tenerife, Canary Islands [10]. In October 2013, the first bidirectional lunar–terrestrial laser communication was successfully carried out between an onboard optical communication terminal and a terrestrial optical communication terminal. It had an uplink data transmission rate of up to 20 Mbit/s and a downlink data transmission rate of up to 622 Mbit/s.

In 2017, the Deep-Space Optical Communications program returned data from Mars at a rate higher than 250 Mbit/s over a communication distance of approximately 630-million km, with a 28-kg terminal mass and 76 W of power [11].

The primary optical ground station for the Lunar Laser Communication Demonstration program was designed and built by Lincoln Laboratory [12]. The optical antenna of this ground station had a space diversity design that suppressed the effects of atmospheric turbulence on the uplink and downlink transmissions; it was scalable, cost-saving, and easily movable. The optical antenna, which included a glass-fiber temperature-controlled housing, was approximately 4.5 m high and weighed approximately 7 t. This is a reduction of approximately 75% in size and weight, compared to conventional radio ground antennas.

The optical antenna contained four homemade refractive-transmitting telescopes with 15-cm apertures, each connected to a transmitter in the control room via a single-mode fiber, which could send an uplink signal light with 10 W of power. In addition, it included four commercial Cassegrain reflecting receiving telescopes with 40-cm apertures. Each telescope coupled the received downlink signal light into a multimode fiber and detected it through an array of photon-counting superconducting nanowires in a control room [13].

On June 5, 2014, the NASA-JPL Optical Communications Telescope Laboratory (OCTL) optical ground station successfully received a 175-megabyte high-definition video called "Hello, World" from an optical communications terminal installed on the International Space Station (ISS) in 3.5 s. This was a data rate equivalent to 50 Mbit/s and marked the success of the Optical Communications Telescope Ground Station demonstration experiment. The Optical Communications Telescope Ground Observatory is a part of the Jet Propulsion Laboratory's Phaeton program. Owing to cost constraints, the Optical Communications Telescope Ground Observatory was designed and built by the JPL using commercial off-the-shelf components, with a design mission run time of 90 days. The project was designed to prepare the ground station for optical communications and low-orbit satellite experiments [14].

The successful liftoff of two 1.5-U CubeSats by NASA in 2017 marked the implementation of the Optical Communications and Sensors Demonstration Validation Program in-orbit experiment. It was designed to validate high-speed laser communications between CubeSats and with optical ground stations. The mission successfully conducted laser communications between CubeSats and optical ground stations in August 2018, with uplink data transfer rates of up to 10 kbit/s and downlink data transfer rates of up to 200 Mbit/s.

The US Marine Corps tested a tactical line-of-sight optical communications network at US Army Camp Hansen in Okinawa, Japan, on August 21, 2018, to observe its performance in a wet, variable weather environment. In 2013, the tactical line-of-sight optical communication network demonstrated a 100 Mbit/s high-resolution image- and video-transmission capability of over 50 km in evaluation tests [15].

In September 2021, Alphabet, Google's parent company, opened the Taara research project to develop an atmospheric laser communication system to establish a laser communication link with a 20-Gbit/s communication rate and 5-km communication distance between the cities of Brazzaville and Kinshasa in the Democratic Republic of Congo. It transmitted 700 TB of data over broadband Internet in 20 days [16].

In October 2023, NASA plans to conduct an exploration mission to Psyche, an asteroid located between Mars and Jupiter whose main components are iron, nickel, and rare metals (gold, platinum, copper, etc.). The mission will include a deep-space optical communication terminal and a technology demonstration of the Deep-Space Optical Communication project [17]. One of the two main objectives of the Deep-Space Optical Communications project is to validate the high photon-efficiency reception technology recommended by the Space Data Systems Advisory Committee [18]. This standard uses the technical solution of a photon-counting receiver and a high-peak-power transmitter that can deliver several bits of information per detected photon. The second objective is to demonstrate acquisition, tracking, and beam-pointing control techniques in deep-space links.

The Deep-Space Optical Communications project consists primarily of the following:

1. A vehicle laser transceiver capable of receiving a 1064-nm uplink/beacon laser and transmitting a 1550-nm downlink laser.
2. A ground-based laser transmitter (GLT) located at the Optical Communications Telescope Laboratory in California to transmit 1064-nm uplink/beacon lasers.
3. The Hale Telescope at Palomar Mountain, California, which was used as a ground-based laser receiver with a tungsten-silicide superconducting nanowire single-photon detector array with photon-counting reception capability.
4. The Mission Operations Center, which is responsible for overall coordination.

The downlink uses a serial cascaded pulse position modulation coding method with a 4-W transmit power and communication rates of approximately 132 Mbit/s and 2 Mbit/s at distances of 0.25 AU and 2 AU, respectively (one astronomical unit

(AU) is the average distance from the Earth to the Sun, which is approximately 150 million km.). The uplink uses low-density parity check coding and a communication rate of approximately 1.6 kbit/s at a 1-AU distance.

Europe

In the late 1970s, the European Space Agency researched and developed high-speed laser signal modulation technology and evaluated the corresponding modulators. This event was considered the formal entry of the European Space Agency into the field of free-space optical communications. Subsequently, the success of the European Space Agency's Semiconductor Laser Inter-satellite Link Experiment (SILEX) and the German laser communication terminal on the TerraSAR–Xsatellite (LCTSX) marked the beginning of Europe's development in the field of free-space optical communications. The success of the German LCTSX project marked a new era in the development of optical communications in Europe [19].

From 2003 to 2009, the European Space Agency conducted up to 393 two-way free-space optical communications between the Earth and stars, using the ARTEMIS satellite and optical ground stations. Experimental statistics show that its communication success rate reached 91%, and its total communication time reached 78 h [20].

In 2002, the DLR started the LCTSX program, which aimed to conduct satellite–ground coherent laser communication experiments, with two sets of laser communication terminals using binary phase-shift keying/coherent detection. The terminals were mainly developed by Tesat–Spacecom. The company used a neodymium-doped (Nd):YAG solid-state laser with a frequency stability of 50 MHz per day, linewidth of approximately 5 kHz, and 1064-nm operating wavelength, as the main light source in its development.

Subsequently, in 2005, the company conducted a spatial optical communication test at a rate of 5.625 Gbit/s and communication distance of 142 km on the islands of Tenerife and Palma, Spain. This experiment verified the performance of a laser communication system based on binary phase-shift keying and zero difference detection in a near-surface atmospheric environment and provided valuable experience for subsequent optical communication between satellites [21].

After completing these experiments, the researchers conducted a coherent optical communication experiment between the satellite and ground station with a communication distance of approximately 1000 km at Haleakala Volcano in 20010. The experiment was performed without the assistance of adaptive optics. Therefore, to reduce the impact of the wavefront distortion introduced by the atmosphere on the system, researchers minimized the receiving aperture of the ground station, while maintaining the receiving power.

During the course of the experiment, the researchers found that the BER of the satellite-to-ground downlink was relatively high, compared to the ground-to-satellite uplink. Finally, after analysis, it was unanimously concluded that this phenomenon was due to the limited transmit power of the transmitter carried by the satellite [22]. Thereafter, several improvements were made to the system in Germany, based on the experimental results, such as increasing the transmitting power and aperture. The improved system was named LCT-TDP1.

Owing to the success of the SILEX and LCTSX programs, at the end of 2008, the European Space Agency began to implement the European Data-Relay System (EDRS) program, which aimed to build a 1.8 Gbit/s space data highway between low-earth orbit (LEO) satellites and ground data centers through two synchronous orbit relay satellites (EDRS-A and EDRS-C). EDRS-A, an onboard optical communication terminal, was successfully lifted into its intended orbit on Eutelsat 9 B in January 2016, and EDRS-C was launched in August 20110. Prior to this, the synchronous orbiting satellite Alphasat and low-orbiting satellites Sentinel 1A and Sentinel 2A, the forerunners of the EDRS program, were launched between 2013 and 2015, respectively [23].

According to Airbus, as of May 18, 2018, the EDRS-A satellite had completed 10,000 laser connections with 910.8% reliability and had transmitted 500 TB of data. The European Space Agency planned to expand the EDRS program with the launch of another synchronous orbit relay satellite (EDRS-D) to become a data relay communication system with global coverage by 2020 [24].

In 2018, Germany used an airborne terminal, MLT-70-ATG, and an optical ground station, GS-200, in the FALCON project. Laser communication with a 10-Gbit/s communication rate and 10-km communication distance was achieved between the stratosphere and ground [25].

In 2019, Russia used the Artolink M1-GE-L model optical transceiver for building-to-building space laser communication experiments, with a communication wavelength in the 1550-nm band, link distance of 4.4 km, and rate of 1.25 Gbit/s. A design with a local static servo mechanism was selected. The weight of the optical transceiver was 9 kg, the system volume was 480 mm $\times$ 300 mm $\times$ 285 mm, and the power consumption was 46 W. In 2020, Russia used the improved Artolink M1-10GE model optical transceiver, and the communication rate increased to 10 Gbit/s with a 1.5-km communication link distance.

In 2021, Oxford University, UK, and Airbus Operations, UK, implemented reverse-modulated free-space laser communications between the ground and commercial unmanned aerial vehicles (UAVs). The system used an electrically absorbed modulator to modulate a backward reflector to establish a data link. The backward reflector had an effective aperture of 11 mm and a full field of view of 6.4°, achieving a 500-Mbit/s communication rate at a 560-m communication distance with a 8.6×10^{-4} BER [26].

Japan

In 1985, the National Space Development Agency (NASDA) of Japan began research on intersatellite laser communication from capture, tracking, and targeting technology, followed by system research and development. In 1986, Japan conducted a large number of research experiments with the United States [27].

Japan proposed the ETS-VI program in 1994 and ground stations successfully communicated with a satellite carrying a laser communication system developed under the program. Japan also proposed the Optical Inter-orbit Communication Engineering Test Satellite Program, which aimed to develop a miniaturized satellite test platform for optical communication in space [28]. In 2000, Japan developed a

two-way ultra-high-speed laser communication terminal to the Earth for use on the International Space Station. It was installed on an experimental platform called the "Kibo" loadable experiment module [29].

In 2006, the National Institute of Information and Communications Technology (NICT) of Japan conducted a two-way communication test with a ground station of the German Space Agency (DLR). The results showed that the BER of the data transmitted from the ground station to the Japanese satellite was only 10^{-7}, which once again verified the laser communication capability between the ground and LEO satellite.

Laser communication equipment also successfully achieved two-way laser communication with KODEN, an optical ground station located in Tokyo. This was the world's first laser communication experiment between a low-orbiting satellite and an optical ground station; an experimental study of uplink multibeam emission technology was also conducted [30].

A satellite-based coherent optical communication receiver, designed independently by the NICT of Japan, was successfully developed in 2009. The receiver adopted a zero difference coherent detection scheme and performed recovery operations on the carrier frequency and phase of the signal using a digital signal processing unit embedded in a field programmable gate array on board. The results showed that the receiver could demodulate binary phase-shift keying signals at a rate of 3 Gbit/s and orthogonal phase-shift keying signals at a rate of 6 Gbit/s [31].

Ten-Gbit/s bidirectional laser communication was achieved between ground stations and synchronous orbiting satellites in 2021. The related technology will be gradually applied to other aspects, such as space ranging and satellite networking. Japan will eventually achieve the goal of using its free-space optical communication technology to create a comprehensive information platform.

Domestic Development Status

Changchun University of Science and Technology has conducted laser communication experiments between the ground, ships, and aircraft. In 2007, a dynamic laser communication experiment with a horizontal channel between a ship and the ground was conducted. In 2011, two-way laser communication experiments were conducted, including a dynamic horizontal channel between two ships, a double dynamic oblique-range channel between an airship and a ship, and a double dynamic airborne horizontal channel between two helicopters.

In 2013, experiments were conducted on dual dynamic long-range and high-rate laser communication between two Y-12 aircraft. In 2015, a laser communication optical terminal between LEO-synchronous orbits was designed and developed, and in 2016, a laser communication optical terminal for synchronous orbit to ground communication was developed [32].

In 2011, a laser communication terminal was successfully launched onboard the OceanSat-2 satellite, which conducted a two-way laser communication test between

the satellite and ground base station. A laser link was established and stable communication was achieved [33].

The University of Electronic Science and Technology has researched intersatellite laser communication, satellite–ground laser communication, and other related fields. These include intersatellite optical communication capture and tracking technology, weak-beacon optical signal processing technology, satellite–ground coherent optical communication technology, and high-precision alignment information acquisition methods [34].

The Shanghai Institute of Optics and Precision Machinery, Chinese Academy of Sciences, has carried out a series of studies on the development of interplanetary and terrestrial laser communication coherent detection devices, optical phase-locking technology, and underwater optical communication [35].

Wuhan University realized laser communication between ships and shore buildings in 2013, and 1.5 Gbit/s high-speed laser communication between ships and shore buildings in 2018. The ship was able to maintain high-definition video communication while sailing [36].

The Air Force Engineering University has conducted research in the fields of space laser communication, star–ground laser communication, unmanned aerial laser communication, and visible-light communication [37].

From late 2016 to early 2017, the high-speed satellite–ground coherent optical communication terminal developed by the Shanghai Institute of Technology and Physics, Chinese Academy of Sciences, successfully carried the "Mozi" satellite to complete dual communication in orbit. The uplink used pulse position modulation with a 20-Mbit/s communication rate; the downlink used binary phase-shift keying modulation with a 5.12-Gbit/s communication rate [38].

Since 2014, the Institute of Optoelectronics Technology, Chinese Academy of Sciences, has developed a coherent optical communication system for long-range satellite–ground free-space communication and analyzed the improvement of its BER after adopting adaptive optical correction. In 2018, a ground station for satellite–ground laser communication was established. In addition, joint experiments were conducted on coherent laser communication between a synchronous orbiting satellite and the ground, by the Fifth Institute of Aerospace and the Institute of Optoelectronics. The laser communication terminal onboard the Practice 20 satellite platform was launched in the second half of 2019 [39].

The Anhui Institute of Optics and Precision Machinery, Chinese Academy of Sciences, has investigated light-wave transmissions in the atmosphere, including constructing observation fields for atmospheric-radiation parameters, and atmospheric-optical parameters. They also investigated the principles and methods of atmospheric-optical parameter measurement and developed key equipment. Long-term atmospheric radiation, optical parameter measurement, and database establishment were also studied [40].

In recent years, the Xi'an University of Technology has conducted in-depth theoretical exploration and experiments on the characteristics of laser transmissions in atmospheric turbulence, coding and decoding wireless laser communication systems, optical wireless subcarrier modulation, channel estimation and

equalization, and alignment tracking and capture techniques. It has also investigated coherent detection techniques, the design of optical transceiver systems, optical orthogonal frequency-division multiplexing modulation, optical multiple-input multiple-output systems, and optical wireless transmission theory and technology in complex environments.

In 2016, a space laser communication system terminal with an intensity modulation/direct detection method was successfully developed. It had standard Ethernet data access capability and could reliably transmit duplex data, voice, and images. Since 2017, the Xi'an University of Technology has successfully developed a differential binary phase-shift keying modulation communication terminal for an external differential coherent detection system, in cooperation with the China Academy of Space Research, with funding from the National Natural Science Foundation of China and major industrial chain projects in Shaanxi Province. It also began research on optical wireless communication network systems with ultra-long-range transmission and communication code rates (5–10 Gbit/s).

In 2018, the team developed a 10-km outfield experiment with an integrated transceiver and successfully transmitted video and voice signals. In 2021, the team initially developed a near-infrared-band space laser communication system with an intensity modulation/direct detection mode, with a maximum transmission rate of 10 Gbit/s. It used image tracking at the transmitter side and two-dimensional reflector control at the receiver side to suppress atmospheric turbulence. The system uses a non-co-axial operating system at the transmitter and receiver sides and achieves fast beam alignment with a 100-km link on the ground.

The development trends of space laser communication systems are in the direction of large bandwidth, high reliability, and beacon-free light and are moving from point-to-point transmission to point-to-multi-point transmission. Application scenarios are developing from initial space laser communications to terrestrial space laser communications. Moreover, 6G is also considered for application in space laser communication.

Space laser communication in atmospheric turbulence has been investigated, as well as traditional transmitters and receivers with centralized control of the common axis alignment tracking and capture technology, and transmitters and receivers with independent control of non-common axis technology development. These gradually reduce the dependence on a dynamic base on a stable platform.

Optical Wireless Communication Systems

Components of Optical Wireless Communication Systems

A complete wireless laser communication system is illustrated in Fig. 1.1. It includes an optical antenna (telescope), laser transceiver, signal processing unit, automatic follow-up system, and other components. The transmitter light source is a laser diode or light-emitting diode. After channel coding and modulation, the laser is used for

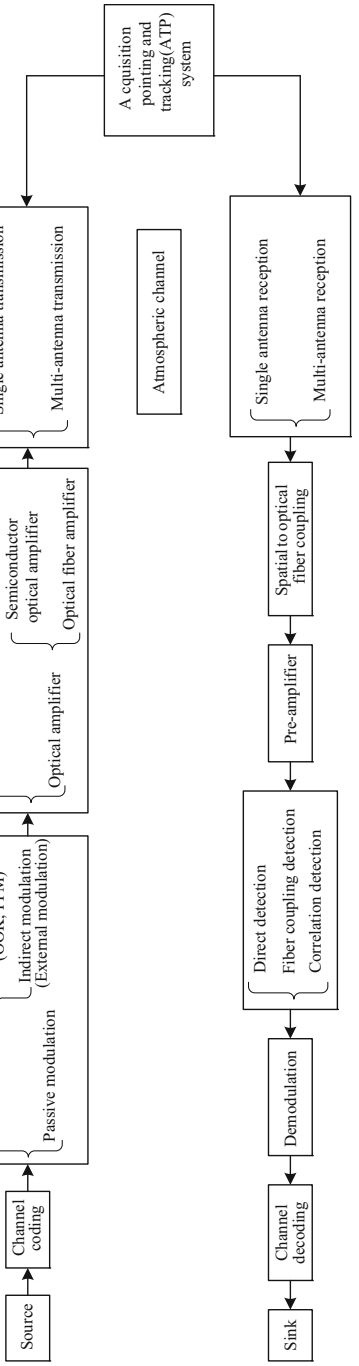

Fig. 1.1 Schematic diagram of a wireless laser communication system

direct output or amplified output by an optical amplifier. The beam is collimated by the transmitting antenna and transmitted through an atmospheric channel.

After being received by the optical antenna, the spatial light is coupled into a single-mode fiber by the optical-coupling module, amplified by the preamplifier, and then converted from an optical signal to an electrical signal by direct or coherent detection. It is then demodulated and decoded to finally complete the transmission from the source to the destination.

Features of Optical Wireless Communication Systems

Wide Communication Bandwidth and Large Information Capacity

Compared to microwaves, a laser carrier has a higher frequency and larger relative bandwidth, owing to its short wavelength, and its bandwidth is theoretically tens of thousands of times higher than microwave bandwidths. At present, transmission rates in fiber-optic communications have reached 1 Tbit/s; 100–622 Mbit/s terrestrial wireless laser communication systems have been practical. Demonstration experiments of a 5.65-Gbit/s wireless laser communication system have been conducted to verify the success.

Large Optical Gain and Small Laser Beam Dispersion Angle

When the antenna structure size is fixed, the shorter the wavelength, the greater the antenna gain, and the smaller the beam dispersion angle. Compared with microwaves, the wavelength of an optical wave is shorter; that is, the optical communication antenna has a higher gain. In addition, the laser beam dispersion angle is smaller than that of a microwave beam. Through the design of a moderate transmitting-antenna aperture, it is easy to achieve a laser beam dispersion angle on the order of microradians, which means better laser beam directionality and higher beam energy density. This feature makes the beam more conducive to long-distance transmissions in high-loss scenarios.

High Immunity to Electromagnetic Interference and High Confidentiality

Because the frequency band of a laser is far from the radio-frequency spectrum, laser communication is free from the interference of other electromagnetic waves in space. Its high confidentiality is reflected in the following:

1. The laser beam is extremely narrow and propagates in a straight direction; hence, it is not easily intercepted;
2. The laser communication beam is in the near-infrared band; this is non-visible light and also not easily detected;
3. Because the laser communication rate is higher, the transmission time is shorter under the same data-volume conditions; hence, it cannot easily be listened to.

Small Device Size, Light Weight, and Low Power Consumption

Because of the short wavelength of light waves (generally a few hundred nanometers to a few microns), according to the relationship between the antenna gain, beam angle, and antenna aperture, the wavelength year-on-year theorem states that the size and mass of an optical antenna in wireless laser communication are much smaller than those of an antenna in electromagnetic-wave communication. Meanwhile, the communication and beacon transmitter units generally use semiconductor lasers, which have low power consumption and high energy-conversion efficiency.

Problems of Optical Wireless Communication Systems

For the development of long-range, high-speed, and integrated practical wireless coherent optical communication technology, specific issues require further in-depth research.

Coherent Detection Must Satisfy More-Demanding Matching Conditions

Coherent optical communication requires a signal light and local oscillation light in the optical mixer to enable the mixing and balancing detector to convert the electrical signals. To meet the conditions of coherent detection, the signal-light and local oscillation-light linewidths must meet strict requirements. The signal light and local oscillation light must have the same wavefront phase, the polarization states must match, and the frequency difference must be within a certain range. The degree of matching between all factors directly affects the mixing efficiency of a wireless coherent optical communication system.

Matching the Complexity of the Adaptive-Optics Algorithm with the Atmospheric Environment

At present, most adaptive optics use the classical proportional–integral–differential control, and the time-varying characteristics of atmospheric turbulence limit traditional control algorithms. Intelligent control algorithms are used, typically based on the number of deformation-mirror drive units and wavefront sensor-array points, as well as the actual atmospheric environment, to make a comprehensive assessment and balance the practicality and control effect of the algorithm. The choice of the algorithm is based on the number of deformation-mirror drive units, wavefront sensor arrays, and the actual atmospheric environment.

Atmospheric Turbulence Reduces the Efficiency of Spatial Light-to-Fiber Coupling

A laser transmission through atmospheric turbulence reduces the spatial coherence of the beam, while the wavefront phase distortion caused by atmospheric turbulence significantly reduces the matching of the beam mode to the fiber mode for free-space transmissions. The coupling efficiency is reduced, which seriously affects the receiver sensitivity, BER, and other performance metrics.

Typically, single-mode fibers have a core diameter of less than 10 μm, which makes it difficult to couple spatial light into single-mode fibers in the presence of atmospheric turbulence. Multimode fibers can accommodate hundreds of single-mode fiber mode fields, because their maximum core diameter of over 61.5 μm allows for improved coupling efficiency with spatial light beams. However, multi-mode fibers are not compatible with existing single-mode fiber-based communication technologies, particularly in the field of coherent detection communications.

Atmospheric Turbulence Complicates Beam Alignment in Long-Range Optical Wireless Communication Systems

For point-to-point laser communication, a light beam with a divergence angle of approximately a micro-arc is used as the carrier for transmitting information. The prerequisite for establishing wireless laser communication is to maintain the precise alignment of the transceiver and transmitter view axes of both optical terminals. However, owing to the narrow beam and strong directional characteristics of a laser, the signal beam must be driven by the servo motor of a high-digit angle coder with extremely precise pointing; hence, it requires considerable time to complete the beam-capture process. This significantly reduces the practicality and efficiency of laser communication.

Key Technologies

High-Quality Optical System Design

Optical system design is one of the key technologies for space laser communication [41–44]. It is mainly reflected in the following three aspects.

Near Diffraction Limit Angle Optical System Design Technology

The beam generation quality can be mainly ensured by the integral beam expansion of the reflection light source and a two-stage telescopic system. This causes it to occur near the diffraction limit and is of great significance for enhancing the stability and safety of space laser communication.

Multi-optical Axis Consistency Mounting Technology

Laser communication systems generally contain five to seven optical axes. In the operation process, the multiple optical axes have high consistency requirements. This is mainly achieved through five-prism shift technology and assisted by charge-coupled device (CCD) subdivision detection technology to further ensure the efficiency of the application of this technology.

Optical Abutment Light and Small Design Technology

The main difficulty of this technology is that the system components are numerous, including dozens of optical components, lasers, acquisition, pointing, and tracking (APT) actuators, and transceiver components. Measures, such as laminated structure

design, modal analysis methods, and selecting lightweight, radiation-resistant materials, can be used to substantially improve the adaptability of space laser communications.

Fast, Accurate, and Stable Capture Alignment Tracking Technology

Highly accurate, precise, and stable acquisition, pointing, and tracking (APT) technology, for capturing alignment tracking under long-range conditions, is one of the most important technologies for space laser communication [45]. The specific implementation steps are as follows:

1. Determine the initial point and capture region.
2. Perform coarse tracking of the capture region.
3. Perform fine-tracking alignment.
4. Communicate the dynamic laser information between the two parties.

The keys to this process are the coarse and fine tracking. For coarse tracking, the scanning capture time is long and the capture probability is low, owing to the large uncertainty area and small beam dispersion angle. The solution is to use precision metering and pointing techniques to compensate for the capturing speed and vibration. For fine tracking, the tracking beam has a small beam dispersion angle and is easily affected by vibrations during the platform operation. The solution is to apply high frame rate camera detection to improve the communication effect and accuracy.

High-Rate, High Power-Emitting Lasers

To ensure that the system can effectively filter out background light, while providing the power required for the actual operation of space laser communication, space laser communication technology requires lasers with a high speed, high power, and narrow linewidth. Usually, high-speed laser emission technology involves external modulation, whereas high-power emission technology involves internal modulation.

For external modulation emission technology, the main technical difficulty is that the bias-voltage operating point of the electro-optical modulation crystal is greatly affected by temperature, that is, it has a high half-wave voltage at high power (inversely proportional to the length of the modulation crystal). The main technical approaches are to increase the peripheral temperature-controlled feedback circuit to suppress the bias-point drift, adopt a folded optical path to increase the optical range, reduce the half-wave voltage, and adopt multi-point lateral pumping to achieve high-power output.

For internal modulation emission technology, the main technical difficulty is meeting the high-speed, high-power, and high-quality requirements of the emitting laser source, that is, a low-power seed source, after amplification to meet the high

extinction ratio. The main technical approach is to develop a high-performance seed source laser and a high-gain amplifier.

Atmospheric Channel Impact Compensation Technology

It has been demonstrated through a large number of applications that laser beams in space laser communication will be affected by atmospheric turbulence when transmitting in the atmosphere. One example is laser energy attenuation, due to atmospheric absorption and scattering, which leads to system error codes; this is more obvious in high-speed laser communication. Another difficulty is atmospheric scattering and scintillation effects, which lead to laser spot-center shift and wavefront aberration problems.

To solve these problems, wide-range laser light-intensity stabilization and high-precision real-time wavefront aberration correction techniques can be used, respectively. The use of wide-range laser-intensity stabilization technology can ensure the signal-to-noise ratio of space laser communication. Using high-precision real-time wavefront aberration correction technology can suppress the influence of atmospheric turbulence on a transmitted beam wavefront. For example, multiaperture wavefront detection using a Hartmann sensor can correct wavefront aberrations to a certain extent.

However, the main difficulty of high-precision real-time wavefront aberration correction technology lies in the compensation of laser arrival-angle undulation, wavefront deformation, and the influence of the attached surface layer during air flight. These can be jointly corrected by introducing wavefront aberration compensation mirror technology into the detection system.

Summary

At present, radio communication is limited by frequency resources and transmission rates, and it has been difficult to meet the requirements of large-capacity data transmissions. Laser communication has a high transmission rate, strong anti-interference, and small size, which can break the low transmission rate bottleneck of traditional RF communication. In addition, unlike RF communication, laser communication is not regulated by the International Telecommunication Union (ITU) and does not require expensive band license fees, which gives it the advantage of a lower cost. Therefore, satellite laser communication has become an important means of high-speed communication for satellites and other space vehicles and has become a popular research topic in recent years.

This chapter compared the development of space laser communication technology at home and abroad and presented typical space laser communication demonstration tests. It analyzed the key technologies and technical difficulties, summarized the future development trends, and discussed directions for the future research and development of space laser communication.

Space laser communication is conducive to the realization of seamless global coverage, barrier-free communication, and the construction of an integrated global heaven-and-earth communication network. It also helps researchers in China understand the vision and planning of developed countries over time, which provides a reference for China's future space laser communication technology research.

Abstract

Satellite laser communication network through space laser communication technology make up for the use of microwave wireless communication in satellite network, while having the global coverage capability of satellite network; it has the advantages of high data transmission rate, large communication capacity, low power consumption, small antenna size, strong anti-interference ability, and so on. This chapter summarizes the research progress of satellite laser communication networks at home and abroad, introduces the key technologies of satellite laser communication, and describes important parts such as orbits, inter-satellite links, and routing algorithms of satellite laser communication networks. Finally, the full chapter is summarized and the development direction of satellite laser communication network is prospected.

Satellite laser communication · Satellite networking · Inter-satellite laser link

Introduction

Conventional satellites use Ka- and Ku-band microwaves for communication, which limits the communication capacity of communication satellites to a certain extent. Satellite laser communication has the advantages of being frequency independent, having a large bandwidth, high transmission rate, and good confidentiality; its load and communication terminals are both small in size, light in mass, and low in energy consumption [1].

Recently, there has been a global boom in satellite networking, and countries have invested in satellite laser communication network construction, competing for space spectra, orbits, and other resources. With the widespread application of multisource remote sensing technologies, such as high space, high spectrum, and high time domains, a large number of requirements for space-based information services have been proposed. However, it has been difficult for single-satellite relays to meet the growing service demand. Satellite laser networks, jointly constituted of multiple satellites, have become an inevitable trend for future communication development.

Satellite Laser Communication

Satellite laser communication uses a laser beam as a carrier wave for direct two-way transmissions of voice, data, and image information in space. Laser communications can be divided into two categories: space and atmospheric. The former is mostly used for inter-satellite communication, interstellar communication, spacecraft, and space stations in vacuum conditions; the latter is used in a wide range of applications, mainly for connections between satellites, land and sea users, and aircraft.

A satellite laser communication system consists of three parts: the ground station, satellite, and user terminal. The ground base station uses an optical antenna to send a laser signal to the satellite, which receives the signal and sends it to the user terminal. They are widely used in inter-satellite communication, remote sensing, and navigation.

Compared with traditional microwave communication technology, satellite laser communication technology has the following advantages:

1. Large communication capacity: The frequency of a laser is three to four orders of magnitude higher than that of a microwave, and the frequency band is wider, allowing for large-scale data transmissions in a shorter period.

2. High communication rate and low power consumption: High-speed communications of 10 Gbit/s or more can be achieved. Owing to its highly concentrated energy and small beam-divergence angle during transmission, a laser does not diffuse easily and consumes less energy than microwave communication.
3. Strong resistance to interference: The laser beam-scattering angle is very small, which is not easy to detect or interfere with.

Satellite laser communication technology also has the following shortcomings and problems:

1. Vulnerability to external environmental factors. These include the influence of the atmospheric environment, space ambient-temperature changes, background light, platform vibration, and relative motion.
2. Sensitivity to external environments, such as atmospheric environments: Fog, rain, snow, and hail can attenuate a laser transmission in the air; thermal coronas, atmospheric turbulence, and airborne suspended matter can all reduce the quality of a laser transmission.
3. Influenced by temperature change: Because each functional module in the laser communication system is located at different locations of the load terminal, a temperature gradient will be generated. Each module material is different, and the coefficient of thermal expansion is also different. A temperature gradient will lead to the deformation of the mechanical structure, which has a greater impact on the installation, as well as the acquisition, pointing, and tracking accuracy of the system.
4. Affected by background light: Background light, such as daylight and moonlight, may interfere with interstellar links, thereby reducing the transmission quality and reliability of the communication system.

Foreign Research Progress

In 1995, the theoretical concept definition and transmission layer design of satellite laser communication networks were investigated by the Information and Decision Systems Laboratory at MIT, and Chan et al. completed a large number of theoretical design definitions and other work related to satellite laser networks, which were important for the development of satellite laser communication networks [2].

In 2000, Karafolas et al. proposed an optical wavelength division multiplexing (WDM) network for application to satellite constellations, analyzed the constellation characteristics of interstellar laser links, and presented the existing problems [3].

In 2001, Ors et al. investigated methods to apply Internet-protocol quality of service (IPQoS) to satellite networks using multiprotocol label switching and described the problems and solutions of this technique [4].

In 2001, Ekici et al. proposed a new distributed routing algorithm called the datagram routing algorithm. This routing algorithm combines virtual nodes with distributed policies to calculate the shortest delay path; it only needs to know the location of the destination satellite to transmit the packet directly [5].

In 2004, Donner et al. proposed a satellite networking concept based on multi-protocol tag switching and explored various networking schemes, according to the characteristics of a dynamic topology [6].

In 2007, Papapetrou et al. proposed a location-assisted distributed routing algorithm that utilized the concept of wireless self-organizing networks to balance the transmission load and increase the data transmission rate [7].

In 2007, Papapetrou et al. applied a location-assisted on-demand routing algorithm to satellite communications. Simulation results showed that the algorithm could reduce end-to-end delay and delay jitter, as well as improve the transmission efficiency of the system. They also designed a deterministic satellite-movement mechanism, based on the number of satellites involved in a traffic transmission [8].

In 2007, Korçak et al. proposed a new priority-based adaptive shortest-path routing algorithm that ranked the historical utilization of links and buffer information to select the appropriate next-hop link from multiple shortest links in a distributed manner. It effectively solved the network-congestion problem in high-latitude regions [9].

In 2011, Fu et al. proposed a routing algorithm for traffic engineering in multi-protocol label-switched networks, which could dynamically establish interstellar laser links with bandwidth guarantees to balance the network load [10].

In 2012, Kawamoto proposed a method for solving interstellar laser link blocking by recalculating the routing table at the ground receiver. This method improved the link-usage efficiency; however, it also introduced a large signaling overhead [11].

In 2013, Pan et al. proposed a minimum-contention routing algorithm that increased the utilization of network resources to a new level and allowed the network to accept more routing requests [12].

In 2014, Chaudary et al. investigated free-space optical communication based on orthogonal amplitude modulation (OAM) and orthogonal frequency-division multiplexing. They used a 10-Gbit/s data stream with a four-level OAM sequence transmitted through a free-space optical communication system in different atmospheric environments. The results showed that the maximum transmission distance was 185 km under ideal weather conditions and 2.5 km in fog [13].

In 2016, Fernls R et al. described the benefits of applying software-defined network/network-function virtualization techniques in satellite laser communications, proposed and analyzed three scenarios, and briefly described the challenges faced by this technique [14].

In 2016, Huang et al. proposed a virtual topology-based routing algorithm to address the challenges posed by the dynamic topology of low earth-orbit (LEO) satellite networks, which discretized the dynamic topology of the satellite network in time, where the topology of the satellite network was constant in each snapshot. The signaling gateway station could calculate the routing table in each snapshot in advance, without the need for real-time satellite calculations [15].

In 2017, Gardisis et al. investigated the application of software-defined networking/network-function virtualization techniques to the satellite communication domain, analyzing the benefits and challenges of integrating satellite infrastructure into software-defined networks [16].

In 2017, Lyras et al. developed a model for cloud-free line-of-sight probability prediction for single optical satellite links and multiple spatially separated optical satellite links by considering a combination of three perspectives: elevation angle, ground-station altitude, and cloud spatial variability [17].

In 2017, Khallaf et al. proposed a modulation method to create a hybrid of orthogonal amplitude modulation and multipulse position modulation over turbulence-free and gamma–gamma free-space optical channels, which had an improved bit-error rate (BER) performance compared to previous modulation methods [18].

In 2018, Lyras et al. analyzed the variation patterns of cloud-coverage statistics, which provided a theoretical basis for selecting optical ground terminals [19].

In 2018, Liu et al. investigated the joint layout of controllers and gateways in a converged network of 5G terrestrial and satellite networks, based on software-defined networks, and provided a solution that could obtain near-optimal delay, as well as maximum network reliability while satisfying delay constraints [20].

In 2019, Wang et al. proposed an adaptive routing algorithm that was applicable to a three-layer satellite architecture. It optimized information links with dynamic changes in the satellite topology to improve the dynamics and flexibility of satellite networks [21].

In 2019, Yang et al. proposed and analyzed a K-means network-partitioning algorithm for integrated satellite–ground networks combined with software-defined networks, which improved the network reliability performance and reduced transmission delay [22].

In 2019, Lyras et al. provided two optimization algorithms for medium earth-orbit (MEO) satellite networks operating in the optical band, both of which ensured the effectiveness of interplanetary links in the presence of cloud blocking and minimized the network size of optical ground stations [23].

In 2019, Liu et al. proposed a routing algorithm based on segmented routing for traffic return to address the load imbalance in LEO satellite networks caused by the uneven distribution of users in various regions of the world. Specifically, heavy- and light-load areas in a recursive network were dynamically divided according to the relative position relationship between the gateway and the reverse seam, and the corresponding routing strategies were adopted in different areas [24].

In 2020, Liu proposed a strategy based on a selective iterative Dijkstra algorithm and selective split-load balancing, which fully exploited the inter-satellite laser links in LEO satellite networks. In addition, for the link-congestion problem caused by uneven traffic distribution in LEO networks, this strategy could reasonably divert the congested nodes' traffic and reduce the load on other regional networks [25].

In 2021, Polnik et al. proposed two types of uncertainty models, based on the predicted cloud volume: robust optimization of polyhedral uncertain sets and robust optimization of matrix-based fuzzy sets. The performances of the different models

were analyzed and calculated, and based on this, a 6-month UK work plan for artificial satellites and ground-based observatories was developed [26].

Domestic Research Progress

In 2004, Chan et al. studied the constellation topology of space-based backbone networks and proposed a fast air-to-air communication scheme for handling space-based resources in orbit [27].

In 2006, Li et al. proposed a method to realize inter-satellite laser link communication networking based on WDM technology and established a WDM/optical code-division multiple-access-based satellite network by analyzing the topology of a satellite laser communication system combined with optical code-division multiple access [28].

In 2007, Yi et al. proposed a routing algorithm for a geosynchronous earth orbit (GEO)/MEO two-layer satellite network architecture, which uploaded data information from the MEO layer to GEO satellites through cluster management and cluster-head backup. The GEO satellites propagated MEO-satellite information to each other to better manage the lower-layer satellites [29].

In 2008, Qi et al. proposed a routing algorithm based on offline computation for LEO constellations. It provided a traffic-adaptive mechanism using backup paths while ensuring routing efficiency. Simulation results showed that the algorithm required only small on-star storage and processing overhead and had good end-to-end delay performance [30].

In 2009, Yang et al. studied satellite laser networks with a WDM architecture and found that network crosstalk had a significant impact on the network performance; simulation results showed that increasing the laser bandwidth effectively reduced the crosstalk [31].

In 2009, Li et al. proposed a global continuous-coverage LEO/MEO double-layer satellite optical network structure using the coverband method. The simulation results showed that the coverage of orbiting satellites in this structure reached 910.9% globally and 100% for domestic ranges [32].

In 2010, after analyzing the wavelength demand for laser transmissions in a non-geosynchronous satellite network, Tan et al. identified the factors affecting the wavelength demand. Simulation results showed that the wavelength demand was related to the percentage of active terminals, the maximum number of allowed inter-satellite link hops, and the inter-satellite link terminals per satellite [33].

In 2010, Tang et al. investigated satellite laser networks using wavelength routing, proposed an algorithm that could label their wavelength demand, and estimated the boundaries of the wavelength demand, based on the proposed wavelength-estimation algorithm [34].

In 2010, Li et al. proposed a set of two-layer LEO/MEO satellite laser networks with global coverage based on a zero phase factor. The network provided minimum pitch angles of 21° and 16° for single-satellite and double-satellite systems in China, respectively. Simulation results showed that the LEO constellation with a zero phase

factor had a great advantage in several performance parameters, such as azimuth and pitch angle. The difference between short- and long-wave bands was small at low traffic, which is well suited for inter-satellite laser links [35].

In 2014, Gao et al. proposed a routing algorithm that changed the manner in which the routing tables were calculated. Simulation results showed that the algorithm was only suitable for satellite networks with a small number of satellites and a simple topology [36].

In 2014, Yang et al. proposed a bandwidth-estimation transmission-control protocol algorithm based on link length. By optimizing the relevant parameters in the congestion window, slow-start threshold, and time-out retransmission timer, the congestion-control algorithm ensured high throughput during abrupt changes in transmission delay and was more suitable for the dynamic environment of satellite networks. Simulation results showed that the throughput performance of the bandwidth-estimation transmission-control protocol algorithm phase in the satellite network was improved by 2.8% compared to that of the transmission-control protocol algorithm, which effectively solved the problems caused by sudden changes in delay [37].

In 2015, Dong et al. investigated an ant-colony algorithm based on a small-window strategy to solve the problems of routing and wavelength assignment in satellite laser networks. Compared with Dijkstra's algorithm, the ant-colony algorithm reduced the blocking probability by up to 50% and improved resource utilization, especially in the case of low wavelength utilization, by up to 45% [38].

In 2015, Chen et al. designed a 2+2 satellite networking architecture, which was combined with the analytical approach of terrestrial-programmed switching technology to define the performance metrics of optical networks. Simulation results showed that this satellite network could support random access to 50 user satellites, while satisfying certain access-loss probabilities and resource utilization [39].

In 2015, Chen proposed a two-layer satellite-network routing algorithm using the predictability of the satellite position, which solved the problem of data loss due to inter-satellite links being cut off when in-orbit satellites entered higher-latitude regions. This greatly reduced the packet-loss probability of the laser network while improving the system reliability [40].

In 2017, Zheng et al. studied the topology of heterogeneous satellite laser networks, addressing the initialization and reconfiguration of the relaxation solution [41]. They also designed a distributed minimum spanning-tree algorithm for a distributed satellite laser network that improved the overall network performance and reduced the computational complexity of the system [42].

In 2017, Wen et al. proposed an ant-colony routing and wavelength assignment algorithm to address the negative effects caused by Doppler-wavelength shifts in satellite laser networks. Simulation results showed that the algorithm performed well in terms of communication success probability and had a good global-search capability [43].

In 2017, Xu et al. proposed an intelligent capacity-analysis method for satellite networks, designed a set of capacity models for satellite communication systems based on their characteristics, and introduced them to the capacity analysis of

satellite communication systems to achieve high computational efficiency and reduce the time overhead [44].

In 2018, Li et al. studied an optical burst-switching architecture for GEO/LEO two-layer satellite networks, focusing on the design of a resource-scheduling mechanism for space-based backbone networks, based on optical burst switching, to provide high-speed data transmission rates and high switching capacity [45].

In 2018, Liu et al. proposed a swarm-optimization algorithm to reduce the cost of laser links and comprehensively consider wavelength-resource utilization and communication hops to efficiently utilize wavelengths, reduce unnecessary bypassing, and guarantee the BER performance of the system [46].

In 2018, Liu et al. established a satellite laser network model and proposed an algorithm based on subtree merging and maximum algebraic connectivity. It effectively improved the algebraic connectivity of the satellite laser network while ensuring that the network topology had higher average edge weights [47].

In 2018, Zhang et al. proposed a multibeam switching mechanism to solve the problem of frequent beam switching due to software-defined networks, based on a traditional satellite network switching mechanism. It achieved high-precision and fine-grained switching by quantitatively analyzing the multiple metrics involved in the switching process [48].

In 2020, Liu et al. proposed a dynamic laser network wavelength-estimation method for the wavelength multiplexing problem in intermittent interstellar links and further analyzed the impact of topology changes on the wavelength demand. The simulation results showed that the higher the network connectivity, the better the network reachability. The wavelength requirement depends on the network connectivity and required reachability time [49].

In 2020, Peng et al. proposed a split-traffic sparse method, which is an algorithm that can satisfy the service traffic demand as much as possible while minimizing the number of wavelengths. It is suitable for sparing static traffic in large networks. This provides an effective approach for the sparse traffic design of wireless networks [50].

In 2020, Sun et al. proposed a super-satellite node computational storage-function algorithm that effectively reduced wavelength requirements and improved network connectivity. This study reduced the cost of onboard lasers, modulators, and establishing inter-satellite links, which was an important reference for establishing satellite laser networks [51].

In 2021, Zhang proposed two satellite communication-network routing algorithms around a low-orbit satellite network and low- and medium-orbit satellite network scenarios to address network-node failures and network-congestion problems [52].

In 2021, Wang et al. proposed a method to improve the capacity of satellite networks using network coding and divided it into two cases: network coding and non-network coding. Simulation results showed that the improvement in network capacity with the network-coding scheme significantly exceeded that with the

non-network coding scheme, and the improvement in network capacity increased with an increase in resources and network size [53].

In 2022, Liu et al. proposed a beacon step-tracking algorithm. Simulation results showed that the proposed tracking method was closer to the tracking performance of the program when the carrier's position and attitude changes were small, and it reduced the service-interruption probability when the user terminal accessed the satellite communication network [54].

In 2022, Zuo et al. proposed a path-selection method for dynamic LEO satellites, which used a path-selection model, built using deep learning, to automatically select paths based on information, such as spatial location, spacing, and available bandwidth of peripheral nodes. Simulation results showed that the algorithm had better delay characteristics, convergence, and generalization capabilities than typical distributed routing algorithms [55].

In 2022, an effective load-balancing algorithm was proposed by Zheng et al. for satellite–ground networks to reduce the propagation delay caused by high loads on ground network links. Simulation results showed that setting an adaptive overload threshold could effectively reduce the link congestion [56].

In 2023, Liu et al. proposed a star cross-cycle link-building strategy (SCLBS) to solve the reverse seam link-building problem for polar-orbiting constellations. Simulation results showed that SCLBS could reduce the data transmission delay of polar-orbiting constellations by 30–60%, compared with previous link-building strategies, which significantly improved the transmission performance of LEO satellite networks [57].

In 2023, Xie et al. proposed a quantum evolutionary algorithm based on an excitation function and processing delay to solve the distributed inference problem of deep neural networks in LEO satellite scenarios. Simulation results showed that the algorithm had both lower delay characteristics and higher overall utility, which could improve the efficiency of intelligent services in low-orbit satellite scenarios [58].

Key Technologies for Satellite Laser Communication

Satellite laser communication is a complex and difficult technology that involves many fields and disciplines, such as optics, mechanics, signal processing, mathematics, and computers. Optical technology mainly refers to high-power light-source technology and the design of high-quality optical systems. Signal-processing technology mainly includes modulation and demodulation, suppression of background noise, compensation for atmospheric-channel effects, and high-sensitivity detection. Mechanical aspects are mainly for the compensation of platform vibration and attitude and high-precision acquisition, pointing, and tracking technology (APT). This section focuses on key technologies in satellite laser communication research.

Key Optical Technology

Optical systems mainly involve wavelength selection and optical-path design. When selecting a wavelength, it is necessary to reduce the loss of optical signals through the atmosphere and the influence of solar radiation, as well as ensure a high response to the detector. With the continuous development of communication services, satellite optical-communication systems often require multiple wavelengths to be transmitted in parallel to guarantee service-transmission quality and bandwidth.

The wavelengths often used between the satellite and ground link are 1550 nm, 850 nm, and 1000 nm. Specific wavelengths should be selected and designed according to the different transmission methods, transmission environments, and service requirements. In satellite laser communication systems, optical antennas are used to transmit and receive optical signals. Traditional optical-antenna technology has become more mature; however, with the development of miniaturized laser communication satellites, the volume and weight of traditional satellites cannot meet these new requirements.

Key Signal-Processing Technologies

The choice of optical-signal modulation and demodulation technology in satellite laser communication requires the consideration of several aspects, including optical-power efficiency, frequency-band utilization, information transmission rate, and interference resistance. Spatial filtering and signal modulation methods are commonly used to reduce the impact of background noise on optical-signal transmissions. Factors, such as the angle of arrival, Doppler shift, and laser linewidth, were considered in the filter design [59].

One of the most widely used modulation techniques for suppressing background noise is multipulse position modulation, which is often used in conjunction with other modulation methods to improve the transmission efficiency of optical signals.

APT Technology

Highly efficient acquisition, pointing, and tracking technology is key to realizing satellite laser communication; it is especially the top priority when building a satellite–ground link. The system consists of two parts: a coarse-tracking system in the acquisition phase and a fine-tracking system in the pointing and tracking phases. The coarse-tracking system is first used to scan a large area, and when the transmitted signal is captured, the fine-tracking system is used to scan a small area. Using these two tracking systems in combination, fast and robust signals are captured.

Opto-Mechanical Design Technology

To reduce the power loss of a laser transmission in free space and increase the gain of the optical system at the transmitting end, the transmitted beam must be emitted near the diffraction-limit angle. Higher design requirements for fiber coupling, beam shaping, and telescope-face shapes are required to obtain a higher transmit-beam gain without affecting the transmission aperture.

When different core diameters, fiber beam-dispersion angles, and optical-system matching-selection methods are used for further research, near-diffraction-limit angle emission technology, launch-end laser-shaping collimation technology, and high-efficiency fiber-coupling technology can achieve breakthroughs. In terms of optical-infrastructure platform technology, a modular and lightweight optical system design is needed, which can meet the need for future simultaneous one-to-many transmissions in space laser communication networks [60].

Satellite Laser Communication Networks

Satellite Orbits

Satellite orbits can be classified according to their orbital altitude and provide the following services.

LEO: Low earth orbit. This is an Earth-centered orbit with an altitude of no more than 2000 km between the earth and the inner Van Allen radiation belts. LEO requires the lowest amount of energy for satellite placement. It provides high bandwidth and low communication latency. The satellites and space stations in LEO are more accessible to astronauts and service personnel.

LEO satellites have a small instantaneous field of view and can only observe and communicate with a small portion of the earth at a time, which means a "constellation" is needed to provide continuous coverage. LEO satellites also have a rapid orbital decay rate and require periodic orbital boosts to maintain a stable orbit or to replace old satellites as they re-enter the atmosphere.

MEO: Medium earth orbit. The orbit altitude is located between LEO and GEO, with a typical orbit altitude of 2000–36,000 km. Compared with LEO, it requires fewer satellites for global coverage and is therefore easier to manage, without the frequent-turnover problem of LEO satellites. Compared with GEO, the number of satellites required to provide global coverage is slightly higher because of the lower orbit altitude and the poorer coverage capability of a single satellite. However, the launch cost of a single satellite is lower, and it has stronger coverage capability in the bipolar region.

GEO: Geosynchronous orbit. This orbit has a constant orbital altitude, that is, the distance between the orbit and the surface is 35,786 km, and all GEOs share the same semi-long axis length. The orbital period of all GEOs is exactly equal to one sidereal day, which means that the satellites in this orbit return to the same point above the earth's surface every day, regardless of other orbital characteristics. Satellites in this

orbit have the largest single-coverage area compared to satellites in other orbits; however, the orbit is farther from the ground, resulting in the largest signal delay.

Satellite Network Architectures

The most widely used satellite network architectures are single layer and multilayer. At this stage, the research on single-layer satellite networks is more mature. However, with the rapid development of satellite laser communication network technology, single-layer satellite networks can barely handle the increasing service demand, and multilayer satellite networks are gradually becoming an important research direction for satellite laser communication networks at present.

Single-Layer Satellite Networks

A single-layer satellite network is a network of satellites that are in the same orbit. These are primarily the LEO, MEO, and GEO networks.

LEO satellite networks generally consist of hundreds of satellites. Because of their low orbit, the satellite–ground link has better performance and lower transmission delay. However, LEO satellite networks require a long time to build, and the large number of satellites leads to a complex satellite network-control system with a high cost, frequent satellite-network switching, and a short beam-switching interval. Because of the large number of signal gateway stations, the LEO satellite network has high requirements for APT systems, and the impact of the Doppler effect must be considered.

MEO satellite networks generally consist of a dozen satellites. Considering the inter-satellite link distance, uplink, and other factors, MEO satellite networks have a much higher transmission delay compared to LEO satellite networks; however, the switching probability is lower, the Doppler effect is reduced, and the space-control and APT systems are simpler [61].

The GEO satellite network has a high global coverage with a small number of satellites. The low switching probability and simplicity of the APT system are also advantageous. Compared with the MEO and LEO satellite networks, the laser link has the farthest transmission distance, resulting in a large link loss and transmission delay, which can only meet the needs of low-orbit high-power services. The coverage of middle- and high-latitude regions is not ideal.

Multilayer Satellite Networks

Because of their limitations, it is difficult for single-layer satellite networks to meet the needs of the current dramatic increases in service volume, higher transmission quality, and global coverage. Multilayer satellite networks make full use of the advantages of each layer of the satellite network and have better performance than single-layer satellite networks in several aspects, such as spectrum utilization, coverage elevation angle, and weight number [62]. The main multilayer satellite networks are double-layer and three-layer types.

Double-layer satellite networks are mostly LEO–MEO. The MEO satellites are connected to each other by an intra-layer inter-satellite link and to the LEO satellites within their visual range by an in-orbit inter-satellite link; the LEO satellites are also connected to each other by an inter-satellite link. LEO layer satellites are responsible for communicating with small mobile terminals to reduce link losses, whereas MEO layer satellites act as relays and provide communication between ground stations and large terminals [63].

A three-layer satellite network combines the advantages and shortcomings of both LEO and GEO network layers. The parent satellite manages the three-layer satellite network and the subsatellite handles the service requirements, thereby solving the problems of signal fading, time delay, and frequent switching. However, a three-layer satellite optical network system is large-scale and complex in structure and contains many satellite nodes, which increases the calculation volume and complexity of the system routing table. In addition, to reflect the routing status of the three-layer satellite optical network in real time, the routing table must be updated frequently, and the repeated calculation of the routing table leads to the generation of new link delays. The accumulation of new delays creates an additional load on the satellite network, increases communication overhead, and can even lead to link blocking.

Satellite-Network Topologies

Network Topology

The topology of a network refers to the interconnection relationship between the nodes in the network, which determines the number of communication links between each node, the transmission path, and the distance traveled by data and messages. Analyzing the network topology is the first step in designing the network, which is directly related to the overall network performance and is also the basis for implementing multiple communication protocols.

The most common satellite-network configurations are star, ring, and mesh topologies. More complex satellite networks are typically formed by combining these three basic network topologies. The following section discusses these three topologies.

Star Topology

In a star topology, all slave nodes in a network are connected to a central node located at the center of the network; however, the slave nodes are not connected to each other. The information transmission between the slave nodes depends on the central node, as shown in Fig. 2.1.

The star topology is more suitable for certain application-oriented satellite networks, which generally have one satellite as the core; the other satellites communicate with each other by relaying through the central satellite. In the star network, satellites in geosynchronous orbits mainly predominate, but satellites may also exist in other orbits.

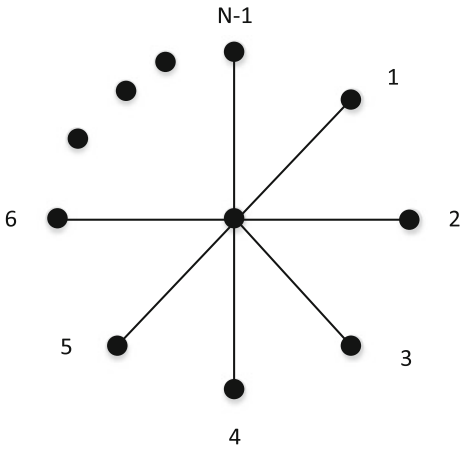

Fig. 2.1 Star topology [64]

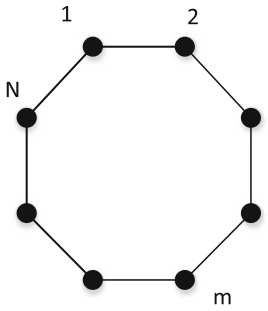

Fig. 2.2 Ring topology [64]

Ring Topology

A ring topology is a static interconnected topology consisting of multiple nodes interconnected in a certain order in a point-to-point manner to form a ring. Ring topologies can be classified as single ring, double ring, modified double ring, banded string ring, etc.

As shown in Fig. 2.2, the single-ring structure is highly symmetric and consists of N nodes, each of which is connected to a neighboring node through two ports, forming a closed-ring system. In an undirected ring, the vertex degree of each node is two, and the diameter of the network is $[N/2]$. In contrast, for a single-loop network, the diameter of the network increases linearly as the number of nodes N increases. In addition, because there are no redundant paths in a single-loop network, the entire system does not function properly if an error occurs in one link.

Figure 2.3 shows a band-chordal ring topology, i.e., a topology consisting of two nodes separated by a certain distance in a single-ring topology. The band-chordal ring topology is simple and reduces the diameter of the linear array and ring network.

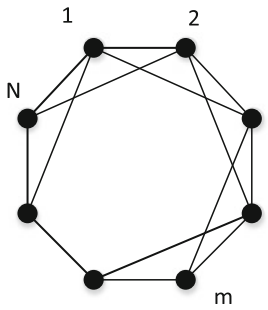

Fig. 2.3 Topology with chordal ring [64]

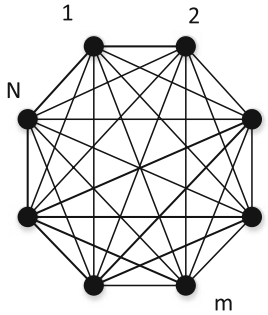

Fig. 2.4 Fully connected topology [64]

As shown in Fig. 2.4, for the banded chordal-ring mesh structure, the vertex degree increases and the mesh hole decreases. When the vertex degree increases to $N-1$, the network diameter reaches a minimum value of 1, the number of links is $N(N-1)/2$, and all nodes in the network are interconnected; this network structure is called a fully connected network.

In theory, a fully connected network is the ideal network topology; that is, every node in the network is connected to the others. Using this method, information can be transmitted between any nodes without passing through intermediate nodes. It can minimize communication delays and maximize point and edge connectivity; this means that fully connected networks have the strongest resistance to destruction, compared with other network structures.

However, in practice, these interconnections are not practical. When all nodes in the network are connected to each other, the number of node ports grows linearly with the number of nodes, but the number of links grows squarely. This makes the entire network more complex, difficult to implement, and expensive.

The advantage of the ring topology is that the structure, routing method, communication interface, and network management are relatively simple and easy to implement. In addition, multiple ring–ring constellations are interconnected, which can achieve a larger range of ground coverage. At present, the ring topology is commonly used in medium- and high-orbit satellite networks to cover the ground

using the minimum number; however, there are problems, such as low transmission bandwidth and large delays.

The shortcomings of the ring topology are that when the number of nodes in the network is too large, the system transmission efficiency decreases and the network response time increases. In addition, if a new satellite joins, the loop needs to be cut off, which is unfavorable to expanding the system.

Mesh Topology

A mesh network topology is composed of neighboring nodes connected to each other in a planar shape. The mesh topology is also called a distributed network topology because each node can connect to other nodes in the network; thus, there are sufficient redundant paths to each node to enable perfect reliability and high fault tolerance.

Various mesh topologies exist, primarily quadrilateral, hexagonal, and triangular, as shown in Fig. 2.5. To reduce the diameter of the network, a new topology can be formed by connecting the nodes located at the periphery of the network in a specific manner, such as a barrel network (Fig. 2.6), wreath network (Fig. 2.7), closed-spiral network, or twisted-spiral network.

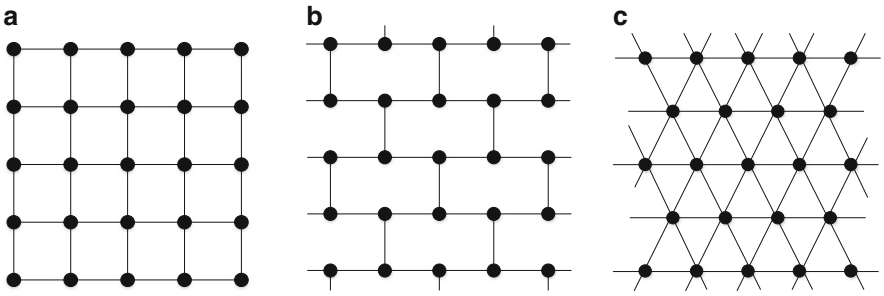

Fig. 2.5 Mesh topology [64]. (**a**) Quadrilateral grid; (**b**) Hexagonal grid; (**c**) Triangular grid

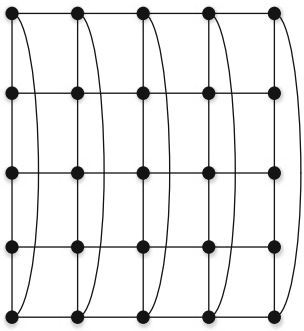

Fig. 2.6 Barrel network topology [64]

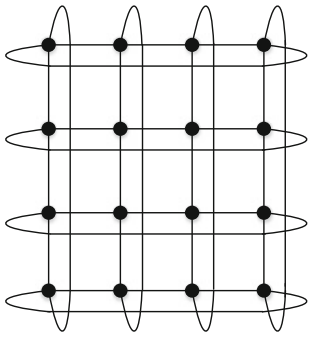

Fig. 2.7 Wreath network topology [64]

The mesh topology has sufficient redundancy, high system reliability, and better scalability with interstellar links. It has the advantages of a higher transmission bandwidth, higher data transmission rate, and lower latency and can achieve world-wide coverage. A mesh topology is typically used to achieve global communication and network support. However, a major drawback of this mesh structure is that it is expensive to build and requires multiple satellites.

Interstellar Laser Links

Interstellar Laser Link Geometry

Multiple satellite nodes are connected using inter-satellite links to form a satellite network. If the number of in-orbit satellites and inter-satellite links is the same, a satellite network with a regular mesh structure can be formed using inter- and intra-orbit links. Satellites in the same orbit are connected by intra-orbit links, which can be maintained durably because each satellite in a circular orbit is in a fixed position. The links between the orbits are not permanent.

When approaching high latitudes, the relationship between neighboring satellites changes, requiring on-board devices capable of turning 180° to track neighboring satellites and maintain the inter-orbit links. It is also possible to cut the original link and rebuild the link when the neighboring nodes change. As the distance decreases, the relative speed of the two satellites increases, and the Doppler shift increases.

Three inter-satellite link geometries are shown in Fig. 2.8: Fig. 2.8a shows a "W" geometry with four inter-satellite links; Fig. 2.8b shows a "tilted" geometry with four inter-satellite links per satellite; in Fig. 2.8c, each satellite has three interstellar links.

Interstellar Laser Link Performance Calculation

The transmitting and receiving gains of the antenna are G_T and G_R, respectively, and the optical transmitter power is P_T; thus, the laser power P_R received by the receiver antenna can be calculated [65]:

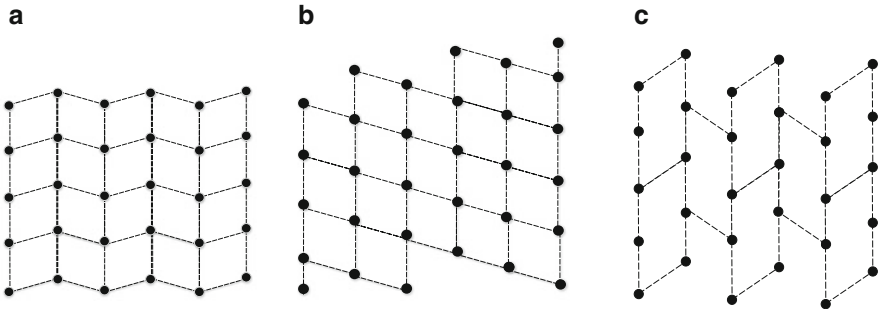

Fig. 2.8 Schematic diagram of interstellar-link geometries [64]. (**a**) W geometry; (**b**) Tilted geometry; (**c**) Three interstellar links

$$P_R = P_T + G_T + G_R - \left[L_P + \sum\nolimits_L + S_F\right] \tag{2.1}$$

where the standard deviation $S_F = 5$ dB, and L_P is the path loss:

$$L_P = \left[82 + 20\lg\frac{d_c}{\lambda}\right] dB \tag{2.2}$$

where d_c is the interstellar distance in kilometers (km) and λ denotes the laser wavelength in meters (m).

Σ_L includes other losses in addition to path loss. Because the position of the satellite is outside the atmosphere, there is no need to consider the attenuation, refraction, bending, or beam tearing of an atmospheric laser during the transmission of a light wave over a laser link. Only the absorption of light by optical elements need be considered. It can avoid beam-pointing errors due to the instability of the satellite attitude; this loss has no fixed value to use. It can be calculated by referring to the equation in [65]:

$$\begin{aligned}\sum\nolimits_L &= L_{TOA} + L_{ROA} + L_{DF} + L_{PT} + L_M = 1.5 + 1.5 + 1 + 1.5 + 1.5 \\ &= 7(dB)\end{aligned} \tag{2.3}$$

L_{TOA} and L_{ROA} are, respectively, the transmitting and receiving optical absorption losses of the transceiver antenna, L_{DF} is the scattering loss, L_{PT} is the pointing and tracking loss, and L_M is the outlier mixing loss.

In Eq. 2.1, if the antenna is a lens or reflection type, both G_T and G_R can be calculated using the following equation [65]:

$$G_i = 10\lg\left(\frac{\pi D_i}{\lambda_i}\right) \tag{2.4}$$

where D_i is the antenna aperture in meters (m).

A PIN photodetector is used for outlier-synchronization detection on an interstellar laser link with a signal to noise ratio S/N of [65]

$$\frac{S}{N} = \frac{\xi P_R}{\Delta f h_\nu} \tag{2.5}$$

where the quantum efficiency ξ is the number of electrons that can be produced per photon at the PIN; ν is the incident-light frequency expressed in hertz (Hz); $h = 6.626 \times 10^{-34}$ J·s, which is Planck's constant; Δf is a one-sided bandwidth, and the baseband-signal code rate $r_b = 2\Delta f$.

The BER P_e can be expressed as [65]

$$\begin{cases} P_e = \frac{1}{2}\, erfc\left(\frac{Q}{\sqrt{2}}\right) = \frac{1}{2}\, erfc(Q') \\ Q' = \frac{Q}{\sqrt{2}} \end{cases} \tag{2.6}$$

where Q is the value proportional to S/N, and *erfc* is the complementary error function.

If P_e is set to 10^{-9}, $Q' = 6$, in connection with Eq. 2.5; setting $\xi = 1$, the required P_R is

$$P_R = \left(\frac{S}{N}\right) \cdot h\nu \cdot \Delta f / \eta = 18 h\nu \cdot r_b \tag{2.7}$$

The interstellar transmission rate of the corresponding interstellar laser link can be calculated as follows:

$$r_b = \frac{P_R}{18 h\nu}. \tag{2.8}$$

Satellite-Routing Algorithms

According to the different aspects of routing decisions, satellite-routing algorithms can be classified as centralized, distributed, or hybrid. Centralized routing means that a central node in the network calculates the routing table and distributes it to each satellite node. Distributed routing means that each satellite node is the subject of the routing decision and can independently calculate the best node for the next hop and send the data. Hybrid routing combines the centralized calculation of centralized routing and the independent decision feature of distributed routing.

Centralized Satellite-Routing Algorithm

The centralized routing algorithm assigns all the calculation and maintenance of the routing table to the central node and distributes it to each satellite node. The satellite

node selects the best node for the next hop against the routing table and transmits the data. The central node collects the information of inter-satellite links with the dynamic change of the network-topology mechanism, completes the calculation of the routing table, and updates it [66].

From a global perspective, a centralized routing algorithm can fully consider the overall network state and routing-table calculation of the satellite network, thus achieving better traffic distribution and load balancing. However, the limited on-satellite processing and computing capability of a single satellite causes the centralized routing algorithm to suffer from high computational complexity and high signaling overhead. Even if a ground station with strong computing power is used as the central node, it is difficult to monitor the state changes of links and nodes and update the routing tables in real time, when satellite nodes or links are abnormal or fail. This has an unpredictable impact on the network performance.

Distributed Satellite-Routing Algorithm

The difference between distributed routing algorithms and centralized routing algorithms is that in the former, each satellite node makes its own routing decisions and can independently calculate the best node for the next hop and send data. Consequently, the routing table can be calculated without going through the central node [67].

The distributed routing algorithm considers the problem of low processing and computing capacity on a single satellite, distributes the computing volume of a single satellite to multiple satellites, reduces the computing burden on the satellite nodes, enables better monitoring of network-traffic changes, and dynamically updates the routing tables.

Distributed routing algorithms also have many shortcomings. Because the satellite nodes select the next hop independently, the path chosen by the routing decision is not necessarily the optimal solution from an overall perspective. This may lead to data being forwarded to nonoptimal paths and increase unnecessary signaling overhead.

Hybrid Satellite Routing Algorithm

The hybrid routing algorithm combines the advantages of centralized routing and distributed routing. In the most widely used method, some of the satellite nodes in the forwarding path can independently calculate the best node for the next hop and send data, and other satellite nodes use the centralized routing algorithm to distribute the routing table to other nodes after calculation.

The disadvantages of the hybrid routing algorithm are its higher complexity, the need for a stable inter-satellite laser link, and higher single-satellite on-satellite processing power. Hybrid routing has become a popular topic in satellite-routing algorithms, owing to its superior network performance.

Summary

As a new communication type, satellite laser communication is characterized by a strong anti-jamming ability, high transmission rate, and large communication capacity. Worldwide research on satellite laser communication networks has mainly focused on satellite networking and inter-satellite transmission. As research on satellite laser communication networks continues to deepen, the technology will become more mature, and its application prospects will become increasingly broad.

This chapter provided an overview of the current status of domestic and international research on satellite laser communication networks, described the key technologies of satellite laser communication, and briefly introduced satellite laser communication networks.

Satellite laser communication networks have broad development prospects, and further developments in the future can be carried out, based on the following points:

1. Reduce the impact of dynamic network-topology changes on network performance. Topological changes in satellite laser networks seriously affect the network performance; for example, they cause frequent inter-satellite laser link interruptions and increase the routing-update frequency. Therefore, satellite laser networks must introduce flexible and dynamic solutions to minimize the impact of dynamic changes in the satellite laser network topology.
2. Rational use of satellite laser communication network resources. Link and hardware resources are scarce in satellite laser communication networks, and maintenance is also a problem. Therefore, improving the utilization of network-link resources and reducing the consumption of on-satellite hardware resources are urgent problems that must be solved.
3. Multi-service bearing. The purpose of a satellite laser network is to provide wide coverage and seamless, all-round, diverse, high-quality, and efficient communication services to users worldwide. Therefore, suitable technology is required to carry multiple transmission services in the network.

Abstract

Modulation and demodulation are key technologies to improve the transmission efficiency of optical wireless communication. Different modulation methods have different performances. This chapter summarizes the research progress of various types of pulse-position modulation at home and abroad and then introduces the research from the Xi'an University of Technology in the area of pulse-position modulation. For on-off keying, pulse-position modulation, multiple pulse-position modulation, differential pulse-position modulation, overlapping pulse-position modulation, dual duration position modulation, dual-amplitude pulse-position modulation, digital pulse interval modulation, double-headed pulse interval modulation, dual-pulse interval modulation, dual-amplitude pulse interval modulation, fixed-length digital pulse interval modulation, fixed-length dual-amplitude pulse interval modulation, shorten pulse position modulation and separated double-pulse position modulation, the performance of the symbol structure, bandwidth requirement, average transmit power, time-slot error rate, and average channel capacity are analyzed and compared. Finally, the development direction of pulse-like position modulation is prospected.

Introduction

Modulation and demodulation are key technologies for improving the transmission efficiency of optical wireless communication. Different modulation methods exhibit different performance. Pulse-like position modulation refers to pulse-position modulation (PPM), differential pulse-position modulation (DPPM), and their combination, as well as various pulse-position modulation modes that have evolved from them. The research progress of pulse-like position modulation at home and abroad is reviewed for the following modes:

1. On-off keying
2. Pulse-position modulation
3. Multiple pulse-position modulation
4. Differential pulse-position modulation
5. Overlapping pulse-position modulation
6. Dual-duration pulse-position modulation
7. Dual-amplitude pulse-position modulation
8. Digital pulse-interval modulation
9. Double-headed pulse-interval modulation
10. Dual-pulse pulse-interval modulation
11. Dual-amplitude pulse-interval modulation
12. Fixed-length digital pulse-interval modulation
13. Fixed-length dual-amplitude pulse-interval modulation
14. Shortened pulse-position modulation
15. Separated double-pulse position modulation

In addition, their symbol structure, bandwidth requirements, average transmit power, time-slot error rate, and average channel capacity are analyzed and compared.

When a laser beam is transmitted through an atmospheric channel, the error-control performance of the optical communication system deteriorates, owing to various factors, such as atmospheric attenuation and atmospheric turbulence. Researchers have studied a series of modulation techniques to improve communication efficiency. An advanced modulation format and corresponding demodulation technology should be selected to ensure efficient transmissions and a low bit-error rate (BER) to reduce the interference of the atmospheric environment on the communication system. Therefore, research on modulation modes is an important topic in the field of optical wireless communication.

Foreign Research Progress

In laser communications, PPM can achieve the highest data-transmission rate with the minimum average optical power for a given laser-pulse repetition rate [1]. Of course, it has some disadvantages, such as increasing the demand for bandwidth, although it improves the anti-interference ability. After decades of development, foreign researchers have studied many types of pulse-position modulation based on PPM. Different modulation methods exhibit different performance in different applications [2].

In 1978, Pierce of the US Jet Propulsion Laboratory (JPL) proposed PPM and applied it to optical wireless communication [3]. In 1982, Prati et al. extended PPM coding to block-pulse coding on multiple PPM frames and proposed a maximum-likelihood demodulation method for the optical-receiver model of shot and thermal noise [4]. In 1983, Prati et al. studied PPM-modulated laser-pulse expansion and discussed several methods for suppressing the expansion, including pulse equalization, extended pulse integration, and pulse-shape matching [5].

In 1983, Garrett et al. used the matched-filter method to analyze the reception sensitivity of a PPM transmission system. The results showed that the reception sensitivity could also be improved using direct detection [6]. In 1986, Gardner et al. analyzed the BER performance of a phase-locked synchronous PPM system and compared it to that of a fully synchronized PPM system. The results showed that when the loop bandwidth is less than 0.1% of the slot frequency, the signal power required to compensate for incomplete synchronization increases only slightly [7].

In 1987, Georgiades et al. derived the maximum-likelihood estimation of PPM symbol synchronization without time-slot synchronization through observing the noise of random modulation data through an M-symbol-wide window [8]. In 1988, Davidson et al. built a 25-Mbit/s direct detection optical communication system using a PPM signal and measured its performance under laboratory conditions [9, 10]. In 1988, Zwillinger et al. used an alternative differential pulse-position modulation (DPPM) coding scheme. The results showed that, in some cases, DPPM has a higher communication rate than PPM in an optical channel with limited noise-free bandwidth and limited average power [11].

In 1989, Sugiyama et al. reported that multi-pulse-position modulation could reduce the transmission bandwidth required by PPM to approximately half, under the same transmission efficiency, thus, improving the bandwidth utilization [12]. In 1994, Barry et al. proposed a method to detect intersymbol interference (ISI) and additive Gaussian white noise when using digital pulse-position modulation. The performance of the recursive equalization scheme was analyzed, and the results showed that the equalizer was effective in mitigating ISI [13].

In 1996, Malik et al. evaluated the performance of PPM on an ISI channel. The BER performance of the unbalanced system was analyzed, and the performance of PPM maximum-likelihood sequence detection (MLSD) in ISI with additive Gaussian white noise was discussed. When MLSD was used, 16-PPM exhibited the best average power efficiency [14].

In 1997, David et al. analyzed the performance of trellis codes using PPM on indoor wireless channels and proved the effectiveness of MLSD in suppressing multipath phenomena. They also evaluated the performance of 8-PPM with a 2/3 encoding rate and 16-PPM with a 3/4 encoding rate on multipath channels [15].

In 1998, Park et al. proposed a trellis code that used multi-pulse-position modulation (MPPM). Compared with trellis codes using PPM, the code was less sensitive to multipath phenomena and provided better power efficiency when the expected bit rate was greater than the channel bandwidth [16]. In 1999, Kahn et al. studied the expressions of the error probability and power spectral density of DPPM in the presence of Gaussian white noise [17].

In 2001, Nikolai et al. studied the use of chaotic pulse-position modulation (CPPM) to modulate binary information to the carrier through the pulse position. They discussed the basic design principles of a chaotic pulse generator, synchronization, and the performance of a chaotic pulse communication scheme in the presence of channel noise [18].

In 2002, Aldibbiat et al. studied the performance of a double-headed pulse-interval modulation (DHPIM) scheme in an indoor multipath light environment. The results showed that DHPIM and PPM required slightly higher optical power than digital pulse-interval modulation (DPIM) [19]. In 2005, Moision et al. proposed serial cascaded pulse-position modulation (SCPPM), which is composed of the serial concatenation of an external convolutional code, interleaver, bit accumulator, and PPM and is encoded by a shift-register operation and table lookup [20].

In 2005, Kiasaleh et al. analyzed the error rate expression and the upper limit of the PPM free-space optical (FSO) communication system when an avalanche photodiode (APD) detector was used to detect the light field [21]. In 2005, Wilson et al. studied a method that combined multiple laser transmitters with multiple photodetectors. A Q-ary PPM mode was adopted. For Rayleigh-fading and lognormal-fading channel models, multiple-input/multiple-output (MIMO) transmission was adopted to suppress the fading effect on turbulent channels [22].

In 2006, Ivan et al. proposed Q-ary PPM for MIMO transmission. It was composed of multistage coding and a low-density parity-check code. This scheme yielded good coding gains under strong turbulence conditions [23].

In 2007, Maged et al. studied and compared two PPM-based iterative-coded modulation techniques for deep-space optical communications. The first encoding was represented by serially concatenated SCPPM, which involved the serial concatenation of an external convolutional code, interleaver, bit accumulator, and PPM. The second was a serially concatenated code, in which the constituent code was composed of a low-density even parity-check (LDPC) code and serially concatenated LDPC-PPM code [24].

In 2008, Sethakaset et al. proposed a concatenated decoding algorithm for hard and soft decision detection. The results showed that when the channel was non-dispersive, the coding gain provided by the concatenated code was about 4 dB. On dispersive channels, when the ratio of the delay spread to bit duration was low, the performance of the coding system was better than that of non-coding systems [25].

In 2009, Bounnane et al. analyzed the use of classical binary convolutional codes, iterative soft deconvolution, and channel decoding in receivers. The influence of bit-symbol mapping on the performance of iterative receivers was studied, and an MPPM mapping design rule was proposed [26].

In 2012, Wasiu et al. studied a modulation scheme that combined spatial shift keying (SSK) and PPM. Shortened pulse-position modulation (SPPM) is a multi-transmitter scheme that combines the simplicity and spectral efficiency of SSK with the energy efficiency of PPM technology [27]. In 2016, Correa et al. carried out numerical simulations of the encoding, decoding, and propagation performance of short pulses and words in on-off keying (OOK), pulse-amplitude modulation (PAM), and PPM modulation modes in optical code-division multiple-access (OCDMA) systems [28].

In 2017, Zohaib et al. discussed the implementation of a binary pulse-position modulation (DuoPPM) coding scheme and its application to visible-light communication systems. The experimental results achieved at a 14 Mbit/s data rate showed that the bit-error rate was less than 10^{-10}. The practicability, robustness, and limitations of DuoPPM were analyzed [29].

In 2020, Sharma et al. studied a free-space optical communication system using a hybrid modulation technology including pulse-position modulation, binary phase-shift keying, and subcarrier-intensity modulation. Lognormal and double-gamma probability-density functions were used as channel-fading statistics under weak, medium, and strong turbulence conditions. The average bit-error rate and closing expression of the hybrid modulation scheme were derived [30].

In 2020, Zaiton et al. studied the performance of two single-carrier modulation schemes for visible-light communication (VLC), namely, OOK and PPM. The results showed that PPM is superior to OOK in terms of transmission distance and path loss, and OOK is the best choice for achieving the highest data rate [31].

Since 1978, research on pulse-like position modulation has focused on improving the communication quality from the initial performance analysis of single PPM and DPPM modulation [4–7] to methods cascading PPM with other coding methods [24–27]. The research content has also developed from theoretical derivations and simulations [3–5] to practical applications [9, 10]. Communication systems have been developed from single-input single-output (SISO) communication systems [18–20] to multiple-input multiple-output (MIMO) communication systems [22, 23]. MIMO can reduce the fading effect on turbulent channels. The bit-error rate performance [7, 21], reception sensitivity [6], frequency-band utilization [12, 17], intersymbol interference [13, 14], and other aspects are analyzed.

Domestic Research Progress

In 1998, Wang et al. studied a time-slot synchronizer using a digital phase-locked loop to realize PPM. The anti-noise performance of the time-slot synchronizer using this method for loop filtering was better than that using the mean, three-point, and screening methods. With other performance indicators unchanged, this algorithm

ensured that the entire synchronization system worked reliably under stronger background noise [32].

In 1999, Huang et al. designed a PPM modulator. Digital circuits, such as counting, latch, and control, were realized using programmable logic devices, which greatly simplified the hardware circuit [33].

In 2000, Zhang et al. proposed a new solution using a digital-logic design for slot synchronization, word synchronization, and word synchronization in the frame synchronization of pulse-position modulation [34].

In 2000, Zou et al. compared the PPM, OOK, and PAM modulation modes in terms of the average optical power and bandwidth utilization. This showed that PPM had a high energy efficiency, at the cost of reducing the bandwidth [35].

In 2000, Zhang et al. analyzed PPM, DPPM, and MPPM, compared them with OOK, and analyzed their advantages and disadvantages [36].

In 2002, Pang et al. analyzed and compared the power utilization ratio, frequency-band utilization ratio, transmission capacity, and anti-symbol interference performance of OOK, PPM, DPPM, and DPIM in optical wireless communication [37].

In 2005, Tang et al. studied the error performance of digital pulse-interval modulation (DPIM), analyzed the symbol structure, transmission power, bandwidth requirements, and other metrics, and compared them with OOK and PPM [38].

In 2006, Zhang et al. designed a PPM optical wireless communication system based on a field-programmable gate array (FPGA), based on the study of PPM modulation technology [39].

In 2007, Wang et al. analyzed and compared the bandwidth requirements, transmission capacity, power requirements, and error performance of OOK, PPM, and DPIM, based on their modulation structures, combined with the characteristics of optical wireless channels [40].

In 2010, Sha et al. used LDPC codes as a channel code, combined with a simplified software information-extraction method, to simulate an LDPC-encoded PPM system in an atmospheric turbulence channel. Simulation results showed that the scheme could meet the requirements of optical wireless communication systems [41].

In 2010, Cheng et al. presented dual-pulse pulse-interval modulation (DPPIM). They analyzed the bandwidth requirement, transmission capacity, and average transmission power, deduced the packet error rate model under a weak turbulence channel, and compared it with PPM, DPIM, fixed-length digital pulse-interval modulation (FDPIM), OOK, and other methods [42, 43].

In 2016, Xiang et al. proposed a method to convert the soft information output by SCPPM decoding into the expected value of each time slot of PPM. The SCPPM decoding output first makes a hard decision and then obtains the accumulator state through the accumulation module. Depending on this state, the next PPM mapping mode is selected to obtain the probability and expectation of each PPM time slot, and the best sampling point is obtained by predicting the clock deviation [44, 45].

In 2019, Liu et al. studied an end-to-end RF–FSO hybrid system using a hybrid pulse-position modulation–binary phase-shift keying–subcarrier-intensity modulation (PPM–BPSK–SIM) scheme. Radio-frequency (RF) links follow a Rayleigh

distribution and FSO links follow a double-gamma distribution. Considering the influence of atmospheric turbulence and pointing-error conditions, the average bit-error rates of various PPM–BPSK–SIM schemes were derived, and the outage probability and average channel capacity of the system were discussed [46].

In 2020, Qinling et al. analyzed and compared the performance of visible-light communication systems based on OOK, PPM, and DPIM. The coding structure, bandwidth requirements, and average transmission power of OOK, PPM, and DPIM were compared [47].

The study of pulse-like position modulation has developed from the study of PPM performance [32–34] to the comparative development of multiple modulation performance [35–38]. Various modulation methods are related to one another. Each modulation method is proposed, based on the shortcomings of existing modulation methods. However, the new modulation methods also have shortcomings. To date, nearly 20 types of pulse-like position modulation have been proposed. However, these 20 modulation methods still have unsolved problems. In future research on atmospheric laser-communication systems, additional modulation methods will be proposed to improve the communication-system performance.

Pulse-Position Modulation Technology

Professor Ke Xizheng of Xi'an University of Technology and others have studied optical wireless communication technology since 2000 and have made good progress in signal modulation, coding, antennas, and automatic tracking and aiming technologies [1]. Atmospheric laser-communication systems, including serial ports, parallel ports, Ethernet interfaces, and other common digital interfaces, have been successfully developed [2]. A PPM modulation and demodulation system was designed. Time-slot synchronization and frame synchronization during demodulation were realized using phase-locked loop technology and Gold codes, respectively. A time-slot synchronization technology was invented [72].

Professor Ke's team comprehensively analyzed and compared the performance of more than ten modulation modes and determined the best modulation modes for certain applications. Matching modulation modes were selected for different channels and the shortcomings of these modulation modes were determined to provide a theoretical basis for selecting the appropriate modulation mode in different situations.

To choose a suitable modulation mode, the research group of Xi'an University of Technology carried out a systematic analysis of pulse-like position modulation modes. In 2005, Ding et al. [48] analyzed the performance of PPM and implemented it using hardware. In 2006, Zhao [55] studied DPPM and analyzed its performance. In 2007, Qinling et al. [49] studied the symbol structure and constellation of MPPM and implemented it using hardware. In 2007, Huang [56] analyzed the basic principles and performance of overlapping pulse-position modulation (OPPM).

In 2010, Ma [54] proposed a new modulation technology for atmospheric laser communication that combined PPM and polarization modulation [73]. In 2011,

Sun [57] analyzed the symbol structure, power spectral density, bandwidth requirements, etc. of dual-amplitude pulse-position modulation (DAPPM). In 2011, Jia [58] analyzed the performance of DHPIM. In 2013, Liu [59] systematically studied the symbol structure, power spectral density, bit-error rate, etc. of pulse-like position modulation.

In 2016, Shi [60] studied quadrature amplitude modulation (QAM) and demodulation programs and analyzed the results. In 2015, Tian [61] discussed an adaptive threshold-detection model and analyzed its performance. In 2012, Pei [62] studied two methods of suppressing turbulence and improving communication performance: multibeam emission and multiaperture reception. In 2019, Liu [63] studied and optimized the response characteristics of semiconductor lasers and photodetectors to improve the modulation rate of communication systems.

Symbol-Structure Analysis of Various Modulation Modes

The main modulation modes of intensity modulation/direct detection systems include OOK, PPM, DPIM, and DHPIM. These modulation modes use a laser as the carrier to transmit information. The receiving end of the transmission determines the transmitted information, based on the position of the optical pulse in an equally spaced time period; this can be collectively referred to as pulse-like position modulation.

Taking the modulation bit number $M = 4$ as an example, the symbol structure of each modulation mode is shown in Fig. 3.1 [53]. In Fig. 3.1, α represents the pulse-width parameter and β represents the amplitude parameter. Among the above code words, fixed-length digital pulse-interval modulation (FDPIM) has the longest symbol length, followed by fixed-length dual-amplitude pulse-interval modulation (FDAPIM), PPM, and dual-amplitude pulse-interval modulation (DAPIM). The shortest is OOK.

Performance Analysis of the Modulation Modes

In optical wireless communication systems, OOK modulation was the earliest used in the intensity modulation/direct detection systems; however, its performance is lacking in various aspects, such as anti-interference ability and power utilization. To improve these metrics, modulation modes, such as PPM [48], DPIM [58], and DHPIM [58], have been proposed. Next, we discuss some basic performance metrics of these modulation methods, such as the average symbol length, bandwidth requirements, and average transmission power.

Average Symbol Length

Figure 3.2 shows the average symbol length of the various modulation modes. To clearly distinguish the average symbol-length curve of different modulation modes, the pulse-width parameter α was set to 10 [1]. It can be seen from the figure that

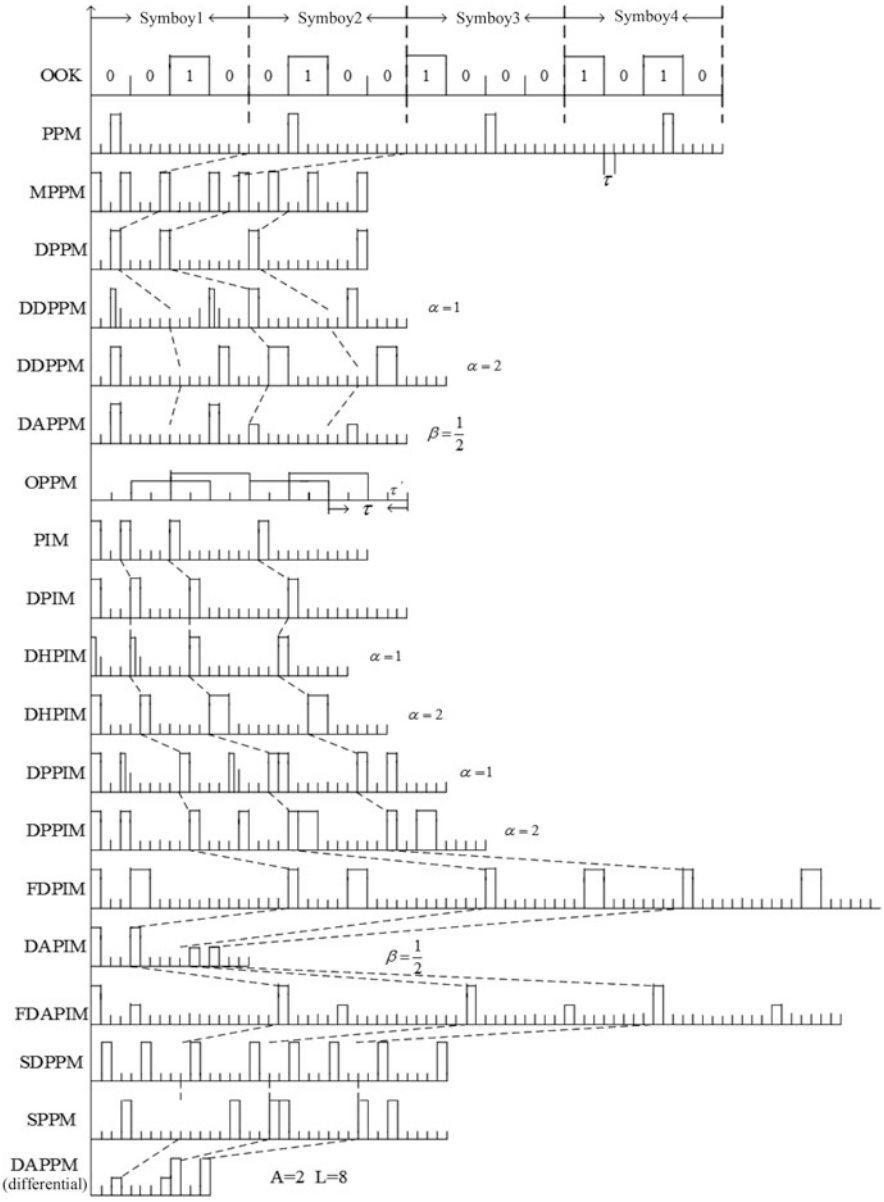

Fig. 3.1 Symbol structure of each modulation mode [53]

when the modulation order M is very small, the average symbol length of these modulation methods makes little difference. With an increase in M, the average symbol lengths of FDPIM, fixed-length dual-amplitude pulse-interval modulation

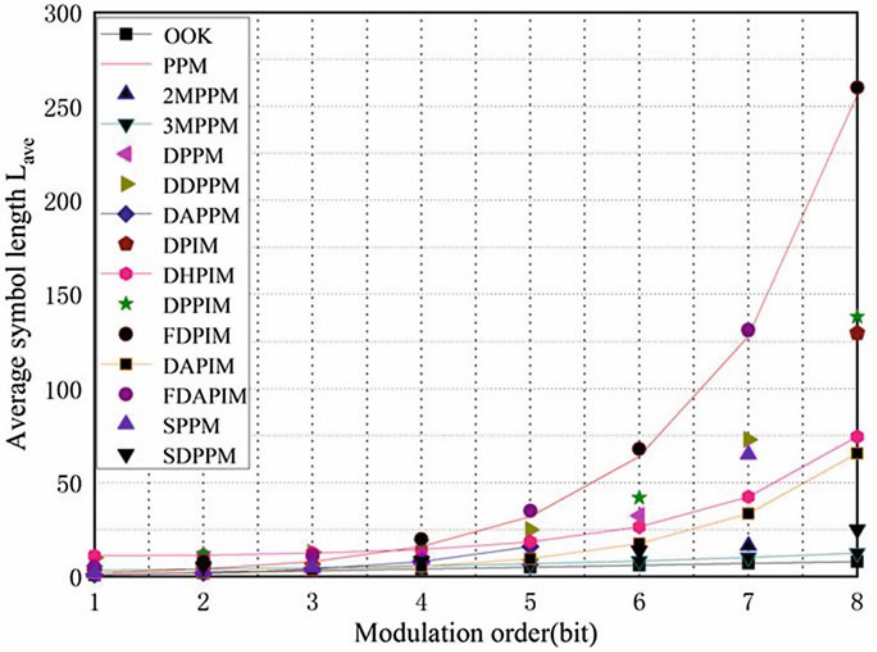

Fig. 3.2 Average symbol length of each modulation mode [53]

(FDAPIM), and PPM increase the fastest. They are longer than the other modulation methods, and their symbol lengths are very close.

For modulation modes with parameters, the average symbol length increases with an increase in the parameters. A comparison of the average symbol lengths of different modulation modes through numerical simulations using MATLAB is shown in Fig. 3.2.

Bandwidth Demand and Utilization

A optical wireless communication system needs a certain bandwidth to transmit information, and the smaller the bandwidth, the better. Figures 3.3 and 3.4 show comparisons of the bandwidth requirements and bandwidth utilization of various modulation modes. The pulse-width parameter α was set to 2, and the information bit rate was 1.

As shown in Fig. 3.3, the bandwidth requirement of each modulation mode increases with an increase in the number of modulation bits, and the bandwidth requirement of the modulation mode with a variable pulse width decreases with an increase in parameter α. As shown in Fig. 3.4, the bandwidth utilization of each modulation mode decreases with an increase in the number of modulation bits [2].

Differential-amplitude pulse-position modulation (DAPPM) and OPPM differ from those mentioned above. The relationship between the DAPPM bandwidth requirements and symbol length is shown in Fig. 3.5. The bandwidth requirement

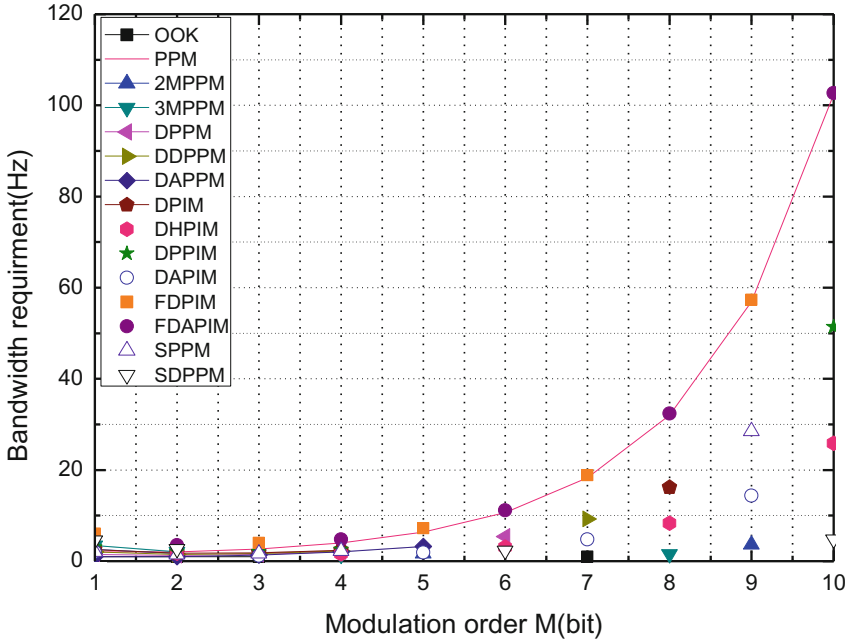

Fig. 3.3 Bandwidth requirements [53]

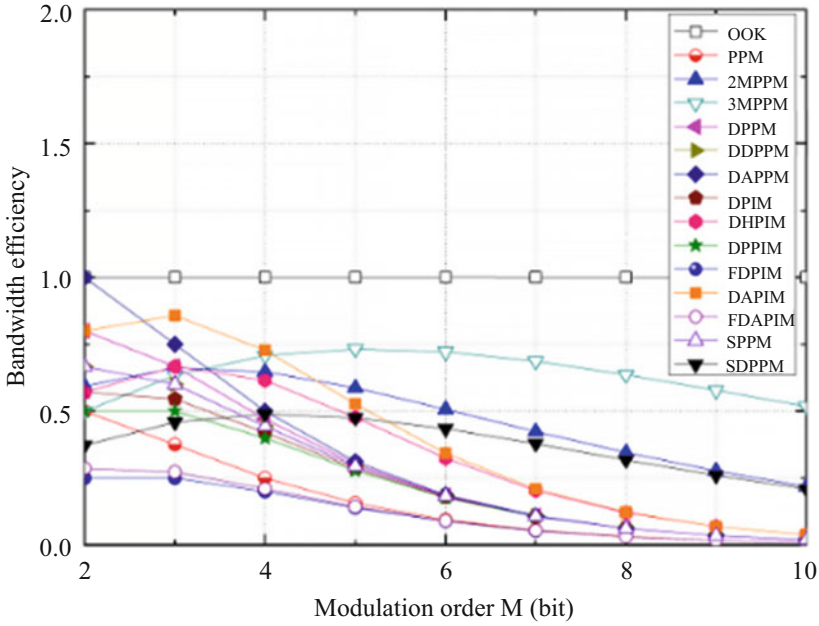

Fig. 3.4 Bandwidth utilization [53]

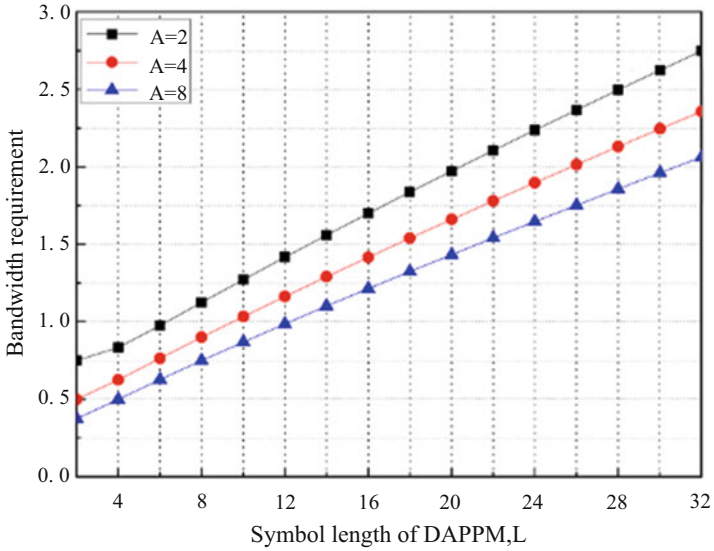

Fig. 3.5 Bandwidth requirements of DAPPM [57]

of DAPPM increases with an increase in the symbol length and decreases with an increase in the pulse amplitude. The relationship between the bandwidth requirement of OPPM and the overlap coefficient is shown in Fig. 3.6. The bandwidth requirement of OPPM decreases with an increase in the overlap coefficient and increases with an increase in the modulation order [50].

Average Transmit Power

In an atmospheric laser communication system, pulse-like position modulation methods can be considered to send "0" and "1" sequences with equal probability. No power is required when sending "0" sequences, and the peak power P_c is required when sending "1" sequences. Therefore, for a given peak-emission power P_c, the average emission power can be simply determined as the probability of sending "1" times the peak power; that is, $P_{\text{ave}} = P_I * P_c$. Figure 3.7 shows the relationship between the average transmission power and modulation order when the peak transmission power is fixed. The pulse-width parameter α was taken as 1, and the amplitude parameter β was taken as 2 [1].

Performance Analysis

The average symbol length, bandwidth requirements, and average transmission power of the various modulation modes are listed in Table 3.1. From the symbol structure and average symbol length of these modulation modes, it is evident that the most important modulation modes are PPM and DPIM. The former represents the transmitted information using the position of the optical pulses in the time slot and

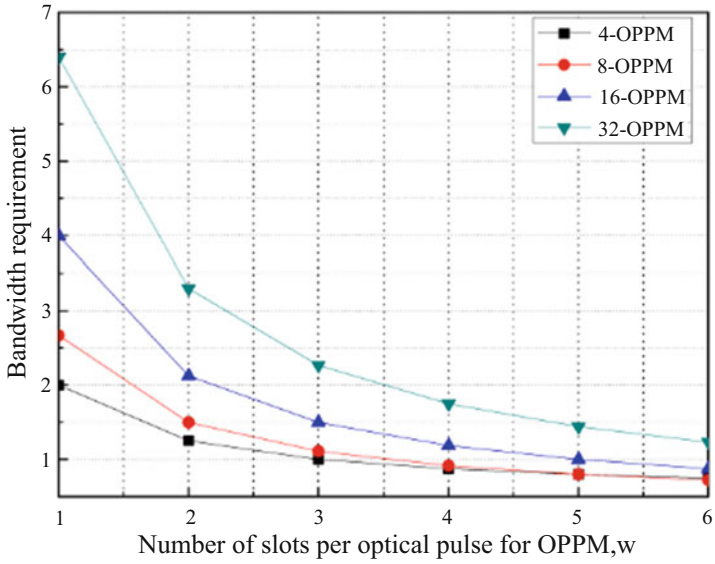

Fig. 3.6 Bandwidth requirements of OPPM [52]

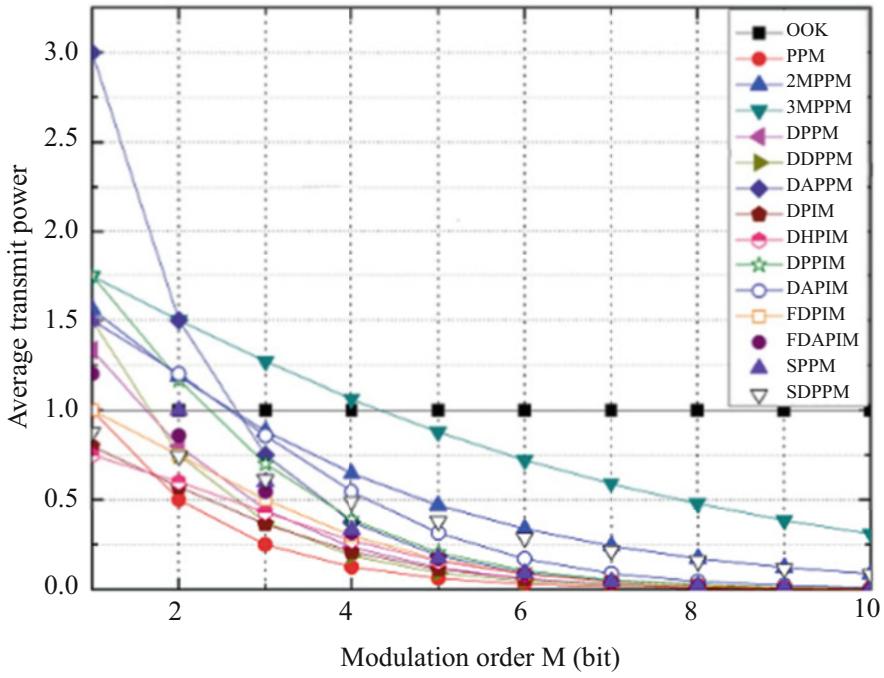

Fig. 3.7 Average transmission power of different modulation methods [53]

Table 3.1 Average symbol length, bandwidth requirements, and average transmission power of each modulation mode

Modulation mode	Average symbol length	Bandwidth requirements	Average transmit power
OOK	M	R_b	$\frac{P_c}{2}$
PPM	2^M	$\frac{2^M R_b}{M}$	$\frac{P_c}{2^M}$
MPPM	n (with p pulses)	$\frac{nR_b}{M}$	$\frac{pP_c}{n}$
DPPM	$\frac{2^M+1}{2}$	$\frac{2^M+1}{2M}R_b$	$\frac{2}{2^M+1}P_c$
DDPPM	$2^{M-1}+\alpha-1$	$\frac{2^M+2\alpha-2}{\alpha M}R_b$	$\frac{3\alpha}{\left(2^{M+1}+4\alpha-4\right)}P_c$
DAPPM	2^{M-1}	$\frac{2^{M-1}}{M}R_b$	$\frac{1+\beta}{2^M}P_c$
PIM	$\frac{2^M+1}{2}$	$\frac{2^M+1}{2M}R_b$	$\frac{2}{2^M+1}P_c$
DPIM	$\frac{2^M+3}{2}$	$\frac{2^M+3}{2M}R_b$	$\frac{2}{2^M+3}P_c$
DHPIM	$\frac{2^{M-1}+2\alpha+1}{2}$	$\frac{2^{M-1}+2\alpha+1}{\alpha M}R_b$	$\frac{3\alpha}{\left(2^M+4\alpha+2\right)}P_c$
DPPIM	$2^{M-1}+\alpha$	$\frac{2^M+2\alpha}{\alpha M}R_b$	$\frac{4+3\alpha}{2^{M+1}+4\alpha}P_c$
DAPIM	$\frac{2^{M-1}+3}{2}$	$\frac{2^{M-1}+3}{2M}R_b$	$\frac{1+\beta}{2^{M-1}+3}P_c$
FDPIM	2^M+4	$\frac{2^M+4}{M}R_b$	$\frac{3}{2^M+4}P_t$
FDAPIM	2^M+3	$\frac{2^M+3}{M}R_b$	$\frac{1+\beta}{2^M+3}P_c$
SPPM	$1+2^{M-1}$	$\frac{2^{M-1}+1}{M}R_b$	$\frac{3}{2^M+2}P_c$
SDPPM	n_s	n_sR_b/M	$2P_c/n_s$

the latter represents the transmitted information using the number of space slots between adjacent pulses.

Other modulation methods are developed by changing the symbol length and the amplitude, width, and number of pulses, based on these two modulation methods. An analysis reveals that the bandwidth requirements of different modulation modes increase with an increase in their average symbol length and decrease with an increase in the pulse width [59].

Slot Error Rate Analysis

In an optical wireless communication system, the information sent by a signal source is encoded and modulated into a group of information sequences composed of multiple time slots. Each time slot takes the value of "1" or "0," according to the presence or absence of an optical pulse, respectively. It is then loaded into the laser and transmitted through an optical antenna. Because a laser transmission in the atmosphere is affected by turbulence, background-light noise, path loss, and other factors, the information will be distorted or lost, and the receiver will receive the wrong information. The slot error rate (SER) refers to the probability of a slot error in

each bit of symbol information, that is, the sum of the probability of sending "1" and receiving "0" and the probability of sending "0" and receiving "1." The slot error rate performance of various modulation methods is analyzed below [50].

Slot Error Rate Analysis Under a Gaussian Channel Model

Figure 3.8 shows the slot error rate comparison of different modulation modes under different modulation bit numbers, without considering the influence of turbulence. The pulse-width parameter was 1 and the amplitude parameter was 2. It can be seen from the three figures that the slot error rate of OOK modulation is independent of the modulation order M; the higher the signal-to-noise ratio (SNR), the smaller the slot error rate for each modulation mode. When the signal-to-noise ratio is constant, the larger the M value, the smaller the slot error rate. When the M value is fixed, the slot error rate of OOK is the largest, and the slot error rate of PPM is the smallest. Moreover, with the increase in M, the gap between the slot error rates of various modulation methods increases [1].

Average Slot Error Rate Under a Weak Turbulence Channel Model

A comparison of the average time-slot error rates of different modulation modes in weak turbulence is shown in Fig. 3.9. The three subgraphs compare the average time-slot error rates of different modulation modes for different transmission distances and different modulation bits in weak turbulence.

Average Slot-Error Rate Under a Medium–Strong Turbulence Channel Model

Figure 3.10 shows a comparison of the slot error rate of each modulation mode under different transmission distances and modulation bit numbers in the case of medium–strong turbulence. It can be seen from the three subgraphs that the change trend of various modulation modes under the corresponding conditions is predominately the same as that under weak turbulence. However, the difference between dual-amplitude pulse-interval modulation (DAPIM), 2MPPM, and separated double-pulse-position modulation (SDPPM) under moderate–strong turbulence is larger than that under weak turbulence, and the average slot error rate under moderate–strong turbulence is higher [53].

Average Slot-Error Rate Under a Strong Turbulence Channel Model

Figure 3.11 shows the average slot error rate comparison of different modulation modes with different a values and different modulation bit numbers under strong turbulence. It can be seen from the three subgraphs that, with the change in the values of a and M, the order of magnitude of the above modulation modes does not change. When the value of a is fixed, the average slot error rate of each modulation mode decreases with an increase in the number of modulation bits, M. When the value of M is fixed, the average slot error rate of each modulation mode decreases with increasing a. The average slot error rate in the three graphs is 10^{-4}–10^{-5}, which is higher than the average slot error rate in the medium–strong turbulence.

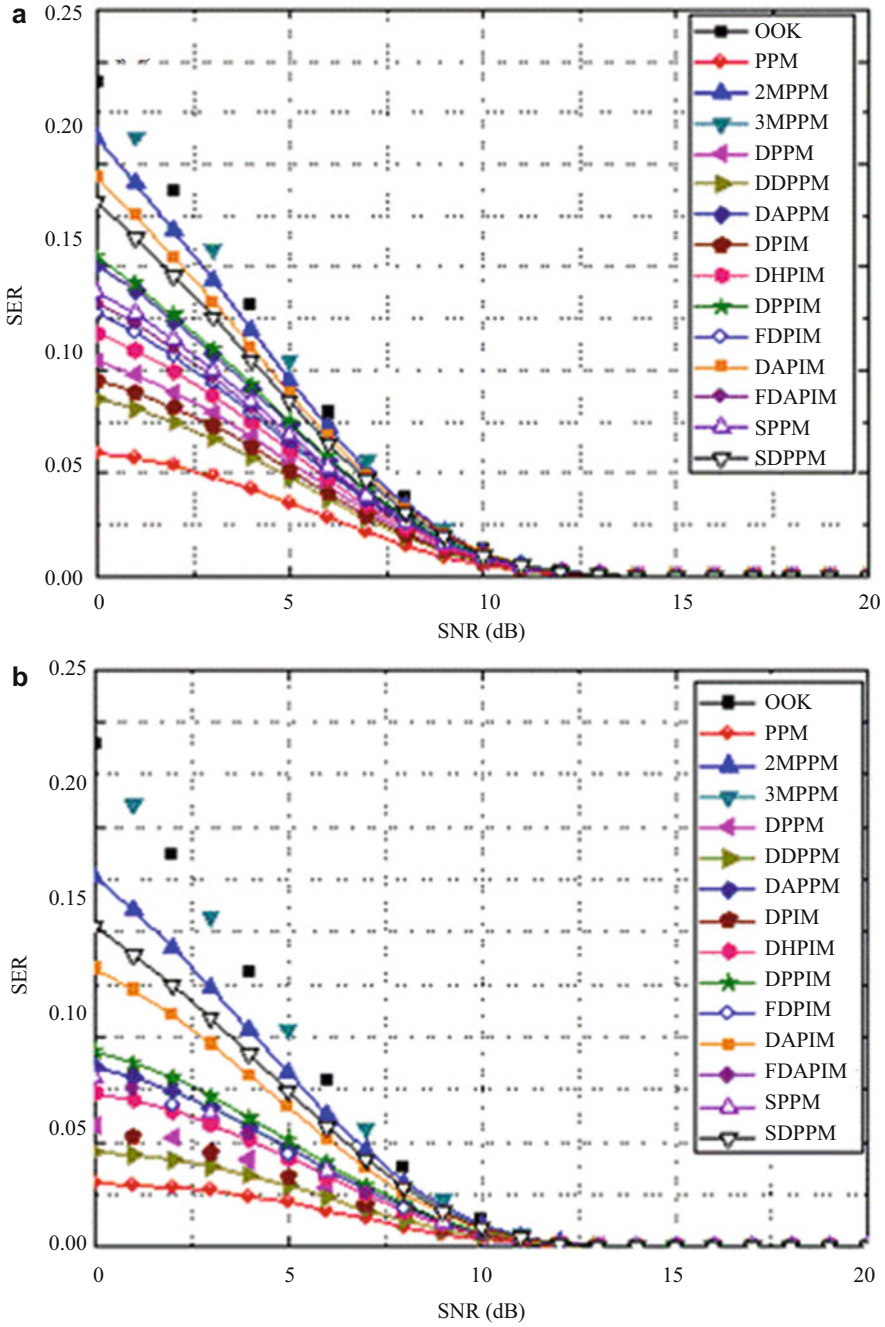

Fig. 3.8 Slot error rate of each modulation mode in a Gaussian channel [59]. (**a**) $M = 4$ bits; (**b**) $M = 5$ bits; and (**c**) $M = 6$ bits

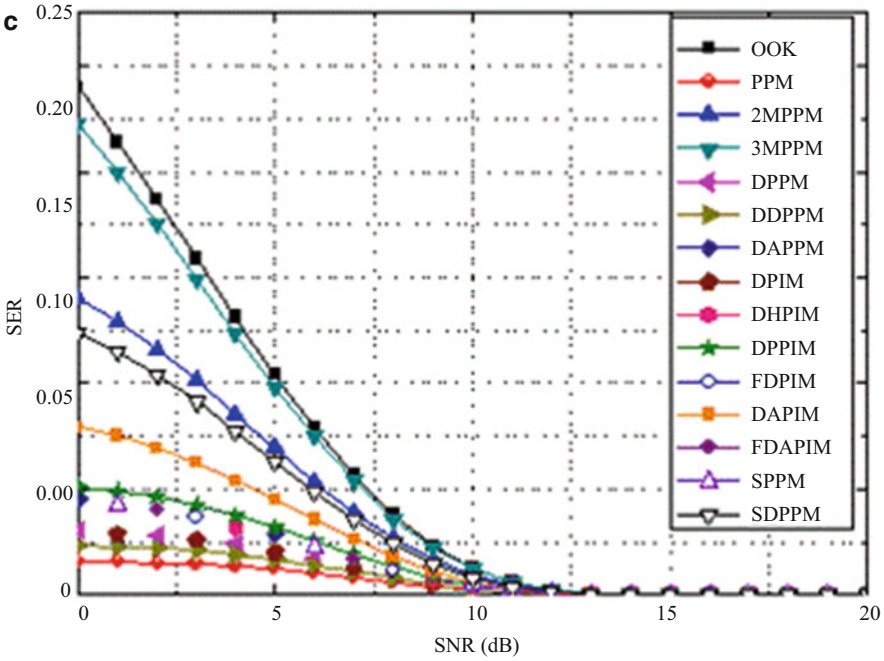

Fig. 3.8 (continued)

This study analyzes the performance of the average slot error rate of different modulation modes when the light intensity obeys lognormal, gamma–gamma, and K distributions under the three turbulence conditions. It obtains the calculation formula of the average slot error rate of each modulation mode through mathematical derivation and carries out numerical simulations on these formulas.

From the analysis process and numerical simulation results, it can be observed that the slot error rate of the OOK modulation mode is independent of the modulation order M; the higher the signal-to-noise ratio, the smaller the slot error rate for each modulation mode. When the signal-to-noise ratio is fixed, the slot error rate decreases with an increase in M, and the change trend of the average slot error rate under the three turbulence conditions is the same. The slot error rate of OOK is the largest and that of PPM is the smallest. The average slot error rate increases with an increase in the turbulence intensity.

Using the same modulation method in the same turbulence channel, the average slot error rate performance of a modulation method can effectively be improved by increasing the modulation ratio M, reducing the information-transmission distance L or increasing the channel parameter α [50].

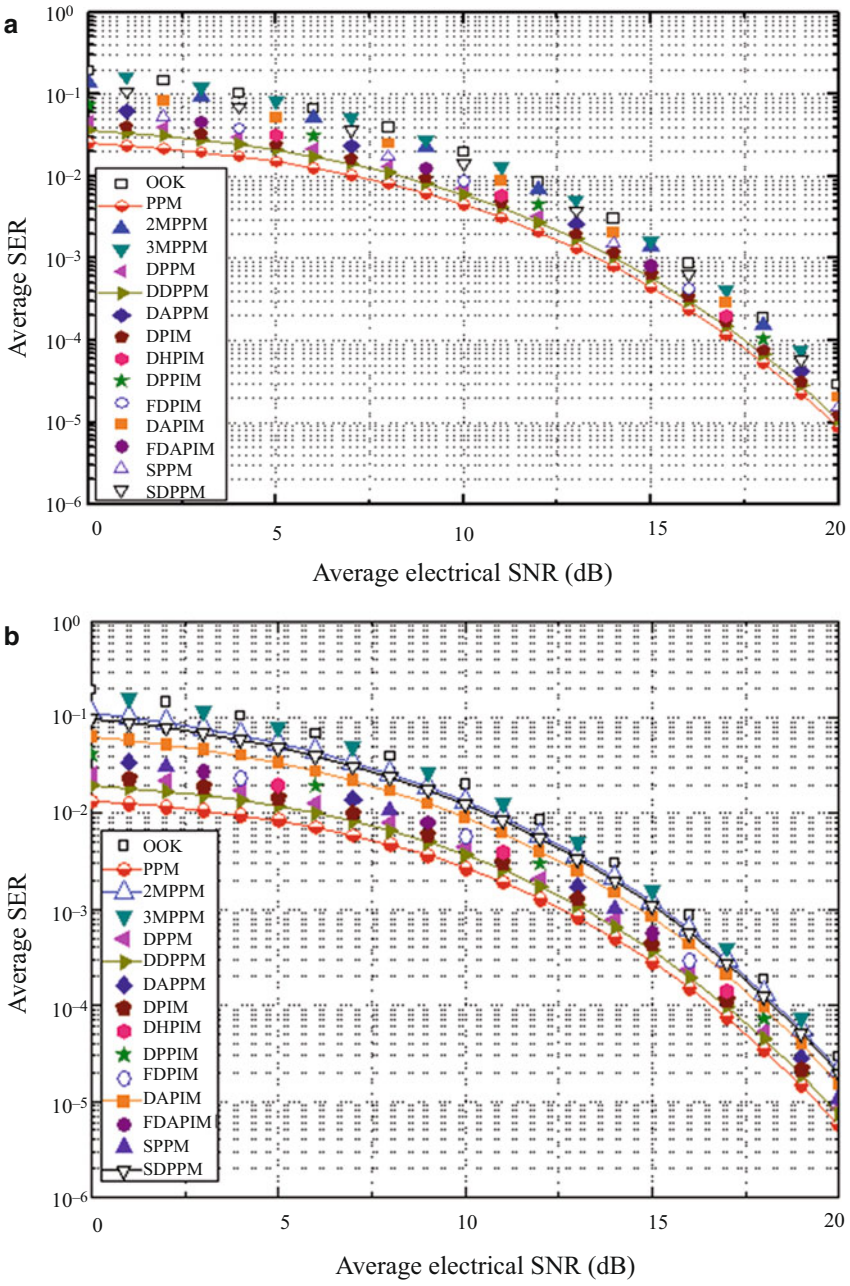

Fig. 3.9 Average slot error rate of each modulation mode in a weak turbulence channel [59]. (**a**) $L = 5000$ m, $M = 5$ bits, $C_n^2 = 1 \times 10^{-15}$ $\mathrm{m}^{\frac{-2}{3}}$; (**b**) $L = 5000$ m, $M = 6$ bits, $C_n^2 = 1 \times 10^{-15}$ $\mathrm{m}^{\frac{-2}{3}}$; (**c**) $L = 3000$ m, $M = 6$ bits, $C_n^2 = 1 \times 10^{-15}$ $\mathrm{m}^{\frac{-2}{3}}$

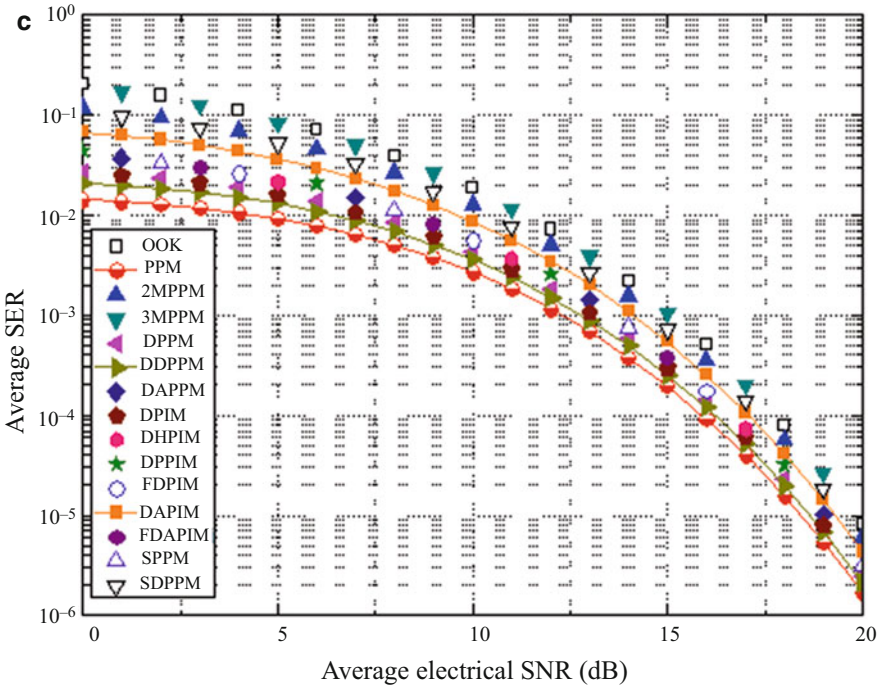

Fig. 3.9 (continued)

Channel Capacity

The channel capacity refers to the maximum average information rate that a channel can transmit. Next, the transmission capacity of various modulation modes and the average channel capacity of different modulation modes in turbulent channels are analyzed.

Transmission Capacity

Figure 3.12 shows a comparison of the transmission capacity of different modulation modes. It can be observed from the figure that the transmission capacity of each modulation mode increases logarithmically with an increase in the number of modulation bits. The transmission capacity of DHPIM is the largest, approaching 4 bit/s, followed by PPM and DPIM. The transmission capacity of these two modulation modes approaches 2 bit/s, and the smallest is that of PPM. For the modulation mode with variable pulse-width parameters, the transmission capacity decreases with an increase in the pulse-width parameter.

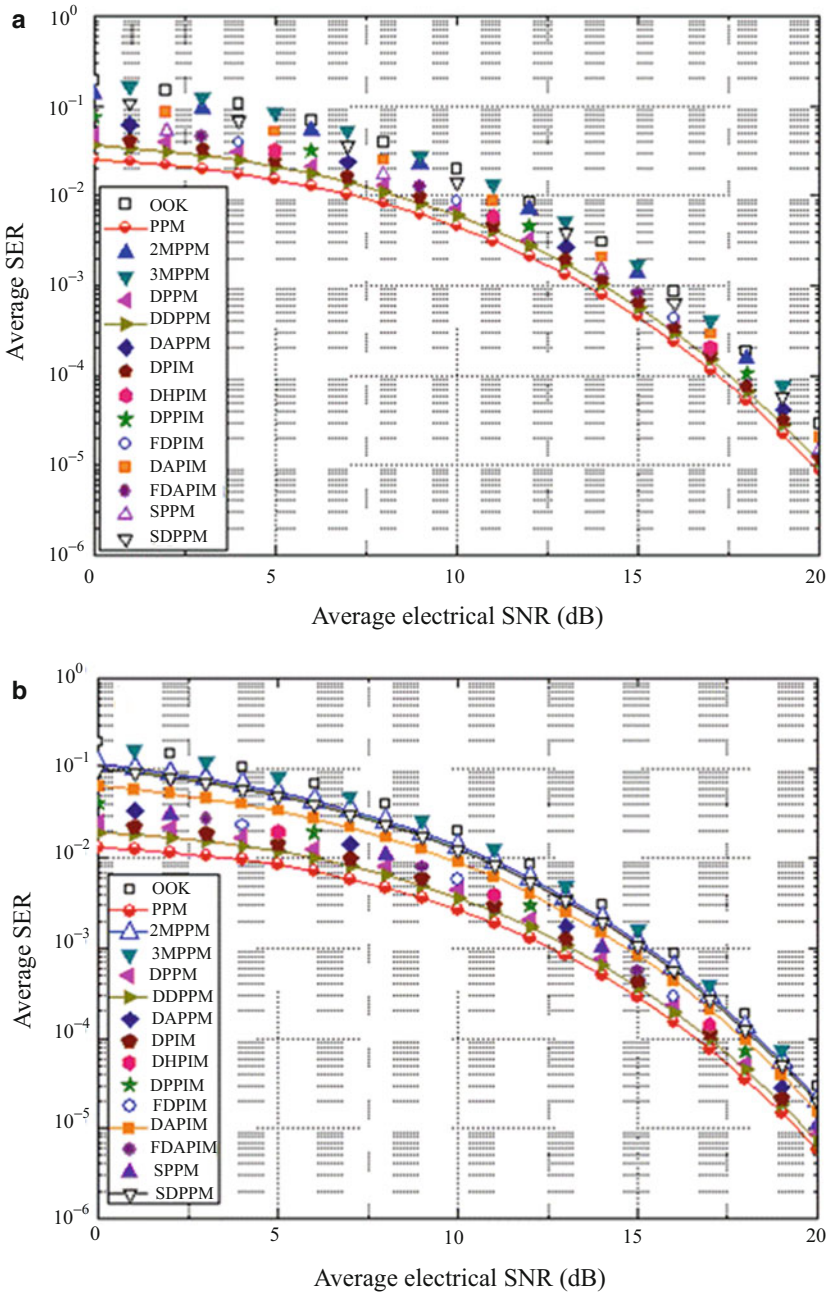

Fig. 3.10 Average slot error rate of each modulation mode in a medium–strong turbulence channel [59]. (**a**) $L = 5000$ m, $M = 5$ bits, $C_n^2 = 9 \times 10^{-15}$ $\mathrm{m}^{\frac{-2}{3}}$; (**b**) $L = 5000$ m, $M = 6$ bits, $C_n^2 = 9 \times 10^{-15}$ $\mathrm{m}^{\frac{-2}{3}}$; (**c**) $L = 3000$ m, $M = 6$ bits, $C_n^2 = 9 \times 10^{-15}$ $\mathrm{m}^{\frac{-2}{3}}$

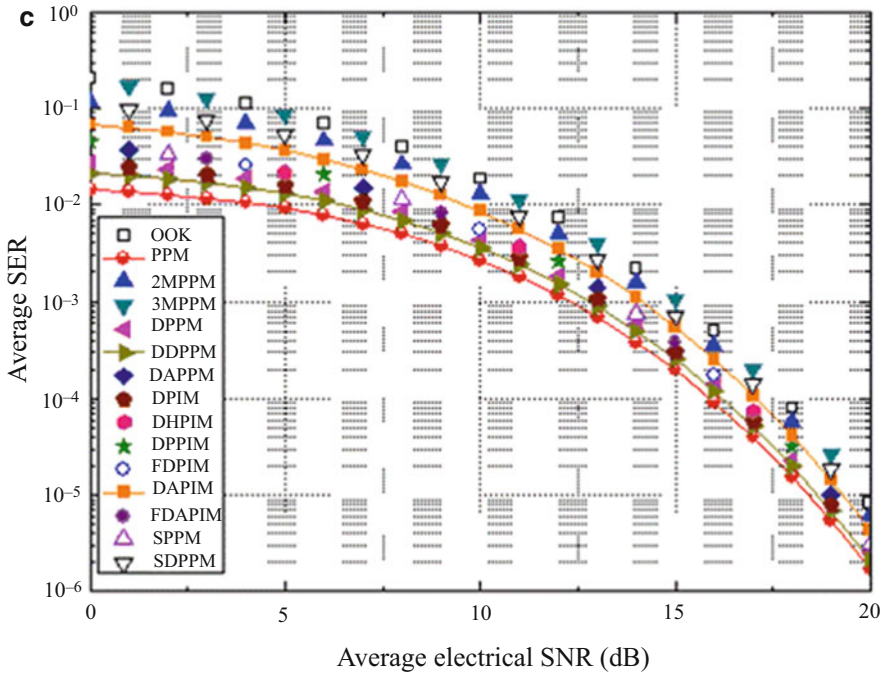

Fig. 3.10 (continued)

Average Channel Capacity Under a Turbulent Channel

Figure 3.13 shows a comparison of the average channel capacity at different transmission distances and light wavelengths in a turbulent channel. The medium–strong turbulence channel was simulated using the gamma–gamma distribution model and distinguished by different atmospheric refractive-index constants.

Figure 3.14 shows a comparison of the average channel capacity when the light intensity follows the K distribution under strong turbulence. It can be observed from the figure that the average channel capacity increases with an increase in the signal-to-noise ratio and channel parameter.

Average Channel Capacity of Different Modulation Modes and Turbulence Intensities

Figure 3.15 shows a comparison of the average channel capacity of different modulation methods at different transmission distances and modulation bits in weak turbulence. It can be observed from the figure that the average channel capacity increases with an increase in the peak transmission power, decreases with an increase in the transmission distance, and decreases with an increase in the number of modulation bits. The average channel capacity of OOK was the largest and that of PPM was the smallest [48].

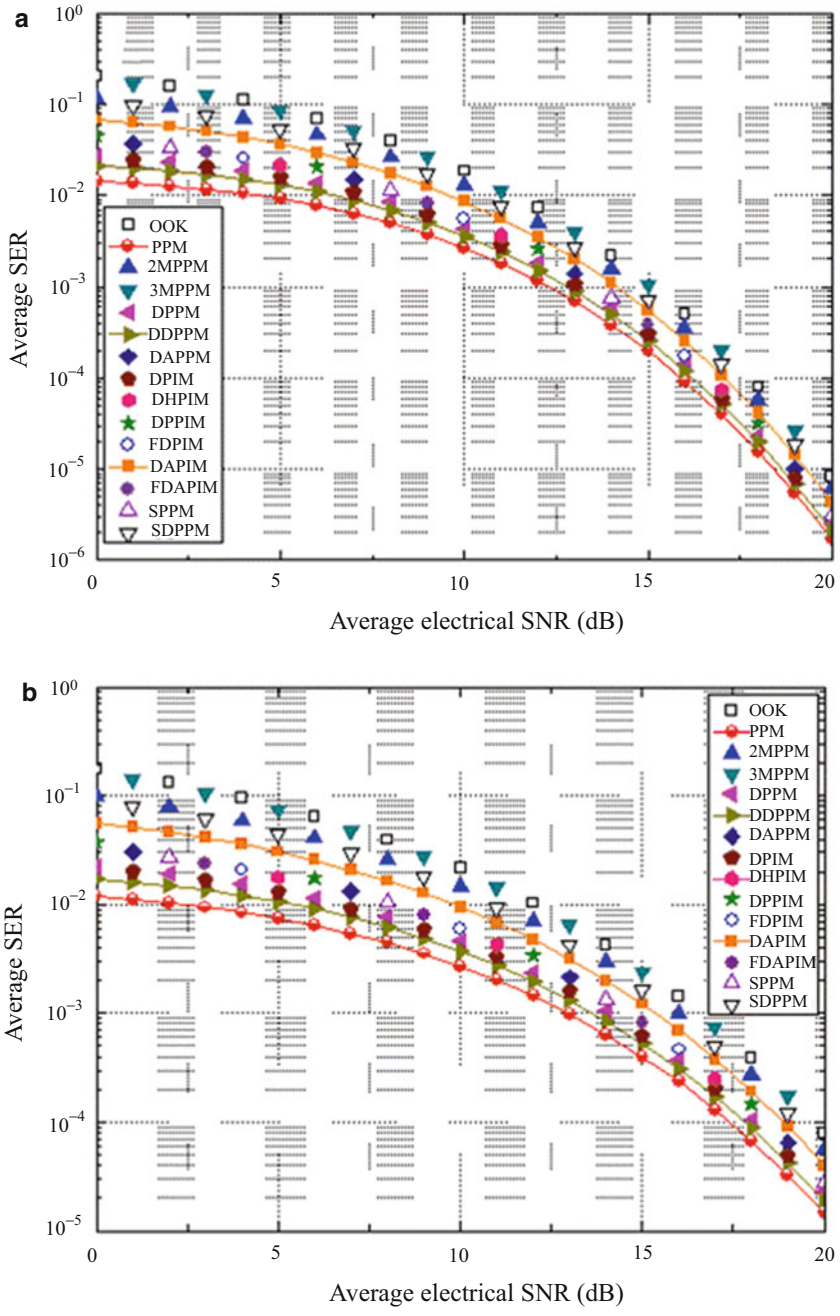

Fig. 3.11 Average slot error rate of each modulation mode under a strong turbulence channel [59]. (**a**) $a = 4$, $M = 5$ bits; (**b**) $a = 4$, $M = 6$ bits; (**c**) $a = 2$, $M = 6$ bits

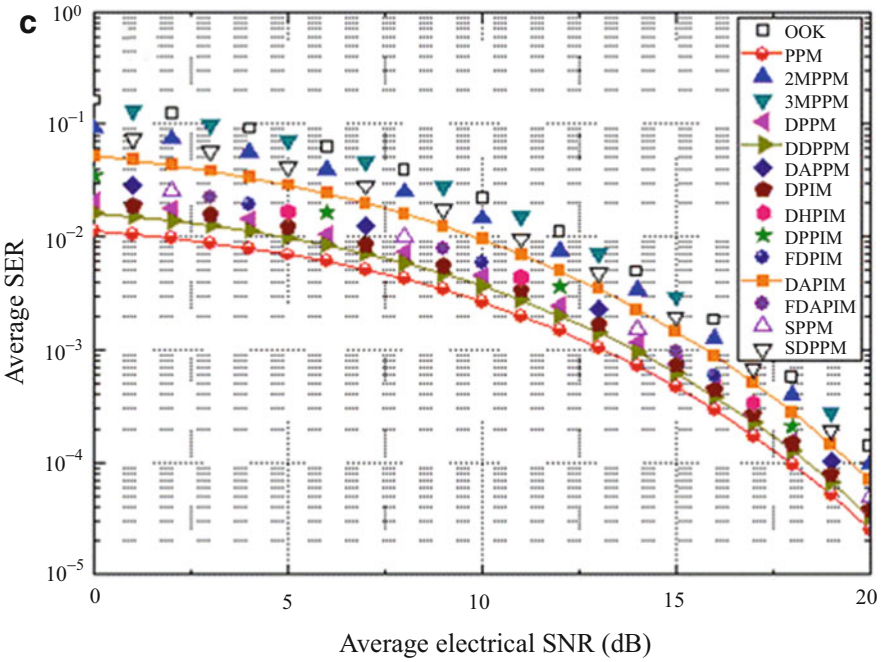

Fig. 3.11 (continued)

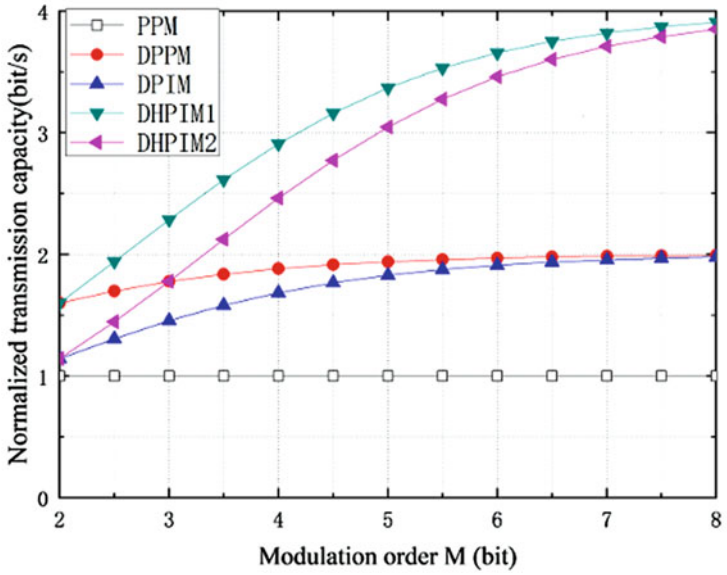

Fig. 3.12 Normalized transmission capacity of various modulation modes [51]

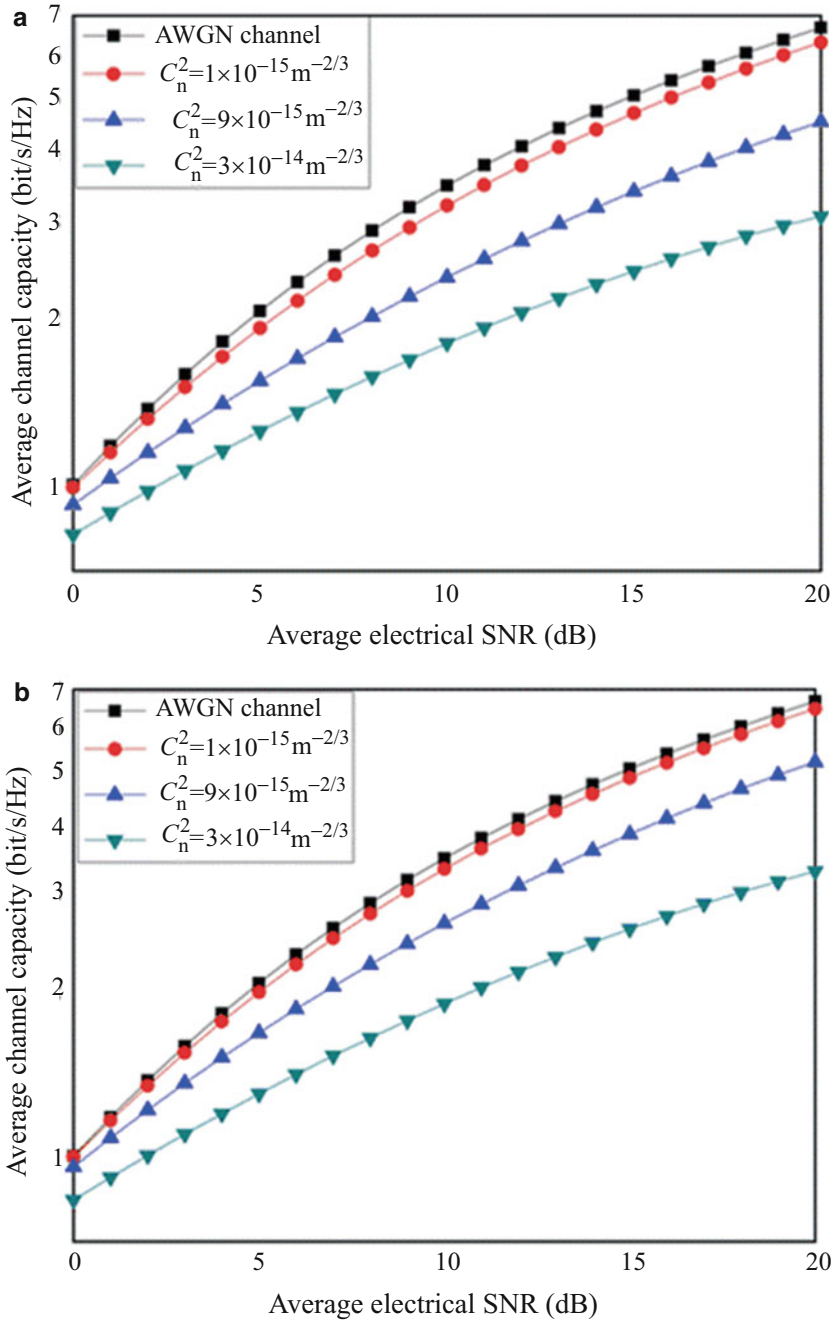

Fig. 3.13 Average channel capacity under a Gaussian turbulence channel [51]. (**a**) $L = 3000$ m, $\lambda = 850$ nm; (**b**) $L = 3000$ m, $\lambda = 1550$ nm; (**c**) $L = 5000$ m, $\lambda = 850$ nm

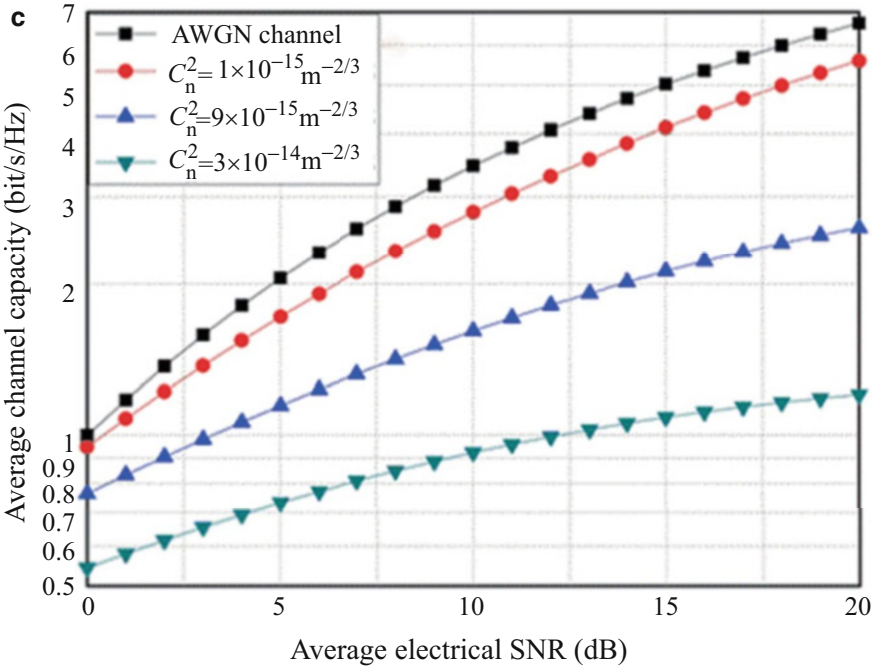

Fig. 3.13 (continued)

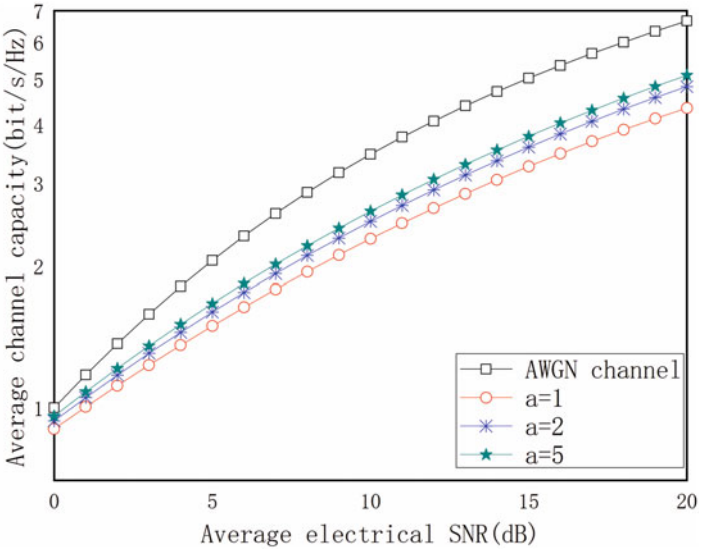

Fig. 3.14 Average channel capacity under a K distribution in a strong turbulence channel [61]

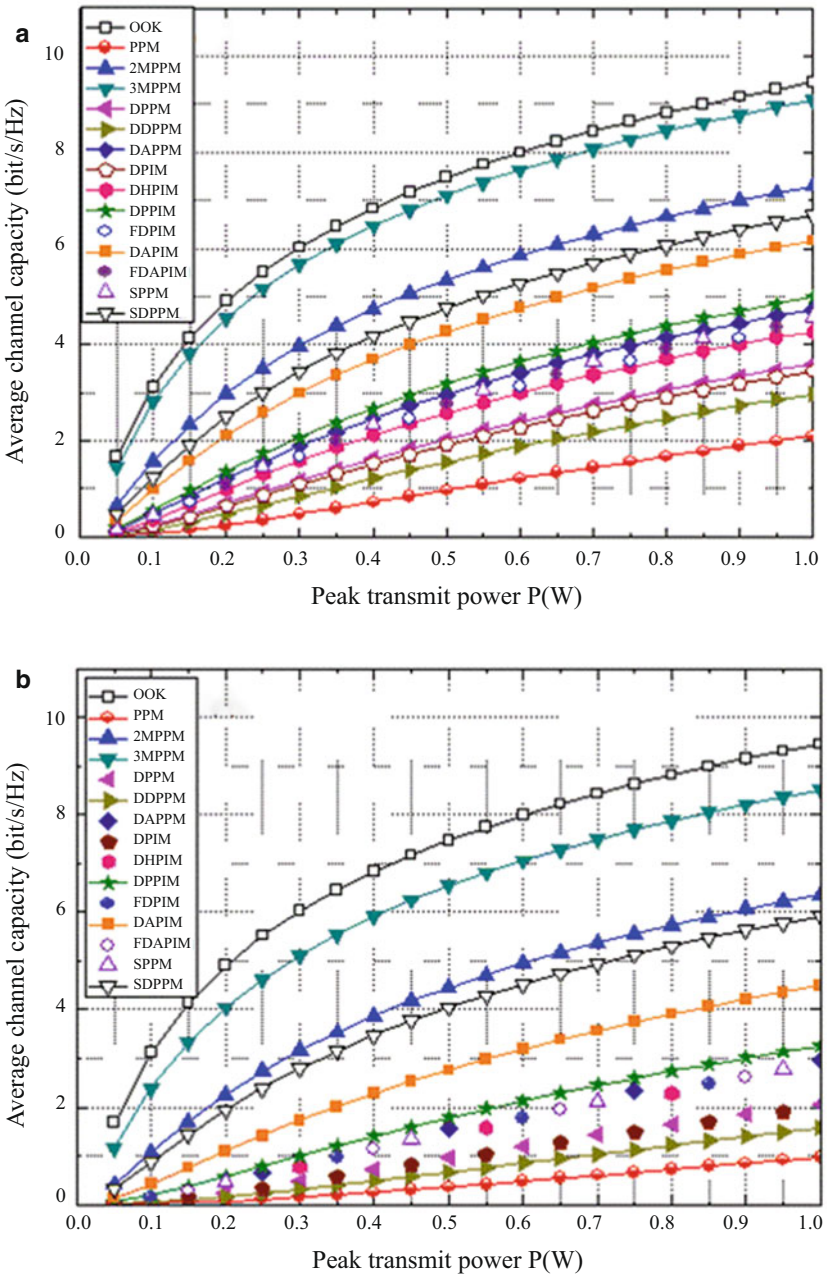

Fig. 3.15 Average channel capacity of each modulation mode under a weak turbulence channel [73]. (**a**) $L = 5000$ m, $M = 5$ bits, $C_n^2 = 1 \times 10^{-15} m^{\frac{-2}{3}}$; (**b**) $L = 5000$ m, $M = 6$ bits, $C_n^2 = 1 \times 10^{-15} m^{\frac{-2}{3}}$; (**c**) $L = 3000$ m, $M = 6$ bits, $C_n^2 = 1 \times 10^{-15}$ $\mathrm{m}^{\frac{-2}{3}}$

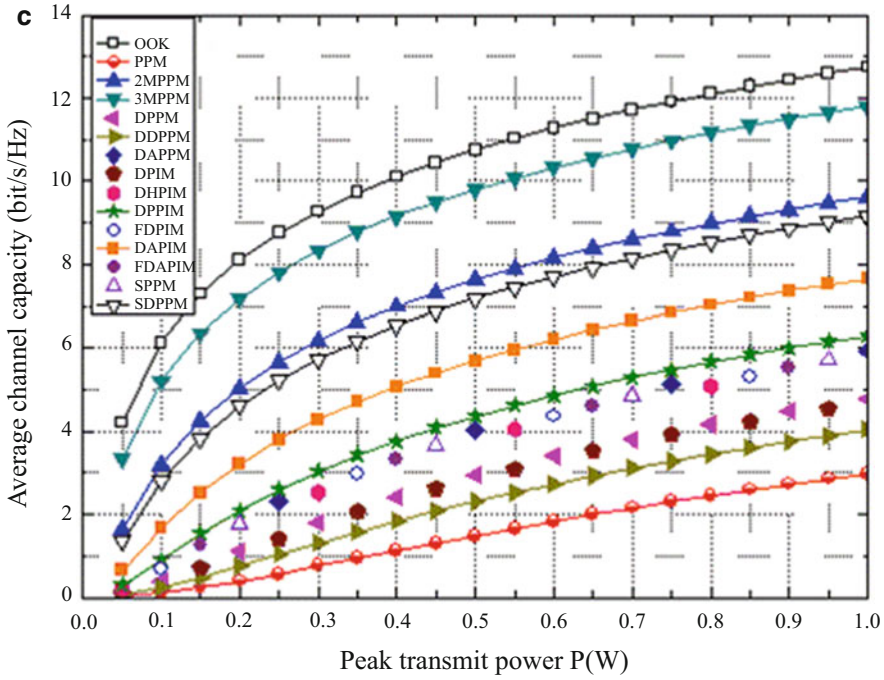

Fig. 3.15 (continued)

Figure 3.16 shows a comparison of the average channel capacity of various modulation methods at different transmission distances and modulation bits in moderate–strong turbulence. From these three subgraphs, we can see that the change trend of the average channel capacity under the same conditions is consistent with that under weak turbulence.

Figure 3.17 shows a comparison of the average channel capacity of each modulation mode under different transmission distances, modulation bits, and α values in strong turbulence. From the four sub-figures (a, b, c, and d), it can be seen that the influence of the transmission distance and modulation bit number on the average channel capacity of each modulation mode is the same as that of weak and medium–strong turbulence. The larger the channel parameter a value, the larger the average channel capacity; however, the difference is not obvious. Compared with the medium–strong turbulence, the average channel capacity of strong turbulence under the same conditions is approximately 1 bit/s/Hz lower.

This section analyzes and obtains the average channel capacity of each modulation mode under three turbulence channels, namely weak, medium, and strong. The simulation results show that the average channel capacity of OOK modulation is the largest and independent of the number of transmitted information bits. It is followed

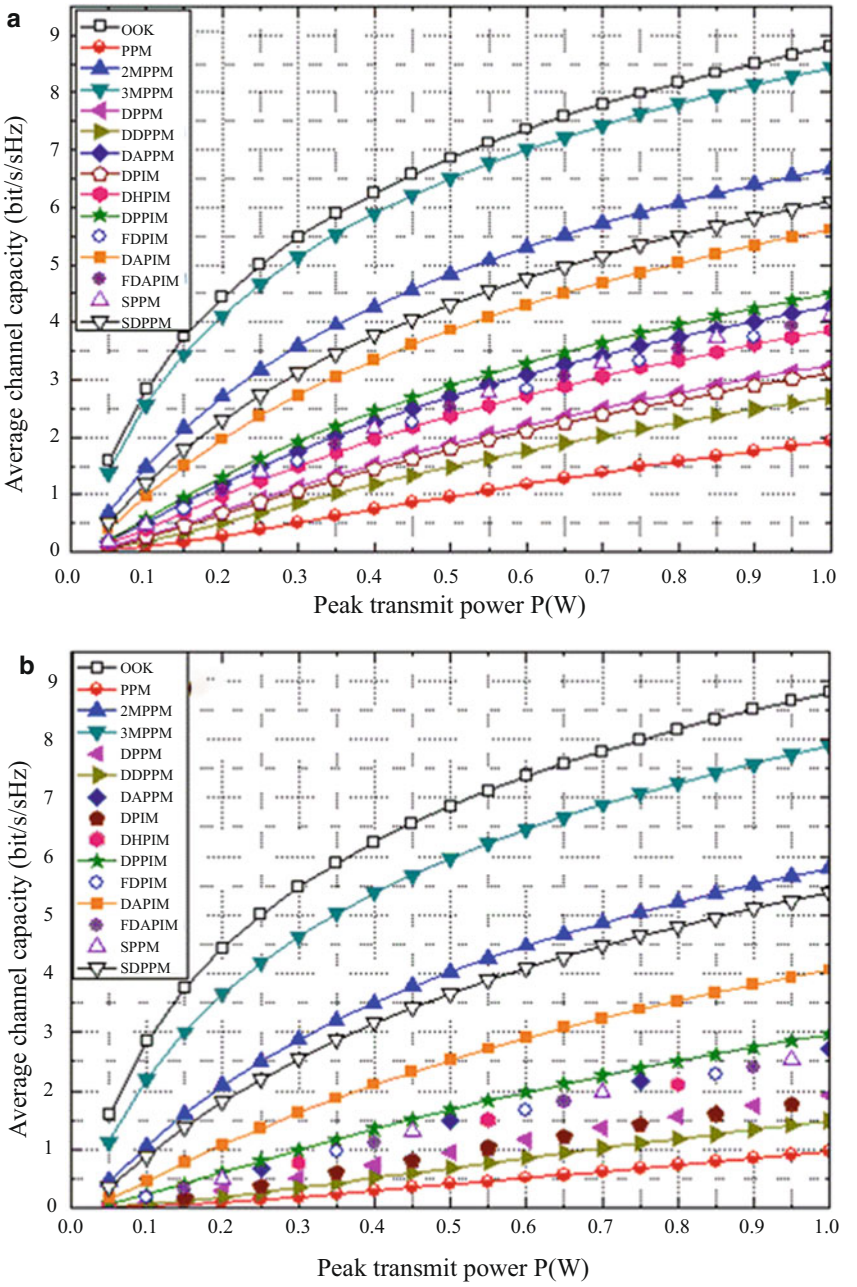

Fig. 3.16 Average channel capacity of each modulation mode under a medium–strong turbulence channel [73]. (**a**) $L = 5000$ m, $M = 5$ bits, $C_n^2 = 9 \times 10^{-15} m^{\frac{-2}{3}}$; (**b**) $L = 5000$ m, $M = 6$ bits, $C_n^2 = 9 \times 10^{-15} \mathrm{m}^{\frac{-2}{3}}$; (**c**) $L = 3000$ m, $M = 5$ bits, $C_n^2 = 9 \times 10^{-15}$ $\mathrm{m}^{\frac{-2}{3}}$

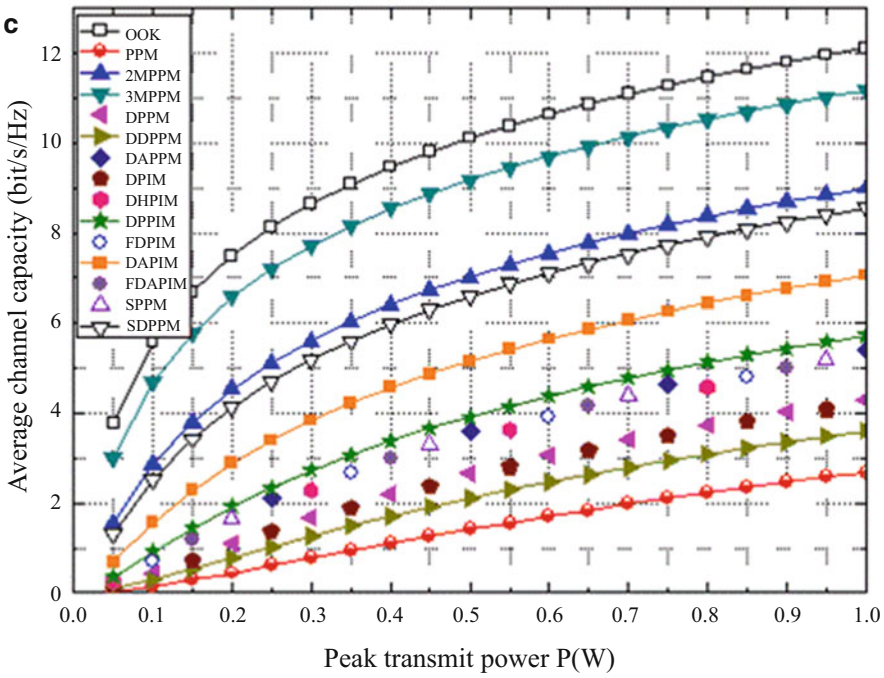

Fig. 3.16 (continued)

by 3MPPM, 2MPPM, SDPPM, then DAPIM, DPPIM, DAPPM, SPPM, FDAPIM, FDPIM, DHPIM, DPPM, and DPIM, and finally, dual-duration pulse-position modulation (DDPPM) and PPM.

When the transmission distance and modulation bit number are fixed, the stronger the turbulence intensity, the smaller the average channel capacity. The average channel capacity in weak turbulence is close to that in medium–strong turbulence; the former is approximately 0.5 bit/s/Hz higher than the latter, and the average channel capacity in medium–strong turbulence is approximately 1 bit/s/Hz higher than that in strong turbulence. The larger the transmission distance, the smaller the average channel capacity.

The average channel capacity at a transmission distance of 3000 m is approximately 3 bit/s/Hz higher than that at 5000 m; the larger the number of information bits transmitted, the smaller the average channel capacity. The average channel capacity with four modulation bits is (1–2) bit/s/Hz higher than when the number of modulation bits is five. Therefore, in terms of the average channel capacity, the best modulation method is MPPM. The average channel capacity can be improved by reducing the transmission distance and increasing the peak transmission power.

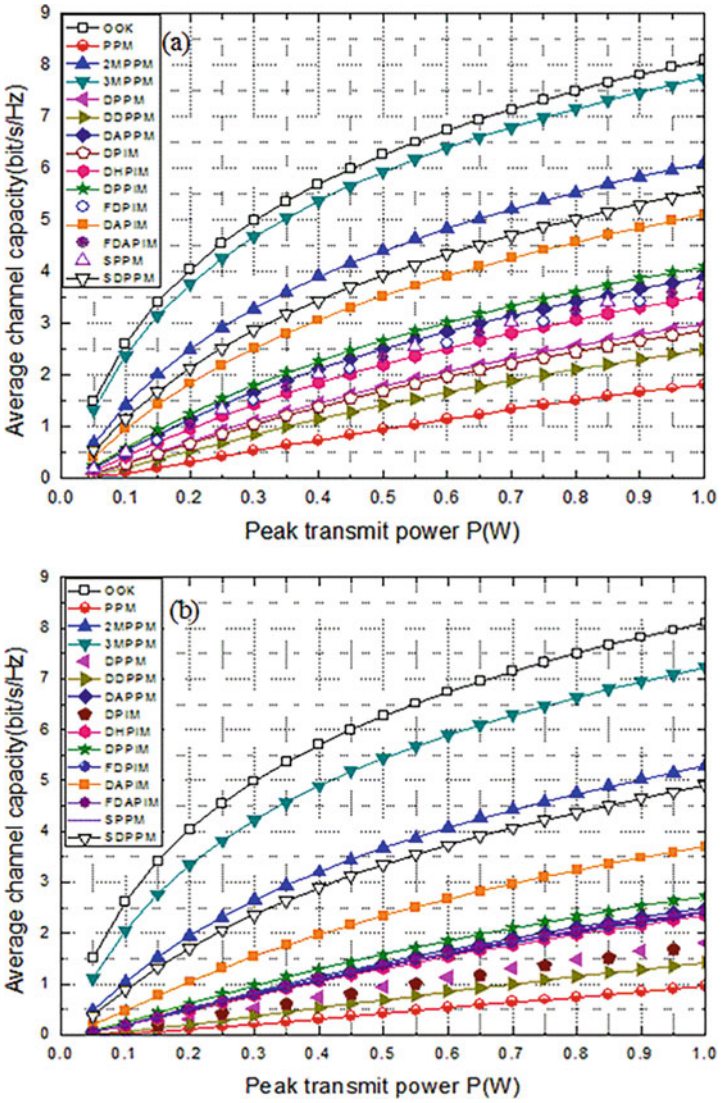

Fig. 3.17 Average channel capacity of each modulation mode under strong turbulence [59]. (**a**) $L = 5000$ m, $M = 5$ bits, $a = 4$; (**b**) $L = 5000$ m, $M = 6$ bits, $a = 4$; (**c**) $L = 3000$ m, $M = 6$ bits, $a = 4$; (**d**) $L = 3000$ m, $M = 6$ bits, $a = 2$

Adaptive Threshold Detection

Figure 3.18 shows the simulation results of the change in bit-error rate with the signal-to-noise ratio. The dotted line in the figure represents the fixed threshold-detection method, and the solid line represents the adaptive threshold-detection method when the sampling numbers M are 8, 16, 32, and 64.

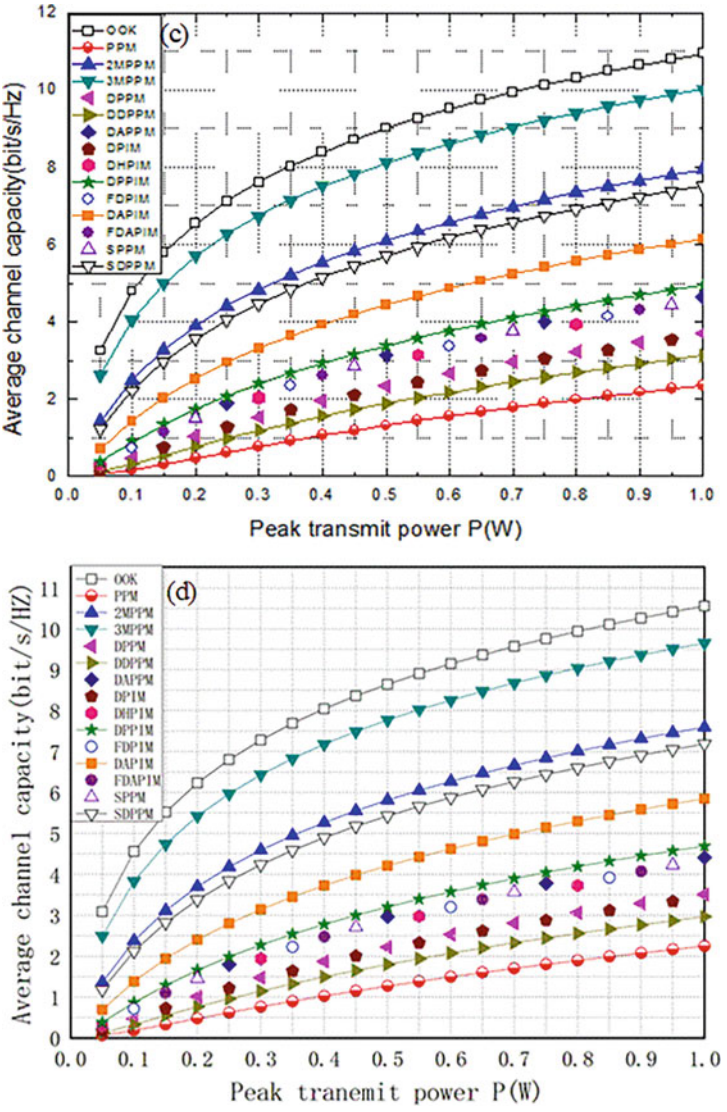

Fig. 3.17 (continued)

Figure 3.18 shows the change curve of the BER with the SNR under the fixed and adaptive threshold-detection methods. It can be observed that the bit-error rate of adaptive threshold detection is significantly lower than that of the fixed threshold-detection method at the same signal-to-noise ratio. Figure 3.19 shows the relationship curve between the signal-to-noise ratio and bit-error rate when 8-PPM, 16-PPM, and 256-PPM signals are used for transmission and three-aperture reception is used.

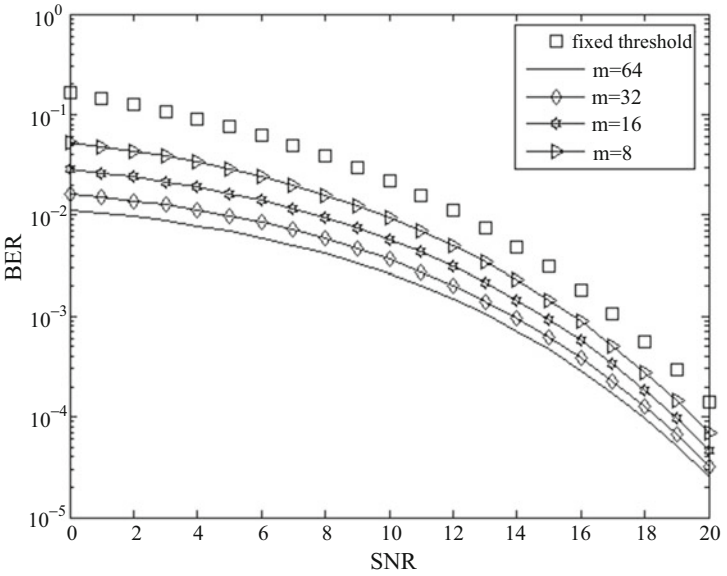

Fig. 3.18 Change curve of BER with SNR [61]

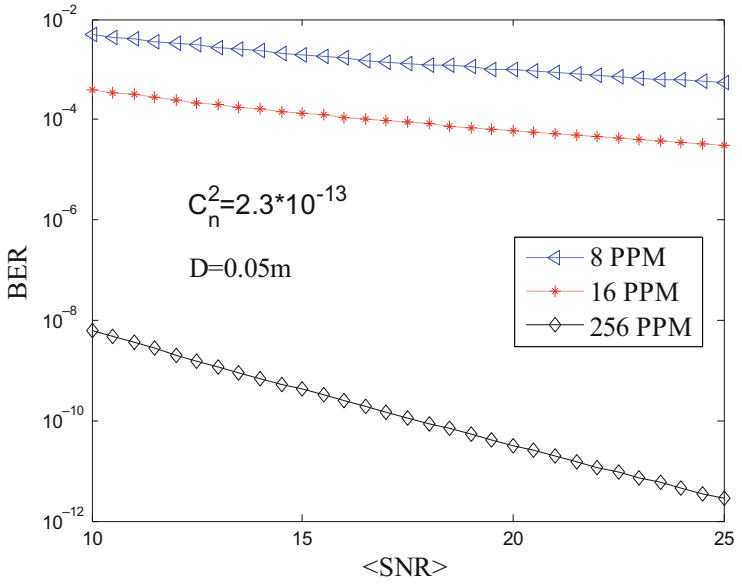

Fig. 3.19 BER curve of receiver [62]

It can be observed that the bit-error rate of the received signal decreases significantly when the number of PPM-signal time slots increases.

Figures 3.20, 3.21, and 3.22 show the change curves of the bit-error rate with the signal-to-noise ratio when the sampling numbers of the measured data are 8, 16,

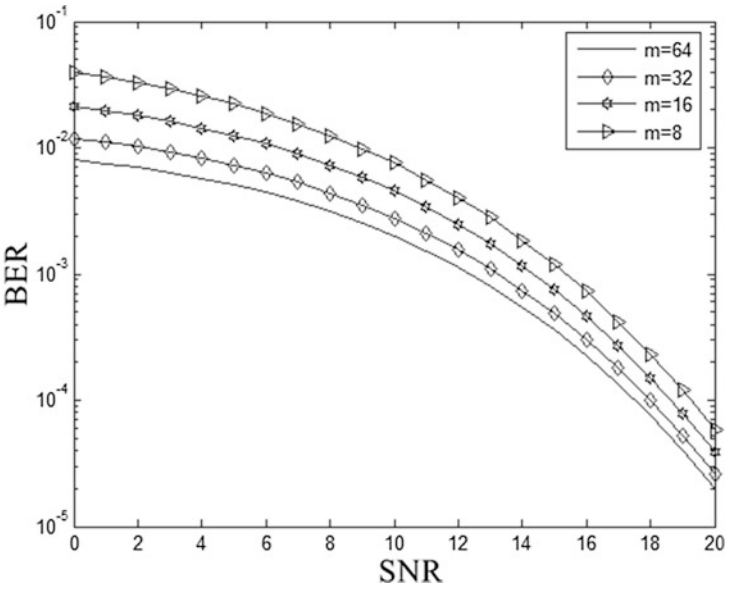

Fig. 3.20 Change curve of the bit-error rate with SNR in heavy rain [61]

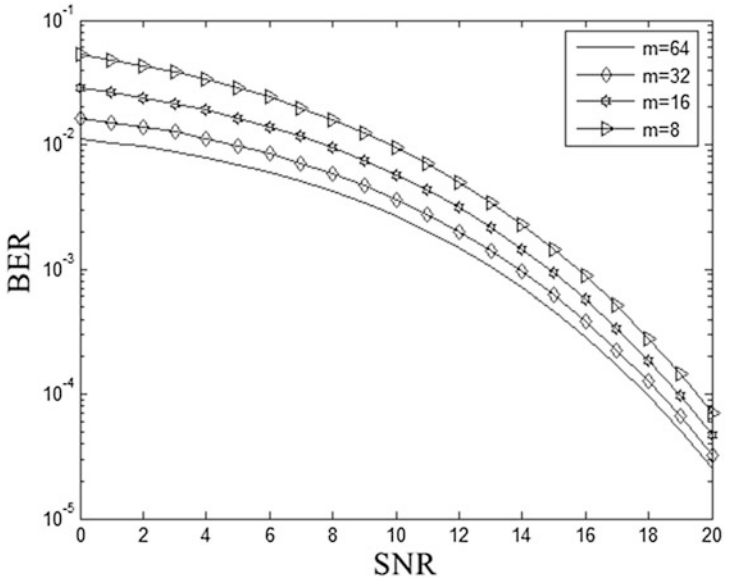

Fig. 3.21 Change curve of the bit-error rate with SNR in moderate rain [61]

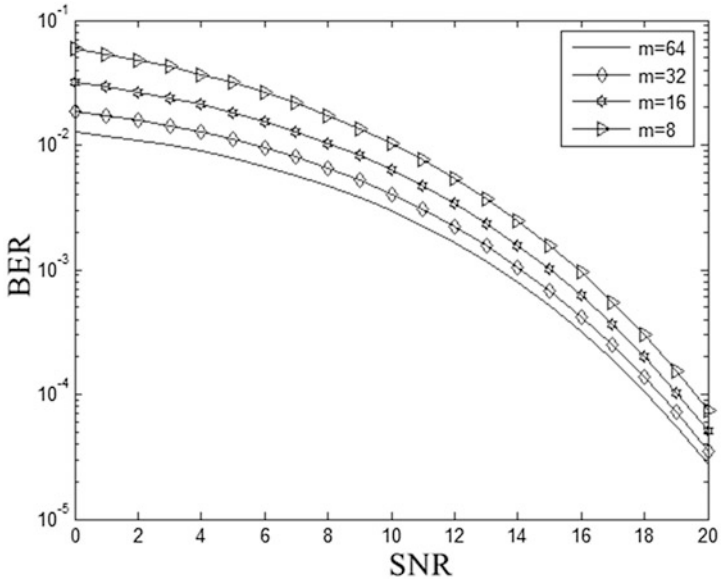

Fig. 3.22 Change curve of the bit-error rate with SNR in light rain [61]

32, and 64 in heavy, moderate, and light rain, respectively. When the number of measured data samples increases from 8 to 64, it can be seen from the figure that, under the same signal-to-noise ratio, the larger the number of samples, the lower the system error rate, and the more obvious the performance improvement of the adaptive detection method. When the number of samples exceeds 32, the performance improvement tends to flatten.

Figure 3.23 shows the change curve of the received-signal error rate with SNR in heavy, moderate, and light rain with 64 samples. It can be seen that when the SNR is the same, with the same number of symbol samples, the bit-error rate of the received signal in heavy rain is smaller than that in moderate and light rain. The received signal quality obviously improves, and the bit-error rate in moderate and light rain increases.

Factors Affecting the Laser-Modulation Rate

A high modulation rate is an important index for optical wireless communications. The main factors affecting optical wireless modulation were analyzed. It can be seen from Fig. 3.24 that when the bias current I_0 changes from 40 mA to 70 mA, the resonance peak of the relaxation oscillation shifts to the right, and the relaxation oscillation frequency f_0 increases from 6.1 GHz to 13.5 GHz.

It can be seen that the relaxation oscillation frequency f_0 can be increased by increasing the bias current I_0. Therefore, to improve the laser-modulation frequency, we can increase the steady-state photon density S_0 by increasing the bias current I_0 and then increase the relaxation oscillation frequency f_0. As shown in Fig. 3.25,

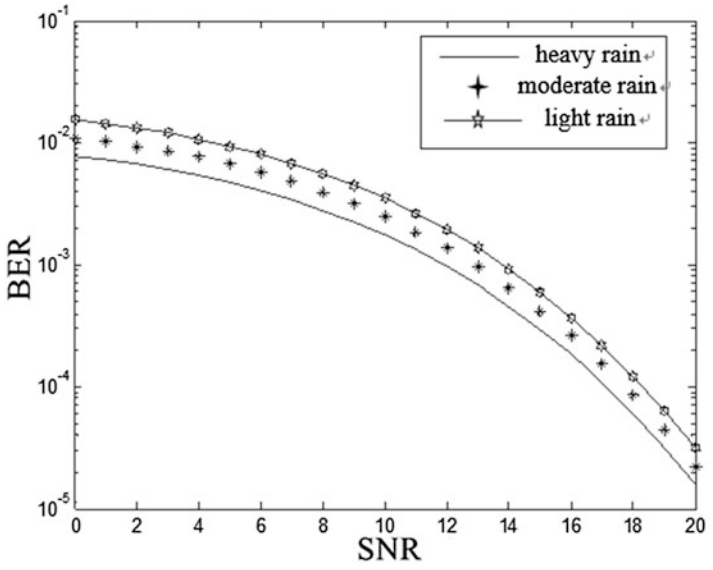

Fig. 3.23 Change curve of the bit-error rate with SNR in different weather conditions [61]

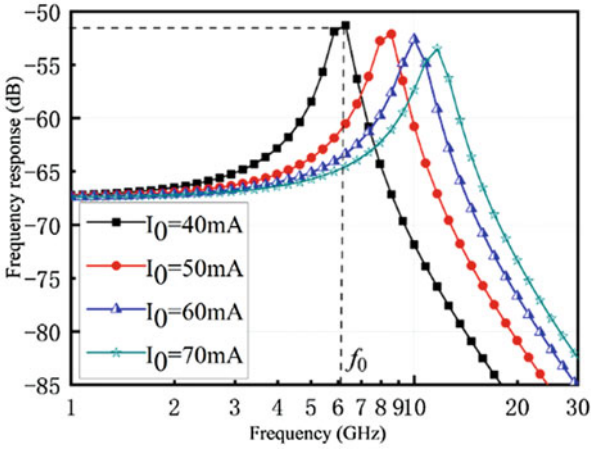

Fig. 3.24 Frequency-response curve under different bias currents I_0 [63]

when the bias current I_0 changes from 40 mA to 70 mA, the output optical power P increases from 14.5 mW to 27 mW.

Increasing the bias current I_0 can increase the relaxation oscillation frequency and reduce the relaxation oscillation amplitude, thereby shortening the relaxation oscillation process. Therefore, pulse waveform distortion can be suppressed by increasing

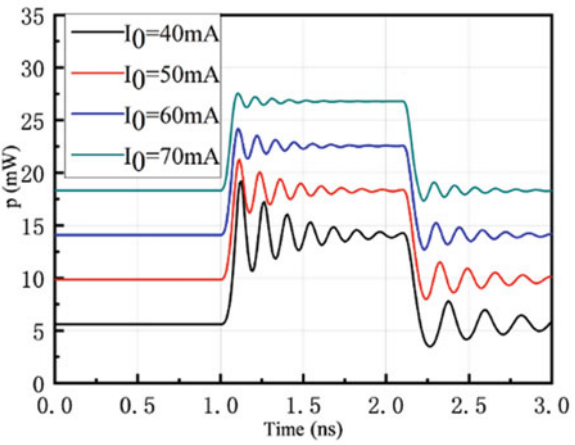

Fig. 3.25 Pulse-response curve under different bias currents I_0 [63]

the steady-state photon density S_0 (bias current I_0). It is difficult to increase the modulation frequency of a laser by increasing the current bias.

Summary

Pulse-position modulation includes PPM, DPPM, and other related and evolved modulation methods. The advantages of pulse-like position modulation are that the modulation modes are simple and the hardware circuits are convenient; however, the influence of the channel on its communication performance cannot be ignored. Researchers are investigating optical wireless communication in the following aspects.

1. Multiple transmission/reception technologies have been adopted to increase the communication capacity and suppress channel noise [64]. PAM4 is a type of PAM technology. The PAM signal is a popular signal-transmission technology after non-return-to-zero (NRZ) and is also representative of multistep modulation technology. It has been widely used in the high-speed signal interconnection field.
2. A longer-wavelength laser is used to transmit signals to avoid the impact of various weather factors, such as rain, fog, and sandstorms, on communication performance [65].
3. New modulation methods, such as reverse modulation [66], have been adopted to meet the needs of specific applications.
4. New coding technologies, such as polarization codes [72], have been investigated, and error correction codes used to suppress channel-noise interference, such as atmospheric turbulence, and improve the anti-interference ability of optical wireless communication.

5. New optical multiple-in-multiple-out (OMIMO) technologies have been studied, such as optical spatial modulation (OSM) [67], and the spatial laser index number has been used to carry additional information, effectively improving the transmission rate and energy efficiency of the system.
6. Coherent detection technology has been investigated to compensate for wavefront distortion caused by atmospheric turbulence and improve the ability to suppress it [68, 69].
7. The influence mechanism of atmospheric turbulence on optical signal transmissions has been explored and the optical communication coding and modulation modes have been adaptively changed, according to the intensity of the atmospheric turbulence, to approach the channel capacity limit [70, 71].

Through analysis and comparison, it can be seen that OOK modulation mode is simple and has low bandwidth requirements; however, the average transmission power is high, the power utilization rate is low, and the anti-interference ability is poor. PPM mode is simple, its power utilization is the highest, the average transmission power is small, and its anti-interference ability is strong; however, the bandwidth efficiency is poor, and simultaneous symbol and frame synchronization are required.

DPIM has a complex modulation structure, shortened symbol length, high bandwidth efficiency, and a higher power efficiency than OOK, without the symbol synchronization. DHPIM mode has a complex structure, which further shortens the symbol length, and improves the bandwidth efficiency and transmission capacity. It does not need symbol synchronization, which greatly simplifies the complexity of the system implementation, and it can use higher modulation modes in exchange for higher power utilization.

Pulse-like position modulation is a type of pulse modulation whose bandwidth occupation is greater than that of sine modulation. This is a disadvantage that is still difficult to overcome at present. The continuous solutions of key technologies in optical wireless communication have created opportunities for its industrialization and application. The continuous improvement of this technology will certainly promote the development and application of optical wireless communication theory and technology in China [73, 74].

Abstract

In the field of optical communication, laser and its modulation bandwidth and modulation rate are very important for optical wireless communication. On the basis of reviewing the development history of communication laser and its modulation technology, this chapter introduces the work done by Xi'an University of Technology in this field; discusses the internal and external factors of nonlinear distortion of semiconductor laser; simulates the effects of various parameters of response characteristics, linearization compensation method, and

Introduction

The laser is an important light-emitting device used in optical wireless communication. Owing to its good monochromaticity, directivity, coherence, and intense brightness, the laser is an ideal choice for a system-emission light source, and it is used as a carrier in optical communication.

Light generation cannot be separated from a suitable light source. Not all light sources can be used in optical communication. The light sources used in optical communication must satisfy a series of requirements, such as adequate wavelength, power, spectral linewidth, modulation bandwidth, integration, and cost. Modulation is the process of converting a signal. After modulation, the information from the source signal is carried in the optical signal, which is transformed into a form that is convenient for transmission through the channel.

Laser modulation refers to a change in one or several characteristic parameters of an optical signal (such as the laser intensity, frequency, phase, or polarization) through a specific method, and the change rule is specific and controllable. Laser modulation is an important application technology that has been widely used in laser communication, sensing, displays, and processing. High-power light sources and high bit-rate modulation technologies are continuous development directions.

Lasers and Optical Wireless Communication

Wireless Communication Systems

An optical-communication system model is illustrated in Fig. 4.1. The system can be divided into three blocks: an optical transmitter, a channel, and an optical receiver. The optical transmitter includes coding equipment, a modulator, a laser, an optical signal amplifier, and a transmitting antenna. Transmission channels can be divided into atmospheric, indoor, underwater, and ultraviolet light-scattering channels. The optical receiver includes receiving antennas, detectors, demodulators, and decoders.

In optical wireless communication, the transmitter first modulates the information generated by the source onto an optical carrier, and then the carrier is transmitted through the atmosphere or free space. An acquisition, pointing, and tracking (APT) system controls the laser beam and ensures a smooth communication link.

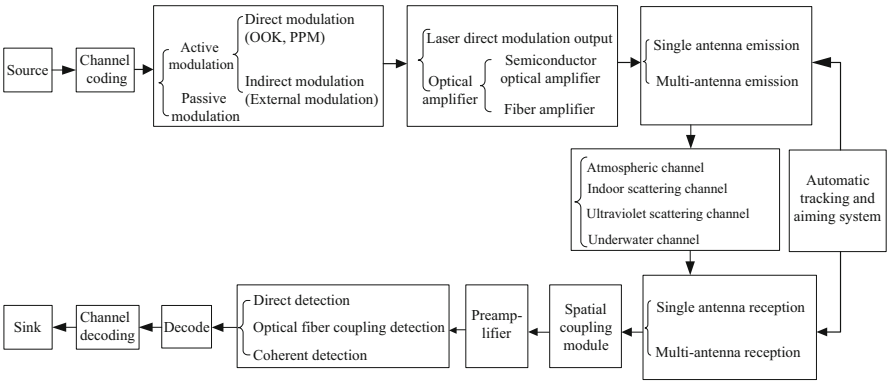

Fig. 4.1 Optical wireless communication model [1]

Subsequently, the optical signal from the transmitter is received by the optical signal antenna, and the received signal light is coupled onto an optical fiber using a space optical-fiber coupling device. Occasionally, the signal light is amplified by a preamplifier before being converted to electricity. Then, the baseband signal is recovered by the demodulator and the original baseband signal is obtained by the decoder.

Laser Structure

A semiconductor laser uses semiconductor material as the gain medium. It emits light as photons transition between semiconductor energy bands and usually takes a natural cleavage plane as the resonant cavity. Therefore, it has the advantages of a wide wavelength coverage, small volume, stable structure, strong radiation resistance, various pumping modes, high yield, good reliability, and easy high-speed modulation. Unfortunately, it has a poor output-beam quality, large beam-divergence angle, asymmetric spots, poor spectral purity owing to the influence of interband radiation, and a difficult preparation process.

As shown in Fig. 4.2, a laser is generally composed of a working substance, excitation source, and resonant cavity. Working substances can be solids (including various semiconductors), liquids, or gases, with different types and pumping methods. The substance must able to invert the particle number. Total and partial reflectors are placed in parallel to form a resonant cavity, which reflects the photons generated by the active gain layer and oscillates coherently to amplify the light. External excitation supplies energy to the working substance, enabling particles at a low energy level to jump to a higher energy level. Therefore, a laser with high photon degeneracy must satisfy three conditions: particle-number inversion, appropriate resonant cavity, and a threshold condition.

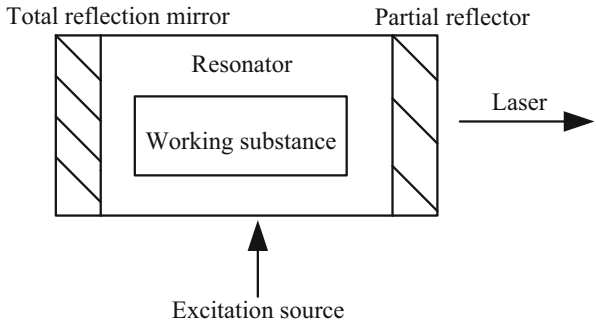

Fig. 4.2 Laser structure [2]

Laser Modulation Modes

Modulation implies that the information (voice, data, etc.) to be transmitted is transmitted through a certain medium by changing the carrier-signal parameters. In optical wireless communication, modulation means that information is loaded onto a laser or other carrier using an electro-optical conversion process, and the signal is converted into a form that is convenient for transmission in the channel.

Modulation can be divided into active and passive, depending on whether the light source and modulation signal are on the same end of the transmission. In active modulation, both the light source and modulated signal are at the transmitting end, whereas in passive modulation, the light source is at the transmitting end and the modulated signal is at the receiving end. Active modulation can be classified into direct and indirect types. The modulation of the laser power is direct, and the modulation of the light source emitted by the laser is indirect; it is also known as external modulation [1].

Laser Research Progress and Present Situation

Based on their different working media, lasers are subdivided into solid-state, gas, semiconductor, and fiber. Their development in communication is discussed.

Solid-State Lasers

In a solid-state laser (SSL), the working medium is mainly a solid metal material. In 1917, Einstein explicitly proposed stimulated radiation, which provided the main theoretical basis for the later discovery of lasers [3]. In 1960, Maiman successfully developed the first chromium (Cr)-doped ruby solid-state laser pumped by a pulsed xenon lamp [4].

Since the 1980s, solid-state lasers have shown clear directions, including all-solid-state, tunable, high-power, and new wavelength [5]. Research on all-

solid-state 532-nm green lasers with high power and miniaturization has played an important role in ocean exploration, underwater communication, and other fields.

With the development of optical-fiber communication networks, particularly after the wide application of dense wavelength-division multiplexing (DWDM) technology in the optical-communication field, researchers have proposed higher requirements for lasers as communication light sources. Currently, fixed-wavelength lasers are traditionally used as light sources. If multiple wavelengths are output, the cost and volume of the laser increase correspondingly; this inevitably limits the flexibility of optical network expansion.

If a wavelength-tunable laser is used, instead of a traditional fixed-wavelength laser, the high cost of the light-source configuration and maintenance in the DWDM system can be reduced, the wavelength resources can be fully utilized, the production cost and management complexity can be reduced, and the cost performance of the network system can be improved.

Next, we introduce the tunable laser whose tuning range is limited by the bandwidth of the gain medium. Tuning involves controlling the loss in the laser cavity to minimize the loss of a specific laser wavelength. Not all wavelengths for a given application can be generated from a laser using the required parameters (such as the function or energy). Wavelengths are typically converted when other laser wavelengths are required.

To create wavelength-tunable lasers, according to the demands of the late 1990s, the wavelength-tuning range should be approximately 40–60 nm. Let us consider nonlinear-wavelength conversion. In 2006, a side-pumped 1064-nm neodymium-doped yttrium–aluminum–garnet (Nd:YAG) rod V-shaped cavity laser was developed by Mukhopadhyay et al. in Pakistan. Potassium titanyl phosphate ($KTiOPO_4$, KTP) was used as a nonlinear frequency-doubling crystal, and a green light with a beam-quality factor of 20 was obtained by frequency doubling [6].

In 2009, a double-headed series structure based on side pumping was used by Xu et al. Lithium triborate (LBO) was used as a nonlinear frequency-doubling crystal. The output power of the continuous green light reached 40 W, and the electro-optical conversion efficiency was 5.0% [7]. In 2011, Singh et al. doubled the intracavity frequency of a diode-pumped Nd:YAG laser in a Z-shaped cavity, showing a continuous green power of 82.5 W, corresponding to a pump-to-green-light conversion efficiency of 11% [8].

In 2012, Ji et al. adopted a compact and unstable V-shaped cavity approximately 300 mm in length. Using the green laser generated by the second harmonic generation (SHG) in the cavity, the light–light conversion efficiency from the diode to green light was 110.7% and the infrared–green conversion efficiency was greater than 80% (81.8%) [9]. The development of all-solid-state lasers can compensate for the shrinking market of traditional solid-state lasers.

Solid-state lasers generally have short wavelengths (ultraviolet and deep ultraviolet), short pulse widths (picoseconds and nanoseconds), and high peak power. To produce an ultraviolet solid-state laser, the pump light source in the laser irradiates the enhancement medium to invert the particle beam; a fundamental infrared light is formed and oscillates in the resonant cavity. After one or more frequency-doubling

cycles in the nonlinear crystal cavity, the required ultraviolet laser is finally output from the resonant cavity through transmission and reflection.

Nd:YAG and neodymium-doped yttrium orthovanadate (Nd:YVO_4) are both common enhancement dielectric crystals. A commonly used method to enhance the resonant cavity is to pump an 808-nm-wavelength Nd:YVO_4 laser crystal into the cavity for frequency doubling to output a 532-nm-wavelength green light, and then send it to the enhancement resonant cavity for frequency doubling to output a 266-nm-wavelength deep ultraviolet laser. The input threshold of a fundamental green light can be as low as 215 mW.

The 28-nm wavelength band has a very important application in ultraviolet resonance Raman spectroscopy. In 2022, Zhao et al. adopted a V-shaped intracavity frequency-doubling and lens-focusing mode intracavity frequency-quadrupling structure. Based on an Nd:YVO_4 quasi-three-level laser system, a 914-nm fundamental-light cascaded nonlinear optical frequency was converted to obtain a continuous-wave (CW) 228-nm laser output [10]. In general, compared to the pulse-operation mode, a continuous-operation laser requires a higher average power and better beam quality to realize the extra-cavity frequency doubling of the lens focus.

Solid-state lasers generally have short wavelengths (ultraviolet and deep ultraviolet), short pulse widths (picosecond and nanosecond), and high peak power. However, their beam quality is affected by temperature; therefore, thermal management is very important for the overall efficiency of the laser system. Commonly used cooling methods include spray (water) cooling [11], solid (diamond) cooling [12], direct heat dissipation of crystal cross sections [13], forced-convection cooling, semiconductor refrigeration, and heat-pipe heat-conduction technology [14].

Further development depends on improving the thermal management, as well as finding new nonlinear materials and obtaining the best wavelength required for specific applications [15].

Gas Lasers

The earliest gas lasers, which use gas as a gain material, were He–Ne gas lasers [16]. In 1965, Patel et al. successfully discharged a N_2–CO_2–He gas mixture, which was the first electrically excited CO_2 laser, and produced a laser with high continuous output power [17].

The acousto-optic Q-switched Q CO_2 laser satisfies the application requirements for space communication. In 1991, Yang et al. developed an acousto-optic Q-switched continuous direct-current (DC)-discharge-excited waveguide CO_2 laser. The acousto-optic medium was a germanium single crystal, and the pulse-repetition frequency range was 0–200 kHz [18].

Since 2009, Professor Xie Yijiang et al. have studied the specific technical parameters of acousto-optic Q-switching, using the rate equation of a Q-switched pulse laser, and manufactured an acousto-optic Q-switched Q CO_2 laser with tunable coding output [18–20]. In 2012, based on their achievements, Xie et al. adopted the

method of inserting an acousto-optic modulator into the cavity. The adjustable laser-pulse frequency range was 1 Hz–100 kHz. When the pulse frequency was 1 kHz, the pulse width was 156 ns, and the peak pulse power was 10 kW [21].

In 2019, Pan et al. successfully used the external cavity method to study modulator characteristics and successfully integrated the optical-path fast-deflection technology of the double acousto-optic modulator with a self-collimating grating method. This enabled the fast tuning of the CO_2 laser over the entire band and the output of the same optical path, while reducing the CO_2 laser and wavelength switching time to milliseconds [22].

Gas lasers were the first lasers to be applied, and they still occupy an irreplaceable position in lithography and other fields. However, owing to their large size and difficult maintenance, the market share of gas lasers in China has been less than 5% in recent years, and they are no longer mainstream lasers.

Semiconductor Lasers

Semiconductor (laser diode, LD) lasers, whose working medium is semiconductor materials, are usually doped with III–V compounds, such as gallium arsenide (GaAs), indium phosphide (InP), gallium nitride (GaN), etc. The lasers used for optical communication are primarily semiconductor lasers. Currently, the development can be roughly divided into two categories: information and power.

Information lasers are mainly used in the field of information technology, such as distributed feedback and dynamic single-mode lasers (DFB-LD) for optical-fiber communication and optical switching systems, tunable lasers with a narrow linewidth, and visible-light wavelength lasers (405 nm, 532 nm, 635 nm, 650 nm, and 670 nm) for information-processing fields, such as optical disks. They exhibit a single frequency, narrow linewidth, and high speed.

Power lasers are used as a pumping source in applications such as pumping solid-state lasers. This has led to a breakthrough in high-power semiconductor lasers, which was marked by a significant increase in their output power. The basic structure of a semiconductor laser is shown in Fig. 4.3.

According to the relationship between the beam exit direction and the substrate surface, semiconductor lasers can be divided into edge-emitting lasers (EEL) and vertical-cavity surface-emitting lasers (VCSEL). Figure 4.4 shows their structures and characteristics.

Edge-Emitting Semiconductor Lasers

Edge-emitting lasers include distributed-feedback lasers (DFB), Fabry–Perot (F–P), distributed Bragg reflectors (DBR), and so forth. They can be used as direct-modulation lasers or coupled with optical fibers or crystals to manufacture diode-pumped solid-state lasers. They have a wide wavelength range and high photoelectric efficiency, and their applications include optical communication, optical storage, material processing, medical treatment, sensing, etc.

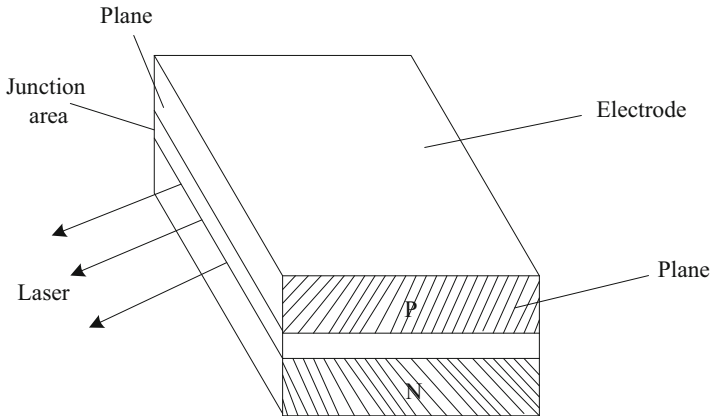

Fig. 4.3 Basic structure of a semiconductor laser [1]

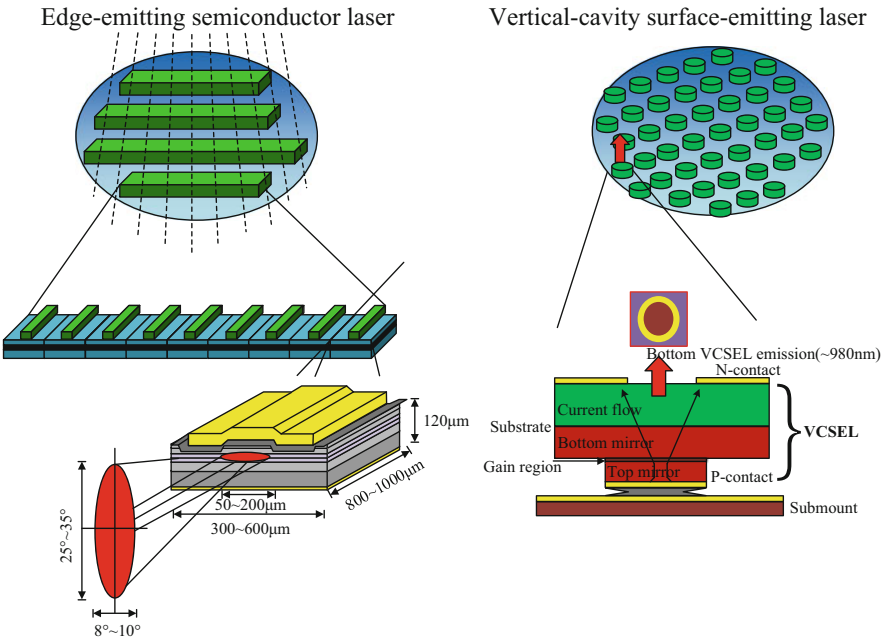

Fig. 4.4 Basic structure and characteristics of edge-emitting and surface-emitting lasers [23]

With the increasing demand for capacity, speed, and stability in optical-fiber communication, semiconductor lasers must have a lower threshold, better dynamic single-longitudinal mode, higher modulation rate, and higher reliability. The difference between F–P, DFB, and DBR lies in the longitudinal mode, which is determined by the design of the resonant cavity. The earliest F–P cavity semiconductor

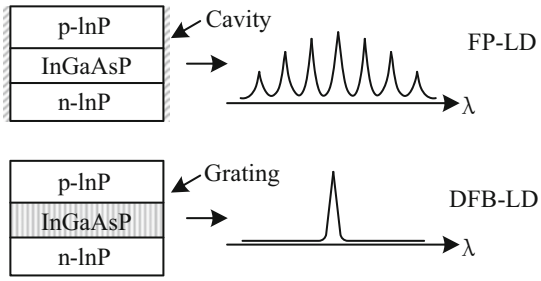

Fig. 4.5 Structural-comparison diagram of FP-LD and DFB-LD

lasers could not meet the demands of a single-mode optical-fiber communication system because of their multiple longitudinal modes.

To solve this problem, Bragg-grating technology was introduced into LD. When the Bragg-grating laser is used instead of the F–P cavity, only half of the grating is needed to adjust the phase by current, that is, the output wavelength can be tuned by the magnitude of the current. Alternatively, a Bragg-grating structure can be applied to the active region, which is the widely used DFB laser. These two types of lasers can stabilize narrow emission linewidths.

For DFB lasers, only one grating can be used for wavelength selection, and they are widely used in medium- and long-distance transmissions, including transmission networks, wireless base stations, and data-center internal interconnections. They are some of the most important light sources used in communication systems. Figure 4.5 shows a structural comparison of the FP-LD and DFB-LD.

From 1971 to 1972, Kogelnik of Bell Laboratories proposed the basic theory of the DFB laser [24, 25]. In 1973, a semiconductor DFB laser was developed [26]. At the end of 1988, a DFB laser with a ridge waveguide at the 1.55-μm band was developed in China, and the side-mode suppression ratio exceeded 30 dB. Direct-modulation DFB-LDs are frequently used in high-speed short-distance optical-fiber communication technology; their research progress will be discussed in the internal-modulation section.

Compared to current quantum-well devices, the future development direction of DFB-LDs will be a combination of large-scale functional integration and various material systems. For example, quantum-dot gain media can significantly improve the manufacturing efficiency, producing DFB lasers with smaller volumes and better performance to meet future market needs [27]. Mid-infrared continuous-wave (CW) semiconductor lasers are very important light sources, especially in spectroscopy. GaSb-based interband emitters can be used as effective seed sources for tunable semiconductor laser spectra, both in external-cavity construction and spectrum-selective distributed feedback, and have relatively low power.

Previously reported semiconductor lasers, based on multiple W-quantum-well active areas, could only output pulsed light, and the working mechanism was due to the hole-tunnel carrier-transport mode in multiple 2-nm-thick InAs layers, which led to the low utilization rate of multiple W-quantum-well active areas. Researchers at Stony Brook University proposed an improved design for W-quantum wells without

an InAs layer. They designed and constructed a CW semiconductor laser based on a three-layer GaInAsSb quantum well at room temperature.

The working wavelength of the laser is flexible and adjustable, and can be independently controlled by the effective electron and hole quantum-well widths. The improved design scheme adopts a quantum well with a 10–12-nm width, so that its working wavelength can reach more than 3.2 μm, and the CW working range at room temperature can be close to 3.3 μm or 3.4 m.

Laser-pumped praseodymium-doped solid-state lasers have also made progress. Researchers in the Department of Electronic Engineering of Xiamen University proposed a praseodymium-doped diode-pumped laser based on $LiYF_4$, which works at 695.8 nm. In the experiment, the high gain conversion was suppressed at wavelengths of 640, 670, 698, and 721 nm. They used InGaN as the laser diode in the pump source, and the output power of the σ polarized light at the central wavelength of 695.8 nm was 51 mW. Its slope efficiency was 13.6% and the threshold of the absorbing pump power was 229 mW. Researchers used a yttrium–lithium–fluoride (YLF) praseodymium-doped laser to obtain the output of the σ polarized light at a central wavelength of 695.8 nm.

Infrared, red, green, and blue lasers have been used practically. In recent years, the industry has generated a demand for more powerful ultraviolet lasers. In February 2020, Professor Susumu Iwatani, Faculty of Science and Technology, Meishiro University, Japan, announced the invention of the world's first mid-wavelength ultraviolet semiconductor laser, using independently developed semiconductor technology and new methods [28].

Compared with gas and solid-state lasers used in the same wavelength range, semiconductor lasers can provide miniaturization, low power consumption, long service life, and low cost. This achievement will open up new possibilities for optical science, which can not only be applied to industry but also be expected to solve problems in other fields, such as chemistry, environment, medical treatment, and biological science.

Surface-Emitting Semiconductor Lasers

In the general structure of a vertical-cavity surface-emitting laser (VCSEL), the upper and lower DBR structures are used as the emitting cavity and gain region in the middle, respectively. A dynamic single-mode operation is ensured, based on the DBR structure. The volume of the gain region is small, the threshold current is low, and the optical-fiber coupling efficiency is extremely high. The outgoing Gaussian beam is astigmatic and forms a high-density two-dimensional array, making it important for applications in optical interconnection and optical information processing [29].

The VCSEL for the optical module includes a multi-transverse mode and a single longitudinal mode. For medium- and low-speed data-communication networks, 850-nm VCSEL is the mainstream short-distance data-communication method because of its low cost, short active optical cavity, and high modulation rate. In 1977, the concept of a VCSEL was first proposed by Iga in Japan [30], with a 900-mA threshold current. In 1988, the VCSEL device successfully produced

continuous lasing at room temperature in the 850-nm band [31], which was a key step towards practical applications. In 1996, Lear et al. used an oxide-limited VCSEL for optical communication. It limited the light field and reduced the threshold current. The main parameter required was the highest-possible modulation speed.

In 2008, Finisar Company successfully fabricated a shortwave communication VCSEL in the non-return-to-zero (NRZ) modulation format using unstrained GaAs quantum wells in the active area. At room temperature, the rate was 30 Gbit/s and the bandwidth reached 19 GHz [32]. In 2015, IBM Corporation cooperated with Chalmers University of Technology in Sweden to integrate driver circuits, decoupling capacitors, and VCSEL, and introduced equalization technology. The error-free data-transmission rate was 71 Gbit/s at 25 °C and 50 Gbit/s at 90 °C [33].

From 2001 to 2015, the modulation rate of VCSEL NRZ increased from 20 to 71 Gbit/s [32–37]. After 2015, the modulation rate and bandwidth increased. Combined with multiwavelength or complex modulation, it was applied at 100, 200, and 400 GHz.

Currently, the transmission rate of a shortwave GaAs-based 850-nm VCSEL exceeds 100 Gbit/s. PAM4 is a type of pulse-amplitude modulation (PAM) technology. PAM is a popular signal-transmission technology after NRZ and is representative of multilevel modulation technology. PAM has been widely used in the field of high-speed signal interconnections. Under the same baud-rate conditions, the bit rate of the PAM4 signal is twice that of the NRZ signal, the transmission efficiency is doubled, and the cost can be effectively reduced.

In 2020, Lavrencik et al. [38] used forward error correction and a receiver equalizer in their system to improve the data rate. Experiments showed that the data rate of four-level pulse-amplitude modulation (PAM4) exceeded 160 Gbit/s. In 2021, Zuo [39] combined a nonlinear equalizer and a noise-cancellation algorithm in digital signal processing to alleviate the intersymbol interference and nonlinear factors caused by PAM4. Consequently, the transmission rate of a VCSEL on 100-m optical mode (OM4) multimode fiber reached 200 Gbit/s. Table 4.1 lists the chip research progress of the 850-nm VCSEL for data communication.

Because the information-transmission distance of shortwave VCSEL optical communication is limited to several hundred meters by modal dispersion, it has

Table 4.1 Research progress of the 850-nm VCSEL chip for data communication [40]

Research institution	Modulation mode	Rate (Gbit/s)	Year	Reference
IBM	NRZ	20	2001	[34]

IBM–Chalmers	NRZ	71	2015	[33]
Lavrencik	PAM4	160	2020	[38]
Zuo	PAM4	200	2021	[39]

been necessary to develop a long-wavelength band with less loss for investigating high-speed VCSEL, such as 1310-nm and 1550-nm band systems [41–44]. It is possible to extend the communication distance to over 20 km.

In contrast to the perfected preparation process of 850-nm VCSEL, at present, the research on long wavelengths mostly lies in optimizing the device structure, which mainly involves preparing a DBR with a high refractive index and high thermal conductivity, forming an effective current-limiting structure, and solving thermal problems [45].

Fiber Lasers

In a fiber laser, the gain substance is called the gain fiber, and its output wavelength is mainly determined by doped rare-earth elements. For example, a Yb^{3+}-doped glass fiber outputs a 1064-nm laser and an Er^{3+}-doped glass fiber outputs a 1310-nm or 1550-nm laser. The fiber modules are divided into single mode and multimode. The fiber core of a single-mode laser is thinner and the beam quality is better than that of a multimode. The energy distribution is Gaussian, and the energy density in the middle is the highest. A three-dimensional figure shows a sharp, round mountain peak.

The fiber core of a multimode laser is thicker, the beam quality is worse, and the energy distribution is more normal than that of single-mode. The three-dimensional image is an inverted cup, and the edge of a multimode laser is much steeper than that of a single-mode. Owing to their excellent beam quality and flexible power-expansion capability (fiber combiner), fiber lasers have developed rapidly and can realize CW operation and high-repetition-rate pulse operations [46].

In 1961, Snitzer [47] of the United States proposed the concept of a fiber laser. In 1966, Gao theoretically analyzed the possibility of using optical fibers as a new type of communication transmission medium and proposed using impurity-free and transparent glass fibers to transmit laser signals. If the loss is as low as 20 dB/km, long-distance optical communication can be realized, promoting the development of optical fibers in the communications field [46].

Mode-locked fiber lasers with tunable wavelengths have important applications in spectroscopy, optical communications, and sensing. This research topic has become popular in recent years. At present, the most common and effective method to build a wavelength-tunable laser uses a filter with wavelength selectivity and a mode-locked device with a nonlinear saturable absorption effect. In 1989, Hanna et al. demonstrated the first mode-locked erbium-doped fiber laser using a bulk lithium–niobate (LN or $LiNbO_3$) phase modulator with a 4.5-W output power and 37-ps mode-locked pulses [48].

In 2015, a mode-locked erbium-doped fiber laser developed by Li et al. adopted nonlinear polarization rotation technology and produced a pulse with a 34.3-fs width [49]. In 2022, Mao et al. proved that birefringence could also be used to modulate the spectrum and time-domain shape of pulses in the positive-dispersion region. This type of fiber laser can generate harmonic mode-locked birefringence management

solitons with an adjustable pulse-energy range exceeding 15 times. It provides an effective method to create a pulse source with a high repetition rate and low power consumption [50].

Since the birth of lasers, the early stage mainly involved improving the basic theory. In the last 30 years, lasers have developed rapidly under the huge driving effect of practical applications. Currently, the research hotspots of communication lasers are high power, short pulses, and wavelength extensions to the mid-infrared region. Research teams worldwide are constantly improving laser performance and expanding their fields of application.

Driven by the application of pumped solid-state and fiber lasers, the output power of semiconductor lasers has increased significantly, and semiconductor optoelectronic devices are developing in the directions of longer and shorter wavelengths, higher power, and higher working frequency; however, further performance improvement is still a goal [40].

Low-Coherence Lasers

Lasers are widely used because of their high coherence, directivity, and monochromaticity. However, in the laser-display and biological-imaging fields, the speckle phenomenon caused by high laser coherence seriously affects the imaging quality. Goodman concluded [51] that shaking screens and laser arrays could reduce speckle; however, these methods have their own problems, such as mechanical instability, huge volume, and high cost. The most direct and thorough way to eliminate speckles is to use a low-coherence laser.

Through innovations in the geometry of the laser cavity and the laser-oscillation feedback mechanism, low-coherence lasers, developed by regulating the number of laser modes and the spatial distribution of the mode field, are receiving increased attention. Over the past 30 years, low-coherence lasers have developed rapidly, and random lasers, degenerate-cavity lasers, chaotic-cavity semiconductor lasers, near-concentric-cavity semiconductor lasers, and dumbbell-shaped-cavity semiconductor lasers have successively emerged. However, low-coherence lasers are still in the laboratory-research stage, and many urgent problems remain to be solved, including poor directivity, low power, continuous lasing, and few means of adjusting the coherence. Therefore, the application of low-coherence lasers requires further investigation.

Ultraviolet Lasers

Ultraviolet lasers are mainly classified into gas and solid-state ultraviolet lasers. Under the action of the pump source, the working medium reaches the excited state by absorbing external energy, and the gain is greater than the loss through the particle-number inversion. Hence, the light is amplified, and part of the amplified-

light feedback continues to be excited, thus creating an oscillation in the resonant cavity to generate laser light.

The gas medium mainly uses a pulse or electron-beam discharge, and gas particles are excited from low to high energy levels by mutual collisions between electrons, resulting in a stimulated transition and thus, producing an ultraviolet laser. A solid medium is a type of ultraviolet laser that radiates outward after one or more frequency conversions in the form of nonlinear frequency-doubling crystals.

Quasimolecular and all-solid-state ultraviolet lasers are commonly used for laser processing. Ultraviolet gas lasers mainly include excimer lasers, argon–ion lasers, nitrogen-molecular lasers, fluorine-molecular lasers, and He–Cd lasers. The advantages of all-solid-state ultraviolet lasers are their convenience, small size, high reliability, and stable operation. See Table 4.2 for the relevant parameters of ultraviolet lasers. Table 4.3 presents a comparison of the properties of common light sources used in optical communications.

Modulation Technology

Light-modulation modes include amplitude, frequency, phase, and pulse modulation. Depending on the type of interaction between light and matter, it can be shown as the control effect of electricity, sound, or magnetism on light and can also be divided into analog and digital modulation. Choosing an efficient and reliable modulation technology guarantees a high transmission rate and low bit-error rate. This section focuses on internal and external modulation in active modulation. As

Table 4.2 Parameters of ultraviolet lasers

Ultraviolet laser classification	Spot shape and wavelength	Characteristics
Solid-state Q Nd:YAG laser	Wavelength: 353 nm Spot: Round (the energy decreases gradually from the center to the edge) Focus magnitude is 10 μm	High temperature sensitivity, which can only be stabilized after a cold-start period. High-repetition frequency, suitable for small-size processing
Excimer laser (gas laser)	Wavelength: Depends on the gas type Spot: Rectangular (Mask technology can produce different shapes of spots)	The processing details can be as small as a few microns, and the distance between the focusing mirror and the workpiece can be 50–100 mm
Metal-vapor laser (mainly copper laser vapor)	Wavelength: Copper vapor with 511-nm and 578-nm wavelengths generates ultraviolet light with 255-nm, 271-nm, and 281-nm wavelengths through frequency mixing and doubling. The light beam has a Gaussian distribution	The application range is the same as that of a solid-state ultraviolet laser

Table 4.3 Comparison of the properties of common optical-communication light sources

Type of light source	Typical wavelength (nm)	Line width	Output power	Beam shape	Fiber coupling	Transmission distance	Modulation bandwidth	Temperature stability	Cost
LED	850, 1300	>20 nm	<0 dBm	Large divergence angle	Simple	Short (<100 m)	<500 MHz	<0.5 nm/°C	Extremely low
VCSEL Laser	850	1–2 nm	<0 dBm	Circular spot, vertical emission	Simple	Short (<500 m)	>10 GHz	<0.1 nm/°C	Low
Fabry–Perot Laser	1280–1330 1480–1650	2–10 nm	>0 dBm	Elliptical spot, side emission	Complex	Medium (<10 km)	>10 GHz	<0.1 nm/°C	Medium
DFB Laser	1280–1330 1480–1650	<0.2 nm	>0 dBm	Elliptical spot, side emission	Complex	Long (>100 m)	>20 GHz	<0.1 nm/°C	High

Table 4.4 Differences between internal and external modulation [52]

Modulation mode		Modulation bandwidth	Chirp factor	Drives current or voltage	Impedance	Conversion relationship
Internal	DFB MQU-DFB	About 12 GHz <20 GHz	3–5 About 2	>50 mA >50 mA	4–8 Ω 4–8 Ω	Linear Linear
External	EA M-Z	About 40 GHz About 50 GHz	<1 0	About 1.5 V About 5–10 V	About 0.1 pF R = 50 Ω	exp(v) $\cos^2(v)$

listed in Table 4.4, external modulation is more suitable for high-speed transmission systems (>10 Gbit/s).

Currently, DFB lasers are commonly used as single-mode semiconductor light sources for optical communication. The modulation bandwidth and spectral purity are satisfactory, and they can be used for high-speed and long-distance transmissions. A general DFB laser modulates the light intensity by changing its driving current. A laser adopting this modulation mode is called a direct modulated laser (DML).

The DML modulation method is simple and low cost; however, it has several disadvantages for high-performance applications:

1. The modulation bandwidth is limited by its own relaxation-oscillation frequency, which restricts the highest data rate it can support.
2. A change in current will change the internal state of the laser, thus causing a wavelength shift.
3. To balance the modulation rate and performance, the laser is not completely off or on during modulation.
4. Its extinction ratio is limited, which limits the modulation rate, modulation quality, and transmission distance of the laser.

To further improve the modulation rate and quality, the optical signal can be modulated by an external modulator, that is, an electroabsorption modulated laser (EML). The EML is an external electroabsorption modulator (EAM) added to a common DFB light source. Mach–Zehnder modulators (MZM) are used for higher-performance applications.

Consider an EAM modulator as an example. The laser light source is always on, and its working current and output power are stable. The electrical signal modulates the power of the optical signal by controlling the voltage of the EAM and changing the light-absorption ratio, thereby avoiding the influence of relaxation oscillation and wavelength drift. If the modulation bandwidth, linearity, and extinction ratio of EAM devices can be improved, the modulation quality can also be improved. The modulation bandwidth of an EML laser can exceed 30 GHz and its wavelength stability is very high.

An MZM may also be used for applications with higher data rates (e.g., >50 Gbaud) or longer transmission distances (>40 km). The MZ modulator is typically composed of lithium niobate ($LiNbO_3$) and includes a pair of coplanar phase modulators on one plane. The input optical signal is divided into two branches, on average, and then combined using two phase modulators.

Lithium niobate has an electro-optic effect; that is, when an electric field is applied to its crystal, its refractive index changes. Therefore, when an electrical modulation signal is applied to one branch of the MZ modulator, the phase of the light passing through this branch will change, owing to the change in refractive index. However, when the light of one branch with a phase change is combined with another branch, the combined light signal may be strengthened or cancelled, depending on the phase difference between the two paths of light, thus modulating the light intensity.

Internal Modulation

Internal modulation, also called direct modulation, changes the laser-oscillation parameters by using the laws of modulation signals to change the characteristics of the laser output. Figure 4.6 shows two methods of realizing internal modulation. The first is to directly adjust the laser pump source (for example, a solid-state laser, which can be changed by the power, frequency, and duty ratio of the pump output); this directly affects the final output of the laser and changes the output laser light intensity, as shown in Fig. 4.6a.

The second is to place the modulation element in the resonant cavity. The output characteristics of the laser can be changed by changing the parameters in the cavity, as shown in Fig. 4.6b. Q-switching is a method for realizing internal laser modulation.

As a direct-current injection device, the change in the driving current of a semiconductor laser has an important impact on the output quality and output-power stability. Figure 4.7 shows the bias-T structure of a direct-modulation laser, which can modulate the data to the linear range of the laser. The bias and modulation currents are simultaneously applied to the laser. Direct-modulated lasers (DML) mainly include the Fabry–Perot laser (FP-LD) and distributed-feedback laser (DFB-LD). Owing to its low-intensity noise and high linearity, the DFB-LD has

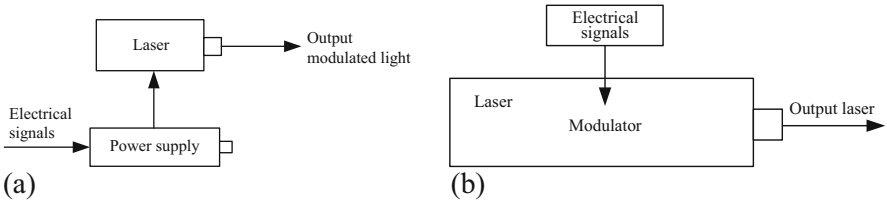

Fig. 4.6 Internal modulation systems [53]

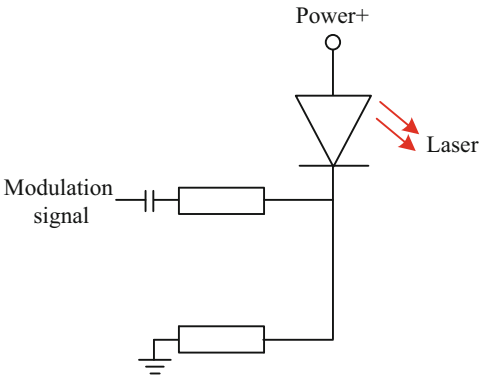

Fig. 4.7 Bias-T structure of a direct-modulation laser

become a key light source in communication systems. Further improvement in the modulation bandwidth of DFB-LD has always been a direction for researchers.

In 1964, Konnerth et al. were the first to study the direct modulation of semiconductor lasers [54]. In the same year, Goldstein et al. modulated GaAs laser microwaves with a modulation bandwidth of 2 GHz [55].

Since the 1990s, the optimization of high-speed direct-modulation lasers has focused on the material system and structural design of the active-gain region. Using a strained (compensated) multi-quantum-well structure in the active region and p-type doping in the active region can yield a very-high differential gain and more uniformly distribute the carriers in the quantum well.

In 1992, Bell Laboratories adopted an active-gain layer with multiple quantum wells and introduced strain into the structure, which effectively improved the differential gain; the modulation bandwidth reached 25 GHz [56].

In 1997, OKI Company realized that the number of quantum wells would affect the output power of lasers and designed 20 pairs of quantum-well DFB lasers with a 30-GHz bandwidth [57].

The selection criteria for the materials were good temperature characteristics and a high differential gain. In 2019, Sasada et al. used AlGaInAs quantum-well materials in the active region to obtain a 1.3-μm directly modulated laser with a 34.2-GHz bandwidth at 25 °C and 23.9 GHz at 80 °C [58].

With the demand for an increased communication rate in short-distance communication systems, the volume of the active area must be reduced to further increase the bandwidth. The width can be reduced using a buried heterogeneous structure or a passive distributed-feedback Bragg reflector (DR), or an active distributed reflector (ADR) can be integrated on one or both sides of the gain region.

In 2018, Huazhong University of Science and Technology made a laser with a 150-μm cavity length using an integrated ADR and conducted a communication-transmission experiment of 28 Gbit/s over 10 km [59]. Optimizing the active area increased the 3-dB bandwidth to approximately 30 dB, but no significant progress

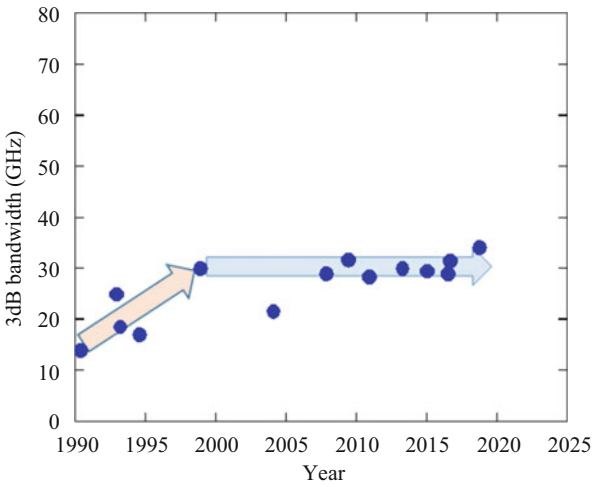

Fig. 4.8 3-dB bandwidth changes of direct-modulation lasers

has been made since then. The change in the 3-dB bandwidth of the direct-modulation laser is shown in Fig. 4.8.

To overcome the bandwidth limitation, researchers have proposed using the photon–photon resonance (PPR) effect produced by optical feedback inside the device. This introduces a response peak at the high frequency of the relaxation oscillation of the laser to broaden its bandwidth [27].

In 2017, Finisar Company achieved a PPR effect through a DR structure and achieved a 3-dB bandwidth of 55 GHz. The 112-Gbit/s PAM4 signal modulation also passed the verification [60]. In 2020, the instrument used by Yanaoka et al. produced a PPR effect near 95 GHz, obtained a 3-dB bandwidth of 108 GHz and a PAM4 signal of 256 Gbit/s, and carried out data transmissions within 2 km [61].

The PPR effect is an important means to significantly increase the bandwidth of the DML; however, it can only can be applied to a DML with external-cavity feedback [62]. Figure 4.9 shows the case of a 3-dB bandwidth in a PPR application. The characteristics of the active region are important factors related to the laser modulation bandwidth, and a large portion of them are related to the relaxation-oscillation frequency. The parasitic parameters of the laser and non-active region factors, such as heat generation, also influence the bandwidth [63].

External Modulation

In external modulation, after the laser is generated, the modulator is placed on the external optical path of the laser, and the physical characteristics of the modulator are changed by modulating the signal. When the laser passes through the modulator, certain parameters of the light wave are modulated and changed [3]. The principle of

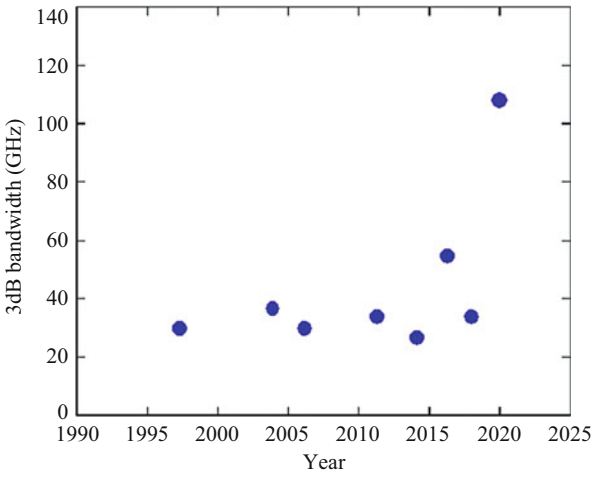

Fig. 4.9 3-dB bandwidth change of a direct-modulation laser when PPR is applied

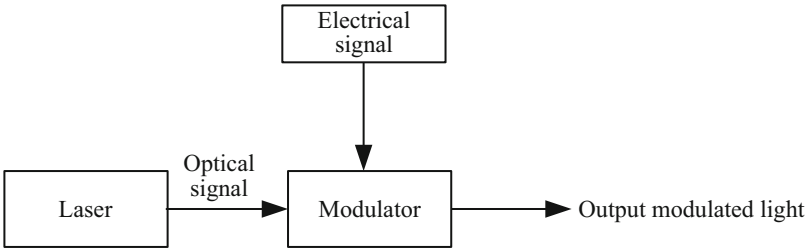

Fig. 4.10 External modulation system [53]

the system is illustrated in Fig. 4.10. External modulation changes the output-laser parameters.

Compared to internal modulation, external modulation applications are more flexible and more easily achieve the required modulation effect. However, because external modulation is based on the existing laser output, it has certain limitations. For example, the laser-peak output cannot be changed by external modulation but can be changed by internal modulation.

Depending on the different working mechanisms, external modulation includes electro-optic, acousto-optic, and magneto-optic modulations. Since 1960, the acousto-optic modulator, based on the acousto-optic effect, Pockels electro-optic modulator, and Faraday rotation magneto-optic modulator have been developed one after another, thus realizing long-distance optical-signal transmissions.

It has been difficult for them to enter the practical stage of laser communications because of the long transit time of acousto-optic modulation and the slow response speed of magneto-optical modulators. Electro-optic modulators meet the requirements of optical information interconnection and transmission and are developing towards high speed, low power consumption, and small volume.

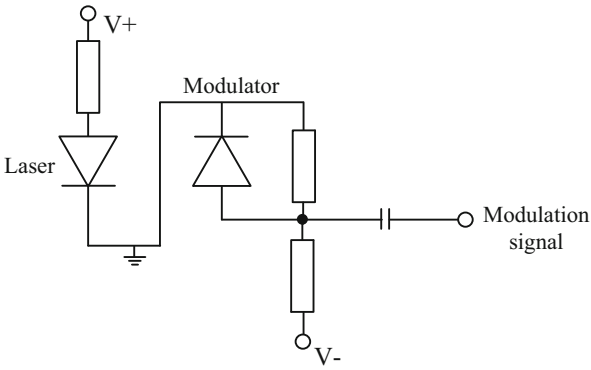

Fig. 4.11 Bias-T structure of an EML

To solve the relaxation-oscillation frequency and frequency-chirp problems when the laser is directly modulated, an electroabsorption modulated laser (EML) has been developed. Generally, a set of biases is applied to the laser, and the bias current is slightly higher than the threshold current. In an EML, the laser is the light-emitting element and the electroabsorption modulator is loaded with information. A bias current is applied to the laser, and the electroabsorption modulator receives a signal-modulation voltage (a bias voltage is also required). The bias-T structure diagram is shown in Fig. 4.11.

The EML, which is monolithically integrated by a distributed-feedback (DFB) laser and an electroabsorption (EA) modulator, is one of the earliest developed and most widely used photonic integrated devices. Its integrated light source has a large modulation bandwidth and low-frequency chirp. Compared with the DML, the EML has advantages in the chirp effect, extinction ratio, eye pattern, jitter, transmission distance, and other performance metrics, and can achieve higher-speed and longer-distance transmissions [64]. The core of the EML is the wavelength matching between the DFB laser and the EA modulator to ensure that the laser output light can pass through the modulator without damage in the zero-modulation bias state.

Research institutes worldwide have conducted studies on high-speed EML-integrated light sources using different integration schemes. For example, the Coldren research group of the University of California, Santa Barbara (UCSB) has developed a high-power integrated light source using selective area etching and quantum-well disorder technology [65]. The Wang Wei Research Group, Institute of Semiconductors, Chinese Academy of Sciences, realized a tunable laser, EA modulator-integrated light source, and array chip using regional selective-epitaxy technology [66]. At present, the modulation bandwidth of single-channel electro-absorption modulation laser technology reaches 59 GHz with a transmission rate of 100 Gbit/s, and it will continue to move towards higher speeds, array types, and lower costs in the future.

In 1970, several countries began to study high-speed $LiNbO_3$ electro-optic modulators. To improve the information-transmission capacity of optical

communications, parameter optimization, thin-film lithium niobate (TFLN), and photon-integration technologies have been proposed [67]. To meet the increasing demand for higher data rates, digital coherent-transmission technology, which is a high-speed coherent signal with a high-order modulation format generated by in-phase quadrature-phase (IQ) modulation, has also received attention.

Parameter Optimization

Traditional $LiNbO_3$ (LN) modulators rely on titanium diffusion or proton-exchange optical waveguides with weak optical limitations; both have large mode sizes and are unsuitable for photonic integrated circuits. Using ridge optical waveguides can effectively reduce the half-wave voltage. The electrode structure changes from an early lumped structure to a traveling-wave electrode structure. The new structure is not affected by the RC time constant of the external circuit, and modulators with bandwidths of hundreds of GHz can be manufactured.

In 1994, Wang et al. made a Ti:$LiNbO_3$ electro-optic modulator with a traveling-wave electrode. This is the earliest reported external modulator with the new electrode structure in China, and its 3-dB modulation bandwidth reaches 8 GHz [68].

In 2001, the Ti:$LiNbO_3$ modulator made by Zhang et al. adopted a T-shaped composite electrode structure, and its bandwidth was increased to 40 GHz. This research achievement was the best in China at that time [69].

In 2005, Gao et al. proposed a combination of a ridge waveguide and T-shaped electrode, which reduced the loss while having a large characteristic impedance. They successfully designed an example of a modulator with a bandwidth of 153 GHz [70].

By 2022, using photolithography, wet etching, high-quality waveguides, and traveling-wave electrodes, Young et al. experimented with a TFLN Mach–Zehnder modulator with a 3-dB bandwidth exceeding 110 GHz and achieved a PAM6 of 250 Gbit/s and PAM4 of 200 Gbit/s [71].

Photonic Integration and Thin-Film Lithium Niobate (TFLN)

To obtain a smaller half-wave voltage and reduce the power consumption of the device, it is hoped that a high refractive-index contrast optical waveguide can be realized by further improving the material and processing technology of single-crystal TFLN. The TFLN material not only retains all the advantages of the traditional LN material but also overcomes all its disadvantages.

In 2018, the TFLN electro-optic modulator based on dry-etching single-crystal integration reported by Loncar's research group in *Nature* had a total length of 1–2 cm, a half-wave voltage as low as 1.4 V, an on-chip optical loss of less than 0.5 dB, and a data-transmission rate as high as 210 Gbit/s [72].

Photonic-integration technology is used to achieve optical communication and interconnection with lower power consumption and higher data transmission. Silicon-based optoelectronic integration has become an important aspect in the development of this technology.

In 2019, Cai et al. completed innovative research on a heterogeneous integrated electro-optic modulating chip of silicon and lithium niobate and retained the

respective advantages of silicon-based and LN materials. The obtained modulation bandwidth exceeded 70 GHz, and its modulation rate (2.2 V·cm) was four times higher than that of a conventional LN modulator. It also showed an ultrahigh data-modulation rate of 112 Gbit/s and a low power consumption of 170 fJ/bit [73].

Based on previous technology, a low-loss TFLN electro-optic modulator with a half-wave voltage of 2.6 V and a modulation bandwidth exceeding 56 GHz was developed. In 2019, an experiment was conducted using this equipment to achieve the highest modulation rate in the world. The experiment verified that, in a single channel, the generated high-speed optical signal reached 120 Gbit/s with NRZ and 220 Gbit/s with PAM4 [73].

In 2021, based on previous research, Professor Loncar's research group created a high-performance modulator with the microwave loss reduced by approximately three times on a TFLN platform of the Shi Ying substrate using a capacitive-loading traveling-wave electrode, which once again broke the upper limit of the bandwidth voltage of TFLN [74].

IQ Modulation

To explore the bandwidth potential of optical-fiber communication and further enhance the transmission capacity of optical communication, around 2008, coherent-optical communication moved from the background to the foreground. In coherent-optical transmission, in addition to amplitude modulation, external modulation methods, such as phase-shift keying (PSK), quadrature phase-shift keying (QPSK), and quadrature amplitude modulation (QAM), can be used to achieve frequency and phase modulation. Owing to the low data-rate requirement, the initial wireless communication adopted analog modulation, such as amplitude modulation (AM), frequency modulation (FM), or phase modulation (PM).

Market demand has not driven progress in large-scale communication technology for a long time. However, with the increasing demand for satellite communication and personal-communication services, traditional analog modulation cannot meet the rate requirement; therefore, it is necessary to seek modulation technology that supports higher data rates. IQ modulation technology is increasingly being used, and almost all wireless communications require this modulation technology.

The main reasons for adopting IQ modulation are as follows:

1. IQ modulation can achieve a higher data rate by increasing the symbol rate or adopting high-order modulation. It is very convenient and flexible, and this is far from the traditional analog modulation.
2. IQ modulation is easier to implement for high-speed communication. IQ modulation can very conveniently map symbols onto vector-coordinate systems, thus completing digital modulation. Similarly, on the receiving side, it can conveniently demodulate the original data bit stream according to the symbol mapping.
3. IQ modulation has a higher spectrum efficiency.

In the last 10 years, in-phase quadrature-phase (IQ) modulators based on LN waveguides with low refractive-index contrast have been the first choice to realize

more modulation formats and have become key devices in digital coherent-optical transmission systems. However, owing to the limitations of the material itself, it is difficult to improve the driving voltage, modulation bandwidth, and integration of LN-IQ modulators, which hinders the upgrading and application of optical-transmission systems.

In 2020, Xu et al. designed high-performance IQ modulator chips for TFLN materials, and their IQ modulator achieved the lowest insertion loss to date. They also generated high-order coherent modulation signals at ultrahigh rates, including 220 Gbit/s per 110 Gbaud and 10 Gbit/s per 80 Gbaud using QPSK.

In 2021, Fujitsu introduced a TFLN modulator and focused on a 130-Gbaud coherent driver module, which achieved a low modulation loss, small package size, and 65-GHz bandwidth. Compared to the InP modulator, the TFLN modulator has a wider bandwidth and lower temperature sensitivity, usually supports broadband operation in the C band, and can eliminate the need for refrigeration, thus reducing the cost and size.

In 2022, Cai et al. first produced a dual-polarization IQ modulator for coherent-optical communication on a TFLN platform, which achieved a CMOS-compatible driving voltage and electro-optical bandwidth of up to 110 GHz. Owing to the excellent bandwidth-voltage performance of the device, a net bit rate of 1.96 Tbit/s per carrier was achieved with an electrical-power consumption of only 1.04 fJ/bit [75]. Coherent-optical communication technology can improve the transmission rate and limit the bandwidth; however, it also results in a high bit-error rate.

Lasers and Modulation Technology

Since 2000, Xi'an University of Technology has conducted extensive basic theoretical research and practical verification, and made progress in optical-communication application fields, such as transmission characteristics in laser atmospheric turbulence, coding and decoding in wireless laser communication systems, optical wireless subcarrier modulation, optical-transceiver system design, capture and alignment-tracking technology, optical orthogonal frequency-division multiplexing modulation, and optical MIMO system research [76].

In 2011, Chen et al. investigated subcarrier-modulation optical wireless communication systems and their key technologies for atmospheric-impact suppression, designed optical wireless communication system hardware for four-way frequency-shift keying (4FSK) and 16PSK modulation modes, and conducted short-distance indoor optical wireless subcarrier-modulation experiments, successfully verifying the feasibility of the system [77].

In 2016, a free-space optical (FSO) communication system terminal with a maximum weight of 8 kg, based on intensity modulation/direct detection (IM/DD), was developed. The terminal was equipped with standard Ethernet data-access capability and safely transmitted duplex data, voice and images.

Laser-Characteristic Optimization

Semiconductor lasers, with high electro-optical conversion efficiency (over 50%), a long service life (over 100,000 h), reliable operation, and easy modulation, emit light waves with a frequency higher than that of microwaves and are widely used. When a signal is loaded onto the LD, nonlinear distortion appears near the threshold and directly affects the system performance [78]. A theoretical derivation and simulation analysis were carried out for its response characteristics, compensation scheme, and proposed power-control system, and a method to improve the nonlinear effect of the laser was obtained.

Response Characteristics

The performance of a communication system depends on its laser-response characteristics. Generally, the response requires a rate equation. The following two formulas briefly explain the relationship between the supply, generation, and disappearance of photons and carriers in a double-heterojunction semiconductor laser (DH-LD) resonator. The rate equation is simplified to [79]:

$$\frac{dN}{dt} = \frac{I}{qV} - A(N - N_{\text{om}})S - \frac{N}{\tau_N} \tag{4.1}$$

$$\frac{dS}{dt} = \Gamma\beta\frac{N}{\tau_N} - \frac{S}{\tau_p} + \Gamma A(N - N_{\text{om}})S, \tag{4.2}$$

where N is the carrier density, S is the photon density, I is the current injected into the gain region, N_{om} is the transparent carrier density, and q is the amount of electron charge. $V = WLD$, where V is the volume of the active region, and W, L, and D are the width, cavity length, and thickness of the gain region, respectively. A is the optical-gain coefficient, τ_p and τ_n are the photon lifetime and carrier lifetime in the resonant cavity, respectively, Γ is the optical-confinement factor, and β is the spontaneous emission.

Modulation-Response Characteristics

The modulation-response characteristics directly reflect the high-speed characteristics of the laser in the frequency domain, and the nonlinearity of the laser reflects the nonlinearity of the modulation response. As shown in Fig. 4.12, the high-frequency modulation characteristics of the laser are closely related to the relaxation-oscillation frequency f_0. Increasing f_0 can increase the modulation frequency ω of the laser. When the resonance peak shifts to the right, the low-frequency band that can be modulated is expanded.

Relaxation oscillation means that when current is injected into the laser, the number of particle inversions oscillates near the threshold; that is, the number of particle inversions is lower than the threshold when stimulated radiation occurs but higher than the threshold when pumped. This phenomenon results in a series of short

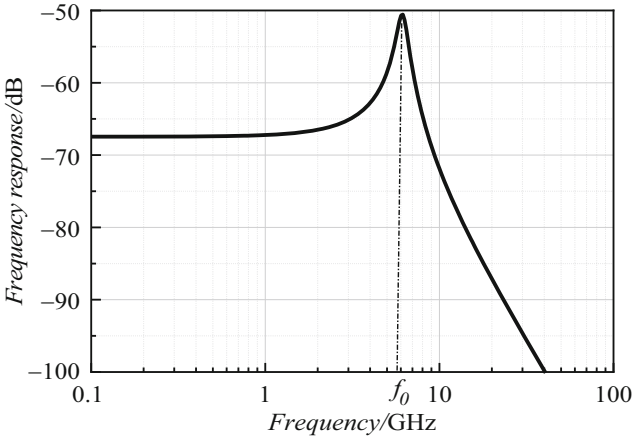

Fig. 4.12 DH-LD frequency-response curve [80]

pulse sequences instead of a smooth pulse. Therefore, the output power and carrier concentration will fluctuate between a steady state and an unsteady state, which is called the relaxation-oscillation phenomenon [81].

The dynamic distortion related to the frequency in nonlinear distortion is caused by the relaxation oscillation. Under small-signal modulation, the relaxation-oscillation frequency can be obtained as:

$$f_0 = \omega = \left(\frac{a_g S_0}{\tau_p (1 + \varepsilon S_0)} \right)^{1/2}. \tag{4.3}$$

It can be seen from the above formula that the relaxation-oscillation frequency f_0 can be increased by increasing the differential-gain coefficient a_g and steady-state photon density S_0, and decreasing the photon lifetime τ_p and gain-saturation factor ε. Subsequently, we simulated the model to verify this correlation.

Figure 4.13 shows the influence of changing the related relaxation-oscillation parameters on the modulation-response characteristics. The simulation results were consistent with the theoretical conclusions.

The modulation-response characteristics are not only related to the internal relaxation-oscillation parameters of the laser but also to the external parasitic parameters. As shown in Fig. 4.14, to achieve a high frequency response, the values of the parasitic parameters can be reasonably regulated by changing the laser packaging type, and the series resistance and parallel capacitance can be reduced.

Impulse-Response Characteristics

The impulse response refers to the response characteristics in the time domain (time amplitude) obtained by a system under test when it receives a pulse-excitation signal

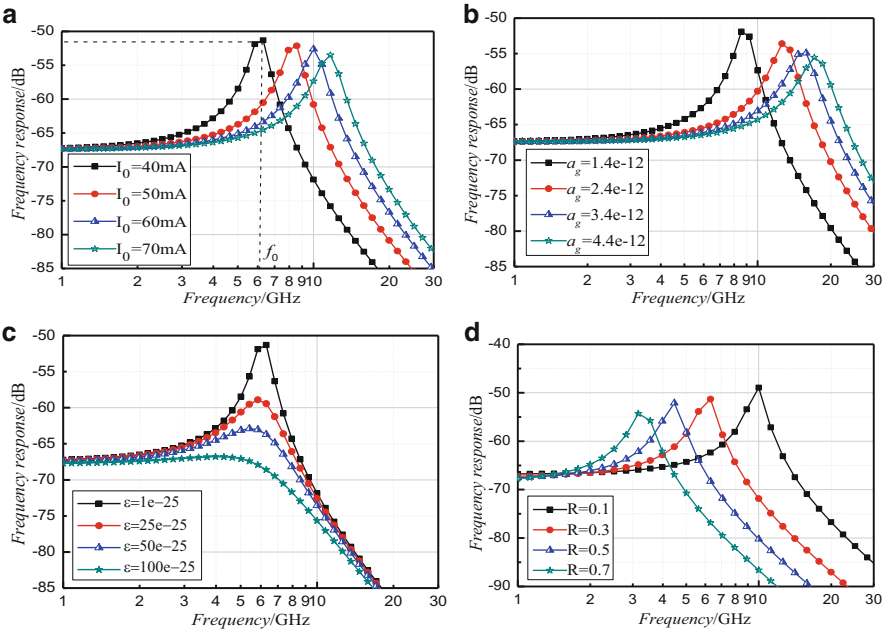

Fig. 4.13 Frequency-response curves under the influence of different relaxation-oscillation parameters [2]. (**a**) Different bias currents I_0. (**b**) Different differential-gain coefficients a_g. (**c**) Different gain-saturation factors ε. (**d**) Different reflectivities R

input. Figure 4.15 shows that relaxation oscillation also occurs before reaching a steady state. We used the transient analysis from the PSpice simulation environment to verify the simulation.

As shown in Fig. 4.16, the trends in the time and frequency domains are the same. When I_0 and a_g increase, ε and R decrease. This increases the relaxation-oscillation frequency f_0, shortens the oscillation process, and improves the waveform distortion (Figs. 4.17 and 4.18).

Compensation Scheme

Studying the nonlinear characteristics of a laser and its nonlinear-distortion compensation methods can effectively improve the nonlinearity produced by the laser. Commonly used compensation methods include optical (electrical) negative feedback, positive feedback, predistortion, etc.

In different turbulence-intensity channels, optical wireless multichannel subcarrier binary phase-shift keying (BPSK) modulation was adopted, and the relationship between the modulation index, nonlinear coefficient, and carrier-intermodulation noise ratio (CINR) of a wireless laser communication system was investigated. Furthermore, the selection of the modulation index and nonlinear coefficient to reduce the adverse interference of the nonlinear intermodulation distortion of the laser on the CINR and bit-error rate (BER) was analyzed.

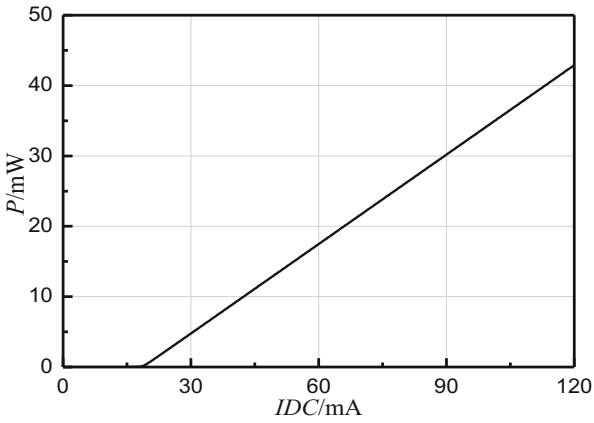

Fig. 4.17 P-I characteristic curves of a DH-LD [2]

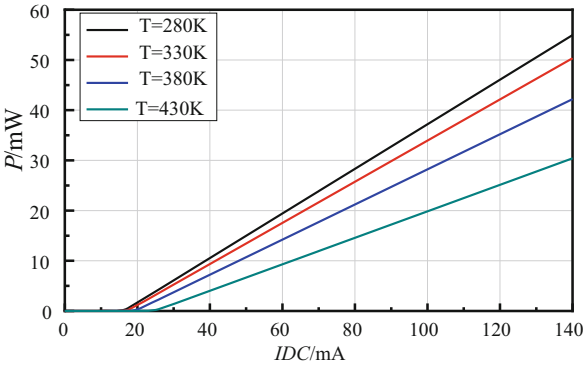

Fig. 4.18 P-I characteristic curves of different temperatures [2]

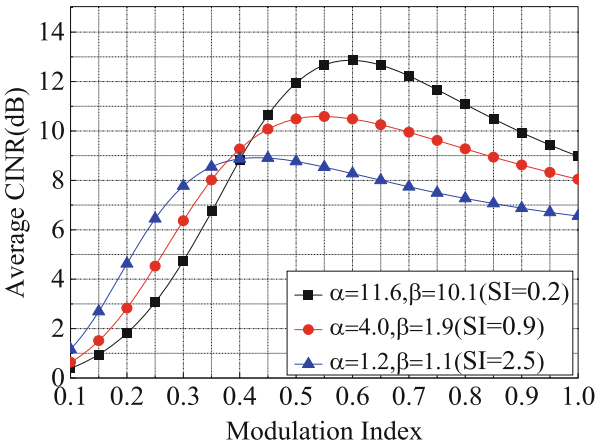

Fig. 4.19 CINR study under a turbulent flow [82]

As shown in Fig. 4.19, under the same turbulence conditions, the closer the modulation index is to the optimal value, the greater the CINR value. When the scintillation index (SI) increases, the optimal modulation index should decrease, and the maximum CINR can be obtained.

Figures 4.20 and 4.21 show that the CINR decreases when the carrier number N increases. When the turbulence intensity is the same, the larger the nonlinear coefficient, the smaller the CINR.

From Fig. 4.22, we can see that when the modulation index is larger than the optimal value, the BER increases with an increase in SI. If the modulation index further increases, the BER becomes saturated and stable under the same modulation index.

A Volterra-series analysis was used to describe the influence of the static nonlinearity of the laser on the non-limiting QPSK-like sinusoidal modulation. The influence of the LD nonlinearity on the signal was simulated by fitting the laser

characteristic curve, and the best predistortion method was selected for nonlinear compensation. Through simulation, the time-domain waveform, frequency spectrum, power spectrum, and constellation of the non-limiting QPSK sinusoidal-modulation signal before and after predistortion compensation were obtained, as shown in Figs. 4.23, 4.24, 4.25, and 4.26.

Power Control System

In optical wireless communication systems, it is necessary for an optical transmitter to provide a stable and reliable light source to ensure the communication quality. The ability of the receiver to receive a high-quality signal is closely related to the power stability of the transmitter. Therefore, Xi'an University of Technology adopted the principle of photoelectric feedback to realize a power control system for a semiconductor laser to ensure the power stability of the laser light source.

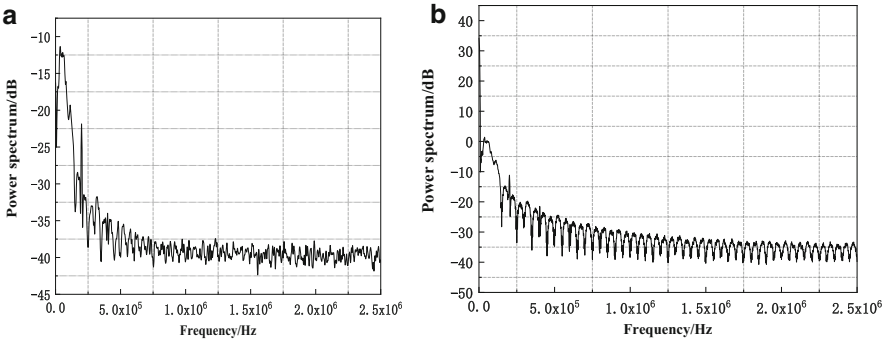

Fig. 4.25 Power spectrum before and after predistortion compensation [83]. (**a**) Before predistortion. (**b**) After predistortion

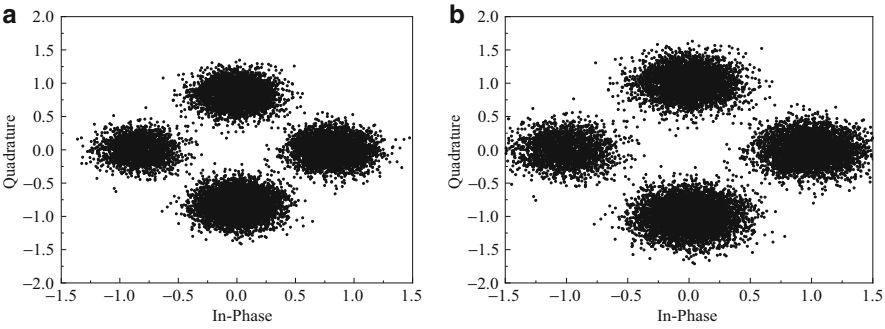

Fig. 4.26 Constellation before and after predistortion compensation [83]. (**a**) Before predistortion. (**b**) After predistortion

The system consists of an automatic power control (APC) and automatic temperature control (ATC). The APC includes a constant current source module and a photoelectric feedback module, whereas the ATC includes a temperature-detection module and refrigeration drive module. Figure 4.27 shows the overall block diagram of the system.

The APC circuit was maintained in an open-loop state, and the stability of the semiconductor laser driven by a constant current source was verified. As shown in Fig. 4.28, the driving performance of the constant current source was relatively stable in the experiment, and the stability was better than 0.014%.

The APC circuit was tested and verified at room temperature; the results are shown in Fig. 4.29. When the circuit is an open loop, the output optical power decreases with the extension of the working time, and the fluctuation range of the output optical power is larger, with a power stability of 4.1%. Under a closed-circuit condition, the output optical power tends to be stable as a whole, and there is no

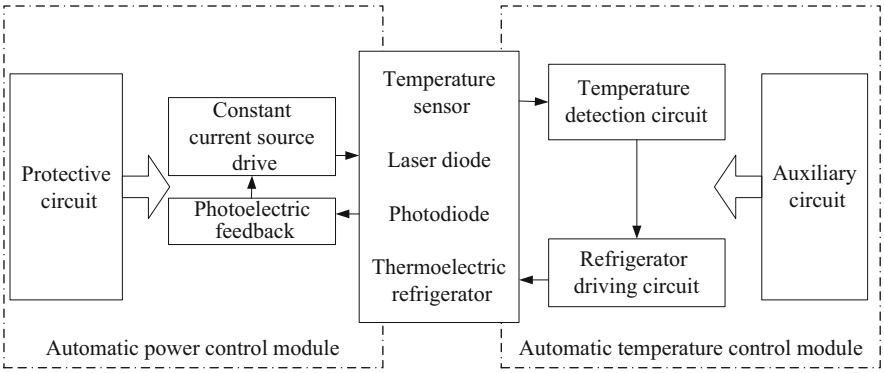

Fig. 4.27 Overall block diagram of the system [84]

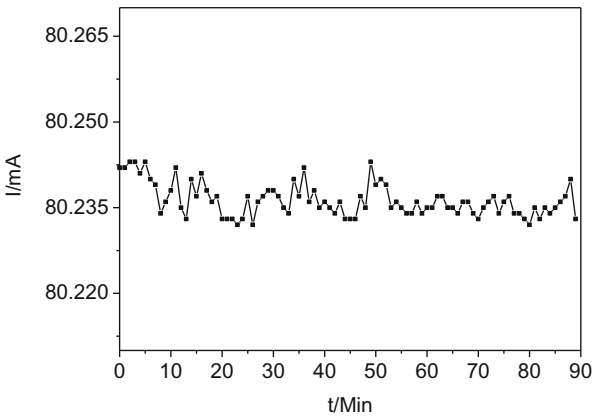

Fig. 4.28 Changes in the driving current under a constant current source [84]

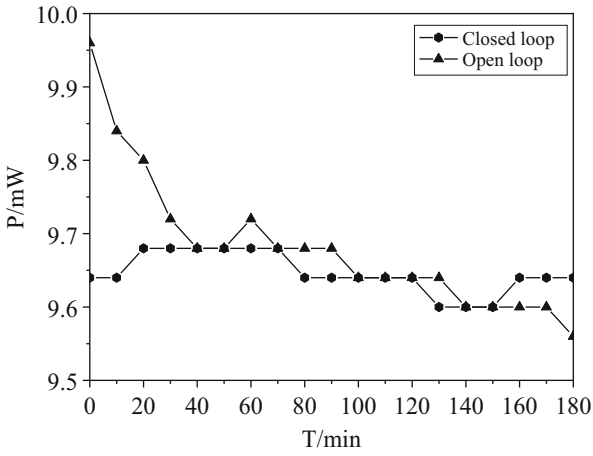

Fig. 4.29 APC output optical power in open and closed loops [84]

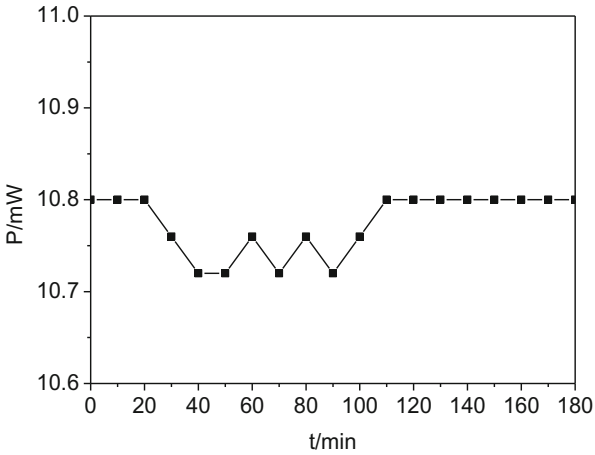

Fig. 4.30 Output power with APC and ATC working simultaneously [84]

obvious fluctuation with the extension of the working time. The stability is calculated to be 0.83%.

Therefore, when the circuit loop is closed, that is, when the reverse input of the proportional amplifier is connected to the photoelectric feedback module, it can stabilize the output optical power, thus verifying the feasibility and effectiveness of the automatic power-control circuit.

Figure 4.30 shows the fluctuation chart of the output power with working time when the APC and ATC are working simultaneously. During the entire operation process, the output power fluctuates between 11.7 MW and 11.8 MW, and the entire process is relatively flat, which proves that the ATC circuit can ensure that the output power is more stable; the calculated stability is better than 0.74%.

The ATC circuit can provide a stable ambient temperature during the semiconductor-laser operation. As shown in Fig. 4.31, when the ATC circuit works, the ambient temperature of the semiconductor laser is kept around 27 °C, and the fluctuation is less than 0.1 °C; thus, the stability is 0.74%.

Modulation Experiment

Xi'an University of Technology systematically conducted experiments on laser modulation, pulse-position modulation, and multi-carrier modulation, and improved the system structure and inevitable nonlinear effects.

Internal Modulation

To compare the first three generations of atmospheric laser communication machines, Xi'an University of Technology investigated a high-speed internal-

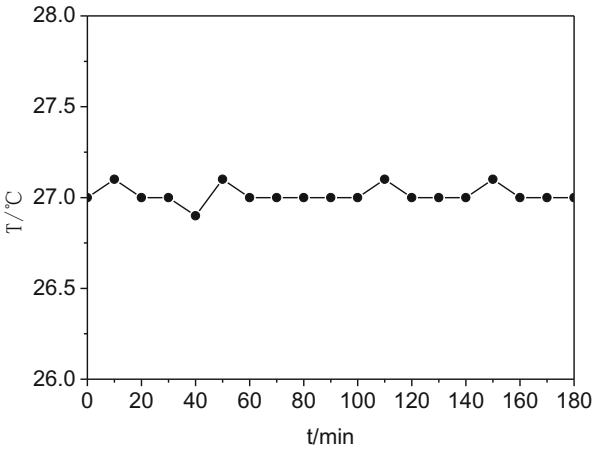

Fig. 4.31 Temperature-change curve with ATC working [84]

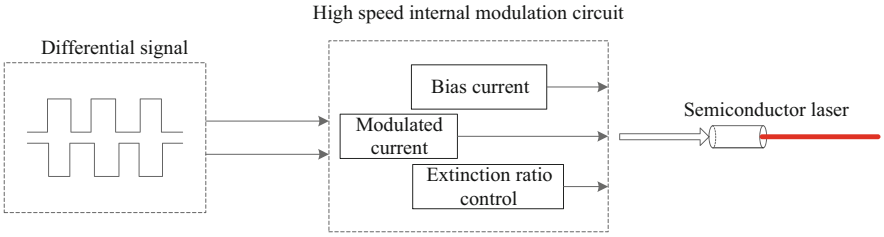

Fig. 4.32 Block diagram of a high-speed internal-modulation circuit [53]

modulation system. Figure 4.32 shows a block diagram of the internal-modulation circuit structure. After the circuit performance is verified, the entire communication system will be debugged. Currently, the communication requirements for a 100-MHz debugging rate can be realized.

Progress on high-speed direct-modulation lasers in China is slow. At present, companies such as Shaanxi Yuanjie, Wuhan Guangxun, and Ningbo Yuanxin have developed direct-modulation lasers with bandwidths above 20 GHz; therefore, great development prospects still exist.

Electro-optic Modulation

Based on internal modulation, an electro-optic modulation experiment was conducted, as shown in Fig. 4.33. The light emitted by the laser passes through the polarizer and becomes linearly polarized. The light is vertically incident on the LN crystal to which the electric field is applied, and the refractive index and polarization state of the light wave are changed. It is output as an elliptically polarized light.

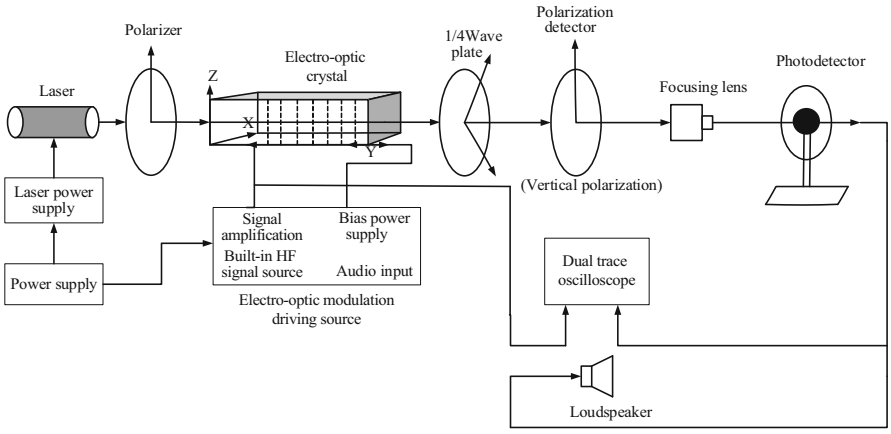

Fig. 4.33 Structural diagram of the electro-optic modulation experimental system [87]

The light can be biased by the DC generated by the modulator driving source or the outgoing light passing through the quarter-wave plate so that the electro-optic modulator can work in the linear region [85]. Elliptically polarized light passes through the analyzer and is output as linearly polarized light, and the light intensity is modulated. Finally, a photoelectric detector receives the modulated light signal, which is observed using an oscilloscope after the photoelectric conversion.

According to the theory of refractive-index ellipsoids, there is a relationship between the refractive index of the electro-optic crystal, output light intensity, transmittance of the light modulator, and temperature [86].

Influence of the Temperature on the Refractive Index of an Electro-optic Crystal

The LN crystal is sensitive to changes in external temperature, and the refractive index of the electro-optic crystal has the greatest influence. Figure 4.34 shows that the refractive index changes linearly with the temperature, and changes in ambient temperature have a greater influence on the refractive index of light.

Influence of the Temperature Electro-optic Modulator on the Output Light Intensity

Depending on whether the direction of the applied electric field is parallel or perpendicular to the light-wave propagation direction, the electro-optic modulation can be divided into longitudinal and transverse. If the intensity of the incident light is I_0, the intensity I_1 of the outgoing light is $I_1 = I_0 \sin^2\left(\frac{\delta}{2}\right)$, where δ is the phase delay.

As shown in Fig. 4.35, when the input light intensity, applied voltage, and light wavelength are fixed, the output light intensity increases linearly with the increasing temperature during longitudinal modulation, which is related to the change in the crystal refractive index.

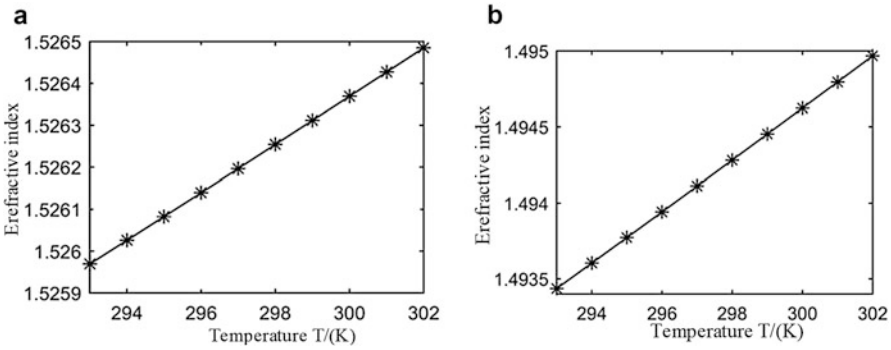

Fig. 4.34 Trends of the refractive index of O and E light with temperature [87]. (**a**) *O* light. (**b**) *E light*

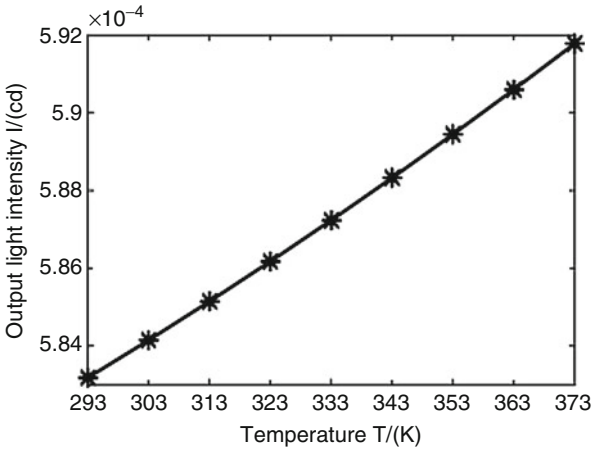

Fig. 4.35 Variation trend of longitudinal-modulated output light intensity with temperature [87]

Under transverse electro-optic modulation, the change in the output light intensity with the temperature is related to many factors, such as the crystal refractive index, linear-expansion coefficient, initial crystal length L_0, and thickness d_0. Figure 4.36 shows the influence of the temperature change on the output light intensity when the crystal size and linear expansion coefficient are constant. In practice, transverse electro-optic modulation is more flexible, and the half-wave voltage can be reduced by reducing the thickness of the modulation device or increasing its length; however, the processing requirements are relatively high.

Influence of the Temperature on the Light-Modulator Transmittance

The light transmittance can be expressed as $\frac{I_1}{I_0} = \sin^2\left(\frac{\delta}{2}\right)$; therefore, the influence of the temperature on the transmittance of the light modulator is its influence on the

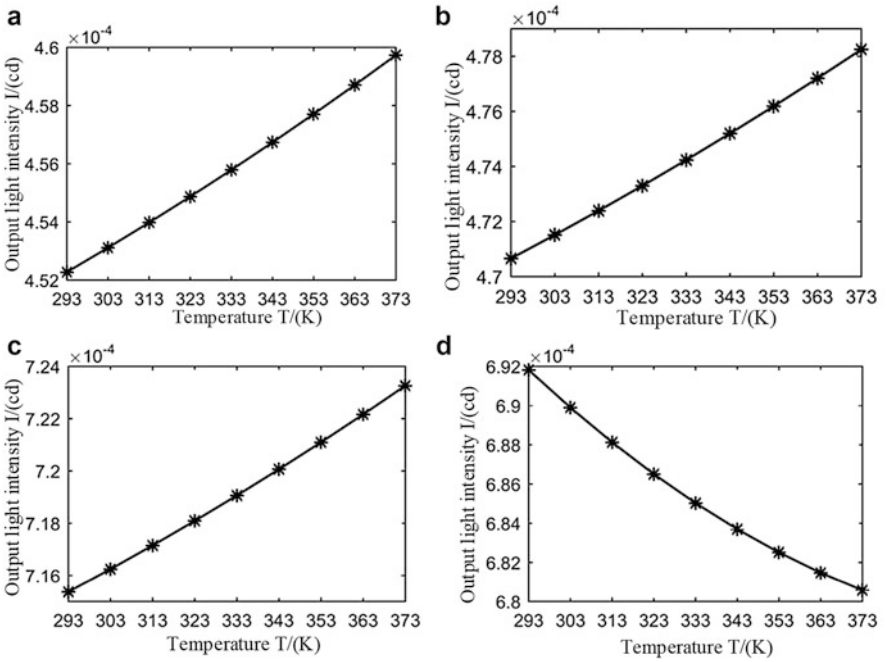

Fig. 4.36 Curves of the relationship between the transverse-modulation output light intensity and temperature change [87]. (**a**) $L_{01} = 0.044$ m, $d_{01} = 0.041$ m. (**b**) $L_{01} = 0.044$ m, $d_{01} = 0.04$ m. (**c**) $L_{01} = 0.044$ m, $d_{01} = 0.03$ m. (**d**) $L_{01} = 0.06$ m, $d_{01} = 0.01$ m

light retardation. The temperature influence on the retardation of horizontal and vertical modulation is different.

In transverse electro-optic modulation, the crystal retardation is affected by multiple factors. The following can be determined from Eq. (4.4): With a given external voltage and 1000-V DC voltage, when the temperature changes by one degree, the delay will correspondingly change by $1.325\Pi \times 10^{-5}$ radians, which is about 0.002°. At a given temperature, when the voltage changes by one volt, the delay changes by $1.3187\Pi \times 10^{-3}$ radians, which is about 0.237°.

$$\delta_T = \left[1.3187\pi \times 10^{-3} + 1.325 \times 10^{-8} \cdot (T - T_0)\right] \cdot U, \tag{4.4}$$

where T_0 is the temperature of the initial state and U is the applied voltage.

As shown in Figs. 4.34, 4.35, and 4.36, the external temperature significantly influences the electro-optic modulator, which causes the linear operating point of the modulator to shift. The designed electro-optic-modulation driving source was used in the electro-optic communication experiment, and the effectiveness of the driving source was verified. The effectiveness was not only reflected in ensuring the normal operation of the electro-optic modulator and stable linear modulation of the laser, to

a certain extent, but also in the improvement of the modulation rate, which increased to 3 Mbit/s after testing.

Summary

Signal generation cannot be separated from suitable light sources. Not all light sources can be used in optical communication. The light sources used in optical communication must satisfy a series of requirements, such as adequate wavelength, power, spectral linewidth, modulation bandwidth, integration, and cost. Currently, almost all light sources used in optical communications are fabricated using semiconductor technology.

The integration of new physics, concepts, and technologies with semiconductor lasers has introduced fresh blood into their development. Many new lasers have been developed through cross-penetration using optics, electromagnetism, microelectronics, topology, and quantum mechanics. They either have large-scale integrated application prospects, excellent beam and spectrum quality, or a higher and more stable output power. The development of these new laser systems represents an advanced level of semiconductor laser technology and also reflects the development status of physical theory, engineering technology, and preparation technology, which are worthy of further study.

1. Optically pumped vertical-external-cavity surface-emitting laser

Optically pumped vertical-external-cavity surface-emitting lasers (OP-VECSELs), also known as optically pumped semiconductor lasers (OPSLs) or semiconductor disk lasers (SDLs), are a combination of semiconductor and solid-state lasers. The gain chip is made of a semiconductor material, which is very similar to a vertical-cavity surface-emitting laser (VCSEL). The resonant cavity adopts the configuration of a solid-state laser, which is typically composed of a distributed Bragg reflector (DBR) on a semiconductor chip and an external cavity mirror. The pumping mode typically involves optical pumping, which provides a more flexible working mode and better device performance.

A VECSEL uses a semiconductor chip as a gain substance, which provides multiple wavelength selections and wide-spectrum tuning ranges. The optical cavity based on a solid-state laser makes it easy to insert optical elements into the cavity, such as pulse compression, sum frequency, difference frequency, and beam shaping. These can produce ultrashort pulse lasers, special wavelength lasers, terahertz lasers, and multicolor lasers to meet various special application requirements.

2. Micro-nano laser

Micro-nano lasers usually refer to lasers whose size or mode size is close to or smaller than the wavelength of the emitted light. Their compact structure, low threshold, and low power consumption provide broad application prospects for high-speed modulation. The micro-nano laser is an important part of the future of

integrated optical circuits, optical memory chips, and photonic computers. It is also widely used in the fields of biochips and laser medicine, and has potential application value in wearable devices and other fields.

3. Topological insulator laser

Topological-insulator lasers combine semiconductor laser technology with the concept of a topological insulator in condensed-matter physics. Using the topological concept of an edge state, this laser is insensitive to disturbances and defects in the internal structure of the device, and lasers with high output power, high robustness, and a stable mode can be easily realized. Especially used in high-power lasers and emerging nano-photon lasers, this type of laser is insensitive to scattering loss and random manufacturing defects, making it suitable for high-power mode-locked laser arrays and quantum-information generation and transmission.

Abstract

Traditional free-space optical communication requires both ends of the communication to be installed at the same time laser transmitting system, laser receiving system and acquisition, tracking and aiming system, resulting in the weight, volume, power consumption, equipment complexity, and technical difficulty of the system have been improved, thus limiting the development of free-space optical communication. Using the passive modulation technology constructed by asymmetric space laser communication link, the design of small volume, light weight, and low power consumption of the communication terminal is successfully realized, which provides convenience for the application of small- and medium-sized space laser communication technology.

In this chapter, the research status of passive modulation at home and abroad is reviewed, which is mainly summarized abroad. In addition, the composition of the reverse modulation system and the working principle of the reverse modulator are described. Common Modulated Retro-Reflector such as Angle reflector reverse modulator and cat's-eye reverse modulator are analyzed. The selection of wavelength and the size of optical receiver aperture are discussed. This chapter summarizes the different implementation types and characteristics of passive modulation, summarizes the application of passive modulation in optical wireless communication, and looks forward to the future development direction and prospect of this technology. In the future, passive modulation can be developed along the direction of high speed, focal plane pixelation, two-way communication, and coherent detection, and there is a lot of room for development. This chapter can provide a reference direction for the research of passive modulation and a new idea for the research of optical wireless communication.

Free-space optical communication · Passive modulation · Modulated retro-reflector · Cat's-eye effect

Introduction

Free-space optical communication (FSO) requires a laser-transmitting or laser-receiving system and an acquisition, tracking, and pointing (ATP) system to be installed at both ends of the communication system. This increases the system's weight, volume, power consumption, and technical complexity and is the main reason limiting the application of free-space optical communication.

Passive-modulation technology uses a modulated retro-reflector (MRR) to modulate the incident light and reflect it back to the transmitting end. Thus, an active light source is not required at the data-sending end [1]. MRR FSO technology does not need to install laser-transmitter and ATP systems at both terminals of the communication link; thus, it can greatly reduce the weight, volume, and power consumption of one end of the link.

In addition, a passive-modulated FSO system does not place high requirements on the interrogator ATP system, and a closed link can be formed by placing the interrogator in the MRR field of view. Therefore, the FSO limitation is effectively solved and the system application is more flexible.

This chapter introduces the system structure of passive-modulation free-space optical communication, the working principle and performance index of modulated retro-reflectors, and analyzes the main parameters. In addition, common MRRs are introduced, which are the angular reflector MRR and cat's-eye MRR [2]. The foreign and domestic research statuses are summarized, and finally, MRR FSO technology is prospected.

Passive Modulation and Its Performance Index

Passive Modulation

In the communication-system modulation process, if the light source and modulating signal are at the transmitter end of the system, it is called active modulation. If the light source and modulating signal are not at the same end of the system, it is called passive modulation. Passive-modulation technology is also called modulated retro-reflector technology [3]. Figure 5.1 shows the communication diagram of passive modulation in a free-space laser link.

Performance Analysis

Bit-Error Rate Analysis

The formula for calculating the average bit-error rate is shown in (5.1), where P_e is the instantaneous bit-error rate.

$$\langle P_e \rangle = \int_0^\infty f(\gamma) P_e \mathrm{d}\gamma \tag{5.1}$$

Because on-off keying (OOK) is easier to realize than other modulation methods, it is generally used in MRR FSO systems at this stage [5]. In OOK modulation, "1" means a light is output, "0" means no light is output, and a threshold-detection method is used to detect and demodulate the threshold voltage m at the receiving end. Therefore, the choice of m is closely related to the accuracy of the decision. The bit-error rate obtained by different selected m is also different [6].

When the sent code element is "1," the probability of erroneously receiving "0" (that is, the receiving voltage $V \leq m$) is as follows:

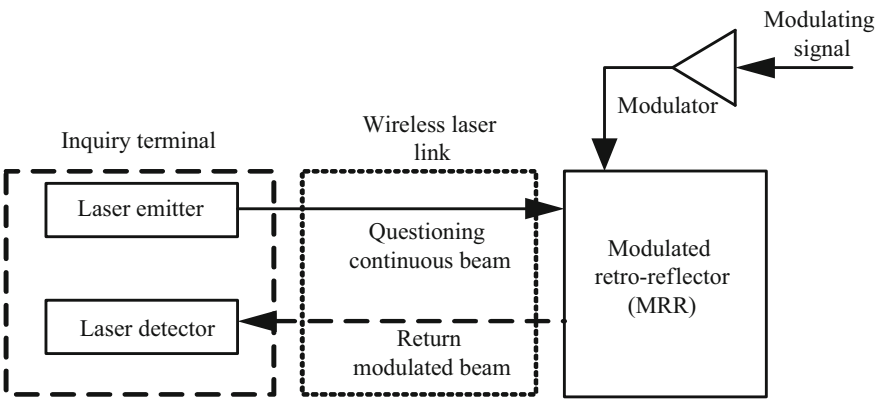

Fig. 5.1 Passive-modulated space laser communication [4]

$$\begin{aligned} P_{e1} &= P(V \leqslant m) = \int_0^m f_1(V)\mathrm{d}V = 1 - \int_m^\infty f_1(V)\mathrm{d}V \\ &= 1 - \int_m^\infty \frac{V}{\boldsymbol{\sigma}_n^2} I_0\left(\frac{aV}{\boldsymbol{\sigma}_n^2}\right) e^{-\left(V^2+a^2\right)/2\sigma_n^2}\mathrm{d}V, \end{aligned} \tag{5.2}$$

where $\boldsymbol{\sigma}_n^2$ is the noise variance; a is the received signal amplitude; and $f_1(V)$ is the probability-density function of the received signal.

The integral value in the above equation can be expressed by the Q function as

$$P_{e1} = 1 - Q\left(\sqrt{2\mathrm{SNR}}, m_0\right), \tag{5.3}$$

where $\mathrm{SNR} = a^2/2\boldsymbol{\sigma}_n^2$ is the signal-to-noise ratio and $m_0 = m/\boldsymbol{\sigma}_n$ is the normalized threshold value.

When the sent code element is "0," the probability of erroneously receiving "1" (receiving voltage $V > m$) is as follows:

$$P_{e0} = P(V > m) = \int_m^\infty f_0(V)\mathrm{d}V = \int_m^\infty e^{-\frac{V^2}{2\sigma_n^2}}\mathrm{d}V = e^{-\frac{m^2}{2\sigma_n^2}} = e^{-\frac{{m_0}^2}{2}}. \tag{5.4}$$

The probabilities of sending code elements "0" and "1" at the modulation end are set to $P(0)$ and $P(1)$, respectively; then, the total bit-error rate of the system is

$$\begin{aligned} P_E &= P(1)P_{e1} + P(0)P_{e0} \\ &= P(1)\left(1 - Q\left(\sqrt{2\mathrm{SNR} = a^2/2\boldsymbol{\sigma}_n^2}, m_0\right)\right) + P(0)e^{-m_0^2/2}. \end{aligned} \tag{5.5}$$

In general, the value is in the range between $\sqrt{2}$ and $\sqrt{\mathrm{SNR}/2}$. When the MRR FSO system works in a high SNR environment, the threshold value is $\sqrt{\mathrm{SNR}/2}$. When $P(0) = P(1) = 0.5$, the bit-error rate can be expressed as

$$P_E = \frac{1}{2}\left[\left(1 - Q\left(\sqrt{2\mathrm{SNR}}, m_0\right)\right) + e^{-\frac{m_0^2}{2}}\right] = \frac{1}{4}\mathrm{erfc}\left(\frac{\sqrt{\mathrm{SNR}}}{2}\right) + \frac{1}{2}e^{-\frac{\mathrm{SNR}}{4}}, \tag{5.6}$$

where $\mathrm{erfc}(\cdot)$ is the complementary error function.

Interruption-Probability Analysis

The interruption probability refers to the probability that the SNR of the received signal from the communication system is lower than the specified threshold γ_{th}. The formula of the interruption-probability pair is shown in Eq. (5.7) [7]:

$$P_{\mathrm{out}} = \Pr\{\gamma \leq \gamma_{\mathrm{th}}\} = \int_0^{\gamma_{\mathrm{th}}} f(\gamma)\mathrm{d}\gamma, \tag{5.7}$$

where $\gamma = \eta^2 h^2 I^2 / 2\sigma_n^2$ is the instantaneous SNR of the received signal; $\overline{\gamma} = \eta^2 \mathrm{E}[h]^2 I^2 / 2\sigma_n^2$ is the average SNR; h is the degraded MRR communication link; η is the photoelectric-conversion coefficient of the photodetector; I is the signal-light intensity when the transmitted item is "1"; and σ_n^2 is the variance.

Channel-Capacity Analysis

The average channel capacity is the maximum error-free information-transmission rate of a communication-system channel. It represents the maximum communication rate that can be transmitted by a communication channel, as shown in Eq. (5.8) [7]:

$$\langle C \rangle = \int_0^\infty B \log_2(1+\gamma) f(\gamma) \mathrm{d}\gamma = \frac{1}{\ln 2} \int_0^\infty B \ln(1+\gamma) f(\gamma) \mathrm{d}\gamma, \tag{5.8}$$

where B is the system bandwidth.

Power Analysis

The laser power of the modulated retro-reflector system [8] and the optical-signal power ultimately received by the active terminal [9] can also be used to measure the communication performance of an MRR FSO system. For a conventional FSO communication system, the attenuation of the system laser power will decrease with $e^{-\alpha R} R^{-2}$. However, for a passive-modulated optical wireless communication system, because its transmission is in accordance with the "back to the original" method, its transmission path is a two-way loop. Therefore, the attenuation of its laser power decreases with $e^{-2\alpha R} R^{-4}$ [10].

The received power expression is shown in Eq. 5.9:

$$P_\gamma = P_t \frac{D_{\mathrm{ret}} D_{\mathrm{rec}} T \beta \gamma}{\Omega_t \Omega_{\mathrm{ret}} R^4}, \tag{5.9}$$

where P_γ is the power of the modulated signal, P_t is the laser power of the transmitting terminal, D_{ret} is the caliber of the MRR, D_{rec} is the caliber of the receiving optical system, $T = \mathrm{e}^{-\alpha R}$ is the air-attenuation constant, β is the modulation coefficient of MRR, γ is the scintillation coefficient of the laser beam after passing through turbulent atmosphere, Ω_t is the unmodulated laser-divergence angle, and Ω_{ret} is the modulated laser-divergence angle.

According to the MRR FSO link-communication process, the optical-signal power finally received by the active terminal is shown in Eq. (5.10):

$$P_{\mathrm{rec}} = \frac{P_t \tau_t \tau_{\mathrm{atm}}^2 D_{\mathrm{rec}}^2 \tau_{\mathrm{rec}} \tau_{\mathrm{MRR}}^2 \rho_{\mathrm{MOD}} D_{\mathrm{ret}}^2 (C_{\mathrm{MOD}} - 1)}{R^4 \Omega_t^2 \Omega_{\mathrm{ret}}^2 C_{\mathrm{MOD}}}, \tag{5.10}$$

where P_t is the laser power at the transmitting end; τ_t is the transmittance of the transmitting optical system; τ_{atm} is the atmospheric transmissivity; τ_{rec} is the transmittance of the receiving optical system; ρ_{MOD} is the surface reflectance of the

photoelectric modulator; τ_{MRR} is the MRR optical-system transmittance; and C_{MOD} is the modulator modulation contrast.

Modulation-Form Analysis

Four types of modulation are used in optical wireless communication systems. They are on-off keying (OOK), pulse-position modulation (PPM), phase-shift keying (PSK), and frequency-shift keying (FSK) [11].

OOK modulation is the most commonly used method; however, in an MRR optical wireless communication system, if both parties use OOK modulation, the communication rate will be greatly restricted and the bit-error rate will increase.

The principle is that the active end of the system sends the "0" code. When the MRR end of the system needs to send the"1" code, an error code will appear because the MRR end omits the laser; hence, the bit-error rate is increased by a quarter.

If the transmission rate is reduced by sending the signal pulse "1" using all-optical storage, the communication rate of the uplink will be reduced to $1/N$ of the communication rate of the downlink. The value of N is determined according to the maximum number of concatenated "0"s when coding. Consequently, it is very restrictive when both sides of the communication adopt OOK modulation in the MRR form.

Therefore, in recent years, many domestic and foreign scientific-research institutions and researchers have been committed to the study of duplex-modulation technology. Using duplex-modulation technology in MRR FSO communication systems can further improve the system transmission rate, increase the spectrum utilization, and reduce the waste of communication resources.

The duplex-modulation technology in MRR FSO communication systems can be divided into two types. One separates the light source and MRR information according to the demodulation orthogonality; it includes PPM [12], carrier modulation [13], and polarization modulation [14]. The other type allocates specific communication resources to the uplink and downlink through separate multiplexing technology to correctly extract the MRR terminal information. It includes time-division multiplexing [15], electrical-domain frequency-division multiplexing, and optical wavelength-division multiplexing [16].

Foreign Research Progress

In 1994, Swenson et al. [17] proposed a model of an MRR FSO system. To verify the feasibility of this communication model, Utah State University and Phillips Air Force Laboratory conducted a communication experiment over a distance of 4 km.

In 1996, the Aerospace Dynamics Laboratory of Utah State University and Swenson carried out an MRR FSO communication experiment between a high altitude and the ground [18]. In this experiment, a ferroelectric liquid-crystal angular

reflector was used to transmit data over a communication distance of about 30 km with a communication rate of 20 Kbit/s.

In 1998, Gilbreath et al. from the United States Naval Research Laboratory experimentally verified an MRR system based on multiple quantum wells (MQWs) [19]. The experiment transmitted image data over 17 m, with a communication rate of 460 Kbit/s. The experiment verified that the MQS-based MRR FSO communication system could transmit data.

In the fall of 1999 and the winter of 2000, Gilbreath et al. experimentally verified MRR FSO communication between rotorcraft unmanned aerial vehicles (UAVs) and the ground in Chesapeake Bay, USA [20]. The experiment transmitted video data over a communication distance of 35–65 m, with a vertical height of 35 m, and a communication rate of 910 Kbit/s.

In 2002, Mahon et al. [21] proposed a new modulation scheme using a cat's-eye MRR. The scheme could simultaneously modulate and reflect incident light. According to this method, the United States Naval Research Laboratory developed an MRR based on the cat's-eye structure and used this MRR in the Chesapeake Bay MRR FSO field experiment. The data transmission had a communication distance of 1 km and a communication rate of 10 Mbit/s.

In 2003, Rabinovich et al. [22] studied a new type of multi-quantum-well modulated retro-reflector. The MQW MRR used a cat's-eye reverse reflector, and the MQW was located on the cat's-eye focal plane. In this study, the size of the modulator was decoupled from the size of the optical aperture to produce a higher data-transmission rate of 50 Mbit/s.

In 2003, Gilbreath et al. [23] carried out an MRR FSO outfield communication experiment in Chesapeake Bay. In this experiment, the data-transmission rate between a UAV and the ground reached 5 Mbit/s. A good bit-error rate was achieved within a communication distance of 30–100 m.

In 2004, Shay et al. [24] from the University of New Mexico used an MRR composed of liquid-crystal materials and angular reflectors to construct an MRR FSO communication system that could realize full-duplex communication with a communication rate of 20 Kbit/s.

In 2006, Plett et al. [25] used an MRR array composed of three MRRs to carry out an MRR FSO outfield-communication experiment in Chesapeake Bay. In this experiment, the communication distance between the two coasts was about 16 km and the communication rate was 2 Mbit/s.

In 2007, Öhgren et al. [26] designed an MRR FSO system using an MQW modulator and a large field-of-view cat's-eye optical system, in which the bandwidth of the MQW modulator exceeded 10 MHz. Multilevel modulation in the MRR FSO was studied, and 90-m indoor and 160-m outdoor transmission experiments were conducted.

In 2008, Rabinovich et al. [27] conducted a sea-surface communication experiment between ships in the Pacific Ocean. The 1550-nm band was used between two moving ships to verify the reliability of MRR FSO communication on the sea surface, when both ends of the communication were in a non-stationary state. An

MRR FSO communication experiment with a communication distance of 4.5 km and communication rate of 2 Mbit/s was realized.

In 2009, Gilbreath et al. [28] conducted an MRR FSO outfield communication experiment on the ground. The experiment transmitted data over a maximum communication distance of 2.5 km at a communication rate of 2 Mbit/s.

In 2010, Rabinovich et al. [29] conducted a communication experiment on the scintillation index in an MRR FSO communication link in China Lake, California. The scintillation index of the MRR FSO communication link was compared with that of a traditional FSO communication link. The results showed that the MRR FSO communication system was more susceptible to atmospheric turbulence.

In 2012, Goetz et al. [30] studied the performance of a micro-UAV modulated retro-reflector laser communication system. In this research, one-to-one and one-to-many communications were carried out using the modulated retro-reflector. The results showed that the application of MRR FSO technology to UAVs could greatly improve the transmission efficiency.

In 2013, Rosenkrantz et al. [31] studied an innovative modulated reflector for free-space optical communication. In this study, an innovative device consisting of a ferroelectric film embedded with nanoparticles was used to construct an MRR, and an asymmetric communication link was established between a base station and multiple robots or astronauts. The research showed that in the entire communication-link range, the bit-error rate was the best when the transmission power was 65 mW.

In 2014, Thueux et al. [32] of Sweden and AIR BUS of France jointly carried out an MRR field-communication experiment between an unmanned aerial vehicle (UAV) and the ground. This experiment transmitted data over a communication distance of 1.2 km at a communication rate of 20 Mbit/s using an MRR application in the UAVs.

In 2016, Anonymous researchers [33] studied a new space optical-communication technology, including communication from earth to a spacecraft in earth orbit and in deep space, such as the moon and Mars. In this study, a new laser-beam pointing technology was used to improve the optical-data transmission of spacecraft. It amplified the laser power received by the modulating reflector on a low-orbit satellite and improved the pointing process between the earth and the spacecraft terminal.

In 2018, Born et al. [34] studied all-optical retro-modulation (AORM) for free-space optical communication and proposed a device and system architecture for free-space optical and optical wireless communication at high data rates over multiway links. The AORM architecture was manufactured and tested and ultimately proved able to meet a total data-rate transmission at the Tbit/s level to achieve multi-directional free-space optical communication.

In 2019, Korotkova et al. [35] from the University of Miami conducted an experimental study on the polarization characteristics of the received signal of an MRR FSO communication system. This study demonstrated that the polarization characteristics of return waves in a single-station dual-pass optical system with a

glass angular-cube mirror were modulated in a complex manner in a clear-air turbulent atmosphere.

In 2020, El Saghir et al. [36] conducted a unified performance analysis of MRR communication systems in all turbulent states, modeled by a generalized Malaga distribution for free-space optical communication links. The probability-density function, cumulative-distribution function, moment-generation function, closing expression of the system fading channel, and system receiving SNR were obtained, and the asymptotic expressions of the average bit-error rate and interruption probability were studied. The results showed that the asymptotic expressions were consistent with those of weak and moderate turbulence at high SNR. With the decrease of the influence of atmospheric turbulence, the performance of the average bit-error rate was improved and the interruption probability was decreased.

In 2021, El Mashade et al. [37] studied the effect of a non-zero axis pointing error on the performance of an MRR FSO communication system. In this study, the mean bit-error rate, system interruption probability, and asymptotic performance of the system's ergodic capacity at low and high SNR were derived, by considering the non-zero displacement of the beam from the center of the optical receiver. The results showed that the performance of the MRR FSO system decreased exponentially with the increase of axial inclination.

In 2021, Trinh et al. [38] conducted a statistical experiment on the experimental channel of a UAV ground-reflecting FSO link and fine-tracking system. In this experiment, a UAV equipped with a modulation mirror was used to modulate the incident beam, and the modulated beam was reflected back along the same path, so that an FSO communication link with the UAV could be established. This technology provided a practical reference for the theoretical performance analysis and engineering design of a UAV reflection FSO system.

Domestic Research Progress

In 2007, Zhang [39] studied optical reverse modulators based on giant magnetostrictive material (GMM) and silicone gels. In this study, the coupling of GMM and silicone gel was used as a reflecting surface on the angular reflector, and the performance of the diagonal reflector was controlled by adjusting the magnetization state of the giant magnetostrictive rod to generate a relatively small displacement. The results showed that under a voltage drive of 1–15 V, the displacement was 0.1–1 μm. In this case, the displacement variation met the modulation condition, which verified the feasibility of the MRR-system design scheme using GMM.

In 2010, Ke et al. [40] from Xi'an University of Technology studied the effect of light beams on MRR FSO link performance and established a mathematical model of the outgoing light beam after a Gaussian light beam was reflected by the MRR of a corner-cube retroreflector (CCR). The results showed that the laser beam reflected by the CCR had a certain channel-compensation effect on the turbulent channel, and the reflected multi-beam could effectively reduce the received SNR instability.

In 2013, Shan et al. [41] studied the effect of the defocus of a cat's-eye optical system on the terminal scintillation in an MRR FSO system. The results showed that a certain amount of defocusing was needed to minimize the scintillation index (SI) with the changing turbulence and transmission distance. As the defocus increased, the SI tended to first decrease and then increase; the larger the distance and turbulence, the larger the SI.

In 2014, Yang et al. [42] designed a cat's-eye MRR laser-communication receiving-amplifier circuit. Its bandwidth could reach 140 MHz, the signal gain was greater than 70 dB, and the total noise current was about 1.34×10^{-7} A. The results showed that the receiving-amplifier circuit met the conditions of low noise, high gain, and high bandwidth in cat's-eye MRR laser communication.

In 2015, Qiu et al. [43] proposed a single light-source full-duplex MRR FSO scheme, which adopted OOK modulation at the data-transmission end and amplitude modulation at the MRR end. After the experiment, the information-communication process of the scheme was analyzed, and a short-distance MRR single light-source full-duplex optical communication experiment was completed in an indoor environment.

In 2015, Xu et al. [44] studied an MRR optical communication system based on acousto-optic modulation. The experimental results showed that this communication system achieved a communication rate of 118.2 Kbit/s and high carrier frequency of 1 MHz, and the bit-error rate was much lower than 10^{-6} for the data transmission.

In 2016, Ke et al. [45] from Xi'an University of Technology established an equivalent model of the defocusing structure of the cat's-eye target using geometric optics and studied the factors affecting the characteristics of reverse-modulated reflected light. The results showed that the MRR receiving distance and internal-structure parameters had obvious effects on the power density and reflected-spot radius of the modulation system. This effect changed regularly. Reducing the lens focal length, increasing the lens aperture, and increasing the receiving distance all accelerated the change of reflected power with the defocus quantity.

In 2017, Ke et al. [46] from Xi'an University of Technology designed an indoor full-duplex communication system with a single light source, which was based on a defocusing cat's-eye MRR scheme. When the communication distance was 3.0 m, the upstream data transmission was 2.0 Kbit/s and the downstream data transmission was 5.0 Mbit/s.

In 2018, Zhang [47] designed a visible-light full-double-mode communication system and proposed a new visible-light reverse-transmission scheme, based on the defocusing cat's-eye. Using an upstream modulator based on the defocusing cat's-eye MRR principle and a signal-processing circuit to remodulate the downlink optical signal, the experiment realized a visible-light bidirectional communication link with a single-LED light source.

In 2019, Chen et al. [48] studied data transmissions in MRR laser-communication links and presented a transmission model based on combinatorial optimization theory. Through research on this topic, the relationship between the data-transmission characteristics and various factors in the MRR optical-fiber

communication system was found. The model effectively improved the success rate of the data transmission in the system and improved the system data-transmission rate.

In 2019, Pan et al. [49] studied the atmospheric-turbulence effect and its control method in an MRR optical-communication echo-reflection link. Based on the phase-screen method, this project constructed traditional FSO and MRR FSO transmission models of Gaussian beams under weak turbulence conditions and theoretically analyzed the flicker characteristics of the Gaussian beam during MRR FSO transmission. The results showed that atmospheric turbulence had a great influence on the MRR optical-communication echo-reflection link, and the influence was much greater than that on the one-way link in traditional FSO.

In 2020, Duan et al. [50] calculated the energy of the cat's-eye laser echo after attenuation in the atmosphere and analyzed the transmission distance, wavelength of the emitted laser, angle of the incident laser, cat's-eye aperture, and other factors and determined the influence of the above factors on the signal-to-noise ratio at the receiving end. The results showed that the larger the transmission distance and the larger the cat's-eye and receiving apertures, the larger the SNR at the receiving end. In contrast, the larger the laser incidence angle, the smaller the signal-to-noise ratio. Moreover, a long-wavelength laser could improve the signal-to-noise ratio of the link.

In 2020, Li [51] proposed an MRR FSO communication system based on an adaptive decision threshold and compared it with an MRR FSO communication system based on an optimal decision threshold. The experiments showed that the MRR FSO communication system with the adaptive decision threshold could communicate with simple equipment and no prior channel information. The difference in the bit-error rate between the two systems was only 1.3 dB.

In 2021, Jia et al. [52] designed an intersatellite laser-communication system for small satellite formations based on a reverse modulator. In this scheme, by constructing a complete satellite navigation-system model, the influence of random pointing errors on the average bit-error rate and average interrupt rate of an MRR communication system was studied. The experimental results showed that the average interrupt rate and the average bit-error rate could be better than 10^{-6} with a 1-Gbit/s communication rate and a 200-km communication distance as experimental conditions.

In 2021, Fang et al. [53] designed an MRR optical-communication signal determination theory based on the K-means algorithm. Considering the characteristics of the received sample points, the sample points in the window were dynamically and adaptively classified according to the similarity of their characteristics, which greatly improved the signal-decision accuracy. The results showed that this signal-decision method based on the K-means algorithm had better error performance in turbulent channels.

In 2022, Chen et al. [54] designed a combinational-logic reverse-pulse bit-modulation scheme to eliminate the downlink-signal interference to the uplink signal, which reduced the bit-error rate of a single-light MRR FSO communication

system. The results showed that the gain of this system was about 5 dB. The scheme obtained better bit-error rate performance when the optical transmitter, optical receiver, and MRR used the reverse-pulse bit-modulation scheme.

In 2022, Xie et al. [55] used the phase-screen method to study the effect of atmospheric turbulence on an MRR optical-communication system. Based on the model, the scintillation index (SI) was calculated and the aperture average effect of the MRR terminal was analyzed. The SI values of the MRR link and direct link were compared in a 506-m transmission link. The experimental results showed that the experimental data were in good agreement with the numerical simulation results, so the feasibility of the theoretical model was verified.

Working Principle of an MRR FSO System

MRR FSO-System Composition

A modulated retro-reflector system can include MRR FSO communication systems based on liquid crystal, piezoelectric ceramics and micro-electromechanical structures, acousto-optic modulators, multi-quantum wells, and advanced modulation formats [51]. From the perspective of a free laser-communication link, an MRR FSO system includes two parts: the drive end and the cat's-eye reverse end.

The drive end of the MRR FSO is composed of an optical base and servo turntable. The optical base consists of a communication transmitting and receiving unit, beacon transmitting and receiving unit, and auxiliary-target viewing unit. The optical base integrates each optical path and ensures their coaxiality. The communication receiving unit receives the communication light reflected back by the reverse end and provides information for tracking the servo turntable. The servo turntable mainly receives the position information given by the beacon and ensures the stability of the communication link.

The reverse end of the MRR FSO consists of three parts: a cat's-eye optical system, laser modulator, and signal modulator. Among them, the cat's-eye optical lens adopts an improved spherical design. The cat's-eye optical lens can be used to receive large-field optical signals; then, the incident light is transmitted to the drive end, according to the original path through the lens. The signal modulator modulates and encodes the information in the link, and the control modulator modulates the incident laser.

The beacon light emitted by the drive end of the MRR FSO returns along the original path of incidence after passing through the cat's-eye optical system. The position information of the reverse end is detected by the beacon receiving unit in the optical base, and the servo turntable accurately locates the reverse end. The cat's-eye optical lens gathers the communication light emitted by the drive end onto the modulator target surface, and the modulator loads the information onto the communication light for transmission by changing the intensity of the incident light.

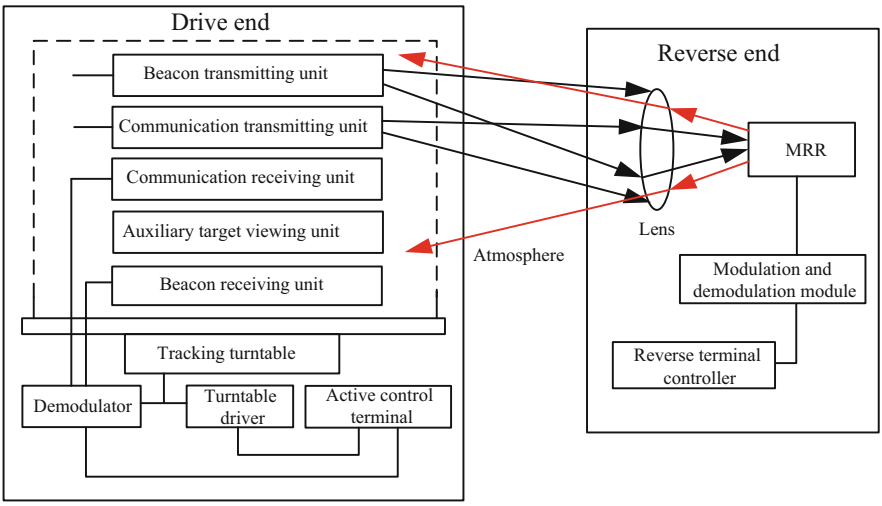

Fig. 5.2 Composition of the modulated retro-reflector laser communication system [56]

It returns the modulated communication light to the receiving unit of the drive end through the original path of the cat's-eye lens, and the drive end demodulates it to obtain the information transmitted by the reverse end, completing the modulated retro-reflector [56]. The composition of the MRR FSO system is shown in Fig. 5.2.

Main-Parameter Analysis

Compared with a traditional FSO system with the same laser-communication link distance, the communication laser needs to pass through the atmospheric channel twice, in accordance with the "back to the original" method, and the transmission loss is squared. To ensure that the drive end of the MRR FSO accurately tracks the reverse end of the non-tracking unit, the following parameters are analyzed.

Wavelength Choice

The system operating wavelength has a very important impact on the communication performance. Under the same intensity turbulence, the longer the wavelength used, the less the impact will be. Limited by the absorption window of the atmosphere and considering the technical complexity of the laser [34], two laser bands are commonly used in laser communication, 800 nm and 1550 nm.

The scattering effect of the atmosphere in these two bands is manifested in the form of Mie scattering, which occurs when the diameter of the particles in the atmosphere is equivalent to the wavelength of the radiation. Mie scattering is related to the atmospheric visibility, wavelength, and correction factor. In general, it is represented by the attenuation coefficient, and its expression is

$$\sigma = \frac{3.912}{V_m}\left(\frac{\lambda}{550}\right)^{-q}, \tag{5.11}$$

where V_m is the atmospheric visibility; λ is the wavelength; and q is the correction factor. The relationship between the size of the correction factor and atmospheric visibility is

$$q = \begin{cases} 1.6 & (V_m > 50\,\text{km}) \\ 1.3 & (6\,\text{km} < V_m \le 50\,\text{km}) \\ 0.16V_m + 0.34 & (1\,\text{km} < V_m \le 6\,\text{km}) \\ V_m - 0.5 & (0.5\,\text{km} < V_m \le 1\,\text{km}) \\ 0 & (V_m \le 0.5\,\text{km}) \end{cases}. \tag{5.12}$$

In actual communication, the relationship between the laser-power attenuation and the change of distance is shown in Eq. (5.13).

$$\beta = -10\sigma \cdot L \tag{5.13}$$

According to the above formula, Fig. 5.3 shows the relationship diagram of the laser-power attenuation with distance when the wavelength is 800 nm (solid line) and 1550 nm (dashed line). As shown in the figure, the laser in the 1550-nm band decreases 0.7-dB per kilometer less than the laser in the 800-nm band; hence, the 1550-nm band is typically used in communication.

Beam-Divergence Angle

The divergence angle of the laser beam can represent the velocity of the beam from the waist. To meet the communication and application requirements, a low beam-

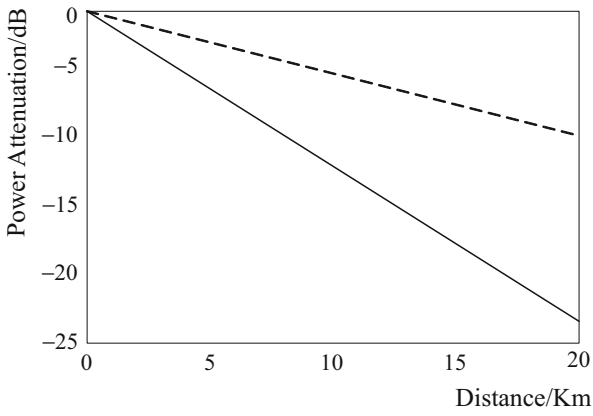

Fig. 5.3 Laser-power attenuation with distance [56]

divergence angle is required in FSO communication. The beam-divergence angle is mainly limited and affected by the following three factors:

1. Free-space loss: The free-space loss is the energy loss of an optical signal propagating in atmosphere. For an FSO system, the free-space attenuation is directly proportional to the square of the communication beam-divergence angle.
2. Communication optical-diffraction limit: The diffraction limit is related to the optical wavelength and communication optical-emission aperture. The specific relationship is shown in Eq. (5.14):

$$\theta = \frac{2.44\lambda}{D}, \tag{5.14}$$

where θ is the diffraction limit; λ is the wavelength; and D is the communication optical-emission aperture.

Registration precision: The alignment accuracy is related to the received power attenuation of the communication system, and the received power-loss coefficient can measure the alignment accuracy of the system. The loss coefficient is related to the tracking error and beam-divergence angle. The specific relationship is shown in Eq. (5.15):

$$\alpha = e^{-8\left(\frac{\theta_e}{\theta_T}\right)^2}, \tag{5.15}$$

where α is the received power-loss coefficient; θ_e is the tracking error; and θ_T is the beam-divergence angle. According to Eq. (5.15), when θ_T decreases, α increases, and the laser power loss is greater.

Optical-Receiver Diameter

Because the atmosphere is the communication carrier of an FSO system, the FSO system is greatly affected by weather in the communication process. To improve the communication efficiency and receiving power of the system, when an FSO system is applied in long-distance communication, the receiving power of the system is usually increased by the square in large-aperture receiving.

When communicating with the atmosphere as the carrier, a flickering smooth atmosphere is called the aperture-smoothing effect [57]. It can be represented by the aperture-smoothing factor F, and the specific relationship is shown in Eq. (5.16):

$$F = \frac{16}{\pi D^2}\int_0^D \frac{C_I(\rho)}{C_I(0)}\left\{\arccos\left(\frac{\rho}{D}\right) - \frac{\rho}{D}\left[1 - \left(\frac{\rho}{D}\right)^2\right]^{1/2}\right\}\rho \mathrm{d}\rho, \tag{5.16}$$

where $C_I(\rho)$ is the light-intensity covariance function; $C_I(0)$ is the light-intensity variance function; and D is the receiver aperture.

Modulated Retro-Reflector

The modulated retro-reflector is the main component and core of a modulated retro-reflector system. The optical modulator and the reverse reflection system are the main components of the MRR. The signal is processed in the optical modulator and converted into a specific driving signal. This changes the properties of specific materials or devices, thereby changing the laser properties interacting with them. There are two common MRRs in MRR communication: angular-reflector and cat's-eye [2].

Angular-Reflector MRR

The angular-reflector MRR consists of two parts [1], namely, the angular reflector and optical modulator. The angular reflector consists of three highly reflective planes that are perpendicular to each other. Its geometric characteristics can improve the reverse-reflection performance of the incident beam [47].

The angular-reflector MRR uses two different modulation principles. One changes the intensity of the reflected beam by changing the reverse-reflection characteristics of the angular reflector. The other places a special light modulator in the angular reflector and modulates the intensity of the reflected light signal through the photoelectric characteristics of the modulator.

These two MRR types change the reflection characteristics of the reflecting-surface and transmission-switching MRR systems. The MRR that changes the reflection characteristics of the reflector uses a micro-electromechanical system (MEMS) to change the reflector structure. The transmission-switching MRR modulates the reflected light by controlling the switching optical modulator and utilizing the reverse-reflection characteristic of the angular reflector [58]. Figure 5.4 shows a schematic diagram of the angular reflector.

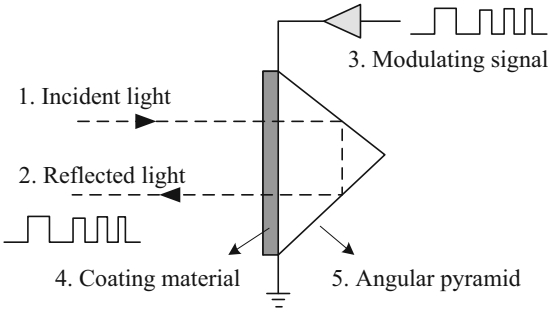

Fig. 5.4 Schematic diagram of an angular-reflection reverse modulator [58]

Cat's-Eye MRR

Cat's-Eye Effect

When a beam of light illuminates a diffused object, its reflected light is reflected in multiple directions, typically with a reflectivity in the range of 0.2–0.5 [59]. When the distance between the light source and the object is large, the reflected light is very weak. However, when the light from the source strikes a photoelectric device with an optical window, the intensity of the reflected light varies greatly.

The position of the photosensitive surface on the photoelectric sensor is near the focal plane of the objective lens of the optical system; therefore, the reflected light is distributed in a small three-dimensional angle range, forming a large reflection cross-section. Just as light from a light source enters a cat's eye, it is focused through the pupil of the cat's eye to the fundus [60]. The cat's-eye effect occurs when an incoming beam of light bounces off the fundus and returns along its original path.

Owing to the cat's-eye effect, the cat's-eye optical system has the same reverse-reflection characteristics as the angular reflector; thus, the cat's-eye system can be combined with an electro-optic modulator to build a cat's-eye MRR.

The cat's-eye MRR consists of two parts: a focusing lens and a modulating reflector. When the laser from the transmitter is transmitted to the cat's-eye lens, the cat's-eye optical system focuses the emitted laser on the reflecting surface of the modulator. The incident light is reflected on the target surface of the modulator of the cat's-eye optical system in accordance with the light characteristics along the original path. The reflected laser passes through modulation and carries useful information back to the light source.

The cat's-eye MRR is passively controlled by the light source. Only when the light source irradiates the optical system of the cat's-eye structure will the incident light be affected by the cat's-eye effect and reflect back to the source in the original manner. It is also known as a passive modulator [3]. Figure 5.5 shows a typical cat's-eye structural physical model.

As the optical antenna of an MRR optical wireless communication system, the performance of the cat's-eye optical structure is directly related to the stability of the

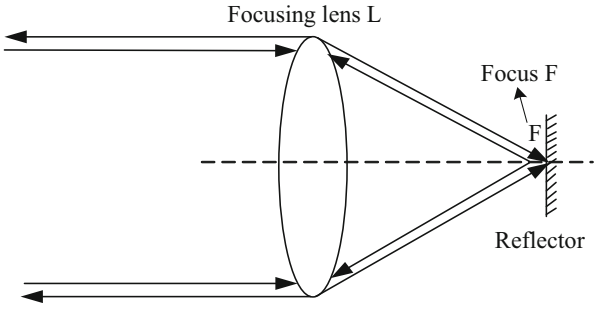

Fig. 5.5 Physical model of a cat's-eye structure [23]

communication link. Therefore, the cat's-eye MRR FSO system in the communication process must meet the following requirements:

1. The cat's-eye optical system must be in accordance with the reverse-reflection characteristics of the system;
2. The cat's-eye optical system must ensure that the divergence angle of the reflected light is as close as possible to the diffraction limit;
3. The F number of the cat's-eye optical system must be as small as possible, where F is the ratio of the equivalent focal length to the optical aperture of the cat's-eye optical system.

Echo-Power Analysis

The cat's-eye MRR modulates the echo power of the incident light to the cat's-eye structure by changing the defocus of the modulator to realize data transmission and communication.

The emitted laser power of the laser-emitting device is P_0, the divergence angle of the emitted laser beam is θ_0, the effective receiving area is A_r, the link distance at which the communication is completed is R, the cat's-eye effective cross-sectional area is A_s, the reflectance is ρ_s, the effective cross-sectional area of small diffuse reflection targets is A_1, the reflectance coefficient is ρ, the two-way atmospheric transmittance is τ_a, the transmittance of the receiving optical system is τ_r, and the divergence angle of the modulated laser beam is θ_s. The cat's-eye-target echo power is shown in Eq. (5.17) [61]:

$$P_s = P_0 \frac{16\tau_a \tau_r A_r A_s \rho_s}{\pi^2 \theta_0^2 \theta_s^2 R^4}. \tag{5.17}$$

The diffuse earth echo power is shown in Eq. (5.18):

$$P_r = P_0 \frac{\tau_a \tau_r A_r \rho}{\pi R^2}. \tag{5.18}$$

From Eqs. (5.17) to (5.18), the ratio of the echo power of the cat's-eye target to the diffuse earth echo power is

$$\frac{P_s}{P_r} = \frac{16 A_s \rho_s}{\pi \theta_0^2 \theta_s^2 R^2 \rho}. \tag{5.19}$$

From Eqs. (5.17–5.19), it can be seen that the ratio of the echo power of the cat's-eye target to the earth echo power becomes increasingly smaller with increasing distance. Because the earth echo power is inversely proportional to the square of the distance, the echo power of the cat's-eye target is inversely proportional to the fourth power of the distance. When the distance reaches a certain value, the ratio between them will be reduced to zero. At this point, cat's-eye MRR communication cannot be used.

Defocusing the Cat's-Eye MRR

When the target lens is in an ideal state, namely, a non-defocused state, there is a high ratio between the intensities of the reflected and incident lights. However, in practical optical-communication systems, owing to manufacturing errors in equipment and components, the photosensitive surface in the optical instrument is not simply in the focal plane; there is usually a certain amount of defocus. Sometimes, to meet specific needs, a certain amount of defocus will be artificially set.

The defocused cat's-eye MRR is an optical reflector placed around the focal plane of the cat's-eye optical system. The intensity of the reverse reflection is modulated by controlling the positions of the reflector and the focal plane [2]. For forward defocusing, where the reflector is positioned in front of the focal point and the optical reflector in the focal plane moves toward the lens, the amount of defocus is negative, also known as negative defocus. The physical model is shown in Fig. 5.6.

For backward defocusing, where the position of the reflector is behind the focal point and the optical reflector on the focal plane moves away from the lens, the defocus is a positive number, also known as positive defocus. The physical model is shown in Fig. 5.7 [56]. In the figure, δ is the defocusing amount, f is the cat's-eye focal length, and F is the focus.

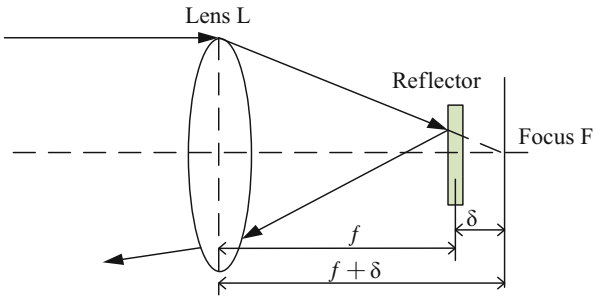

Fig. 5.6 Physical model of forward-defocusing light propagation [56]

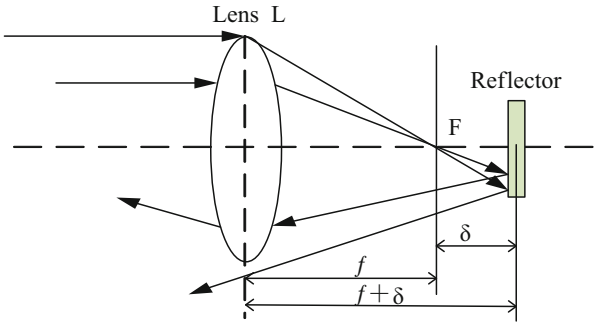

Fig. 5.7 Physical model of backward-defocusing light propagation [56]

Defocusing complicates the reflection characteristics of the laser on the reflecting elements and has some influence on the backward-reflection characteristics and cat's-eye effect [62].

Theoretical Analysis of Non-defocusing

When the cat's-eye optical system is in the non-defocused state, the full field angle of the cat's-eye lens is set as β. Research shows that no beam returns when the incidence angle meets $\theta > 0.5\beta$. When $0 < \theta \leq 0.5\beta$, the light reflects. Therefore, it can be seen that θ must be less than half the field angle, so that the light can reflect backward.

Moreover, when the incident beam is oblique, the divergence angle of the reflected beam will not be affected; however, the change of effective aperture will be affected, and the energy passing rate will be reduced. Within the half-field angle, the effective aperture and the divergence angle of the backward-reflected beam satisfy the following relation:

$$D' = D - 2f\tan\theta \tag{5.20}$$

$$\theta_s = \theta_{in}, \tag{5.21}$$

where D is the cat's-eye-target lens caliber and θ_{in} is the divergence angle of the incident laser beam.

According to Eq. (5.20), when the incident angle is 0°, the incident beams can all return in the same way, which is the cat's-eye effect in the perfect ideal case.

Theoretical Analysis of Defocusing

When the cat's-eye optical system is out of focus, the detector can receive the critical field of view β' of the incident light. When the incident angle satisfies $0 < \theta \leqslant 0.5\beta'$, the beam partially returns. The effective aperture and the divergence angle of the backward-reflection beam satisfies the following relation:

$$D' = (D - 2f\tan\theta)\frac{f+\delta}{f+2\delta} \tag{5.22}$$

$$\theta_s = \theta_{in} + \frac{2\delta}{f^2}(D - 2f\tan\theta)\frac{f+\delta}{f+2\delta}. \tag{5.23}$$

When $\delta = 0$, Eqs. (5.22) and (5.23) can be simplified to Eqs. (5.20) and (5.21), where the forward and backward defocusing satisfy the same formula. The forward defocusing satisfies Eqs. (5.24) and (5.25), and the backward defocusing satisfies Eqs. (5.26) and (5.27) within a range of very small incident angles:

$$D' = D \tag{5.24}$$

$$\theta_s = \theta_{in} + 2\delta D/f^2 \tag{5.25}$$

$$D' = \frac{Df}{f + 2\delta} \tag{5.26}$$

$$\theta_s = \theta_{in} + \frac{2\delta D}{f(f + 2\delta)}. \tag{5.27}$$

From the above formulas, it can be seen that the different focusing points lead to different effects of the two defocusing conditions on the cat's-eye effect. Because the beam propagates according to the diffraction-propagation law and the special propagation law of the laser beam, the far-field characteristics of the reflected beam are more obviously affected by the defocus, and the difference between the two defocus conditions is more obvious.

Electro-Absorption Cat's-Eye MRR

The electro-absorption MRR places an electro-absorption optical modulator at the focal plane of the cat's-eye optical system. Commonly used electro-absorption modulated reflectors include multiple-quantum-well (MQW) modulators and micro-electromechanical system (MEMS) modulators [63]. The MQW and MEMS modulators are shown in Figs. 5.8 and 5.9, respectively.

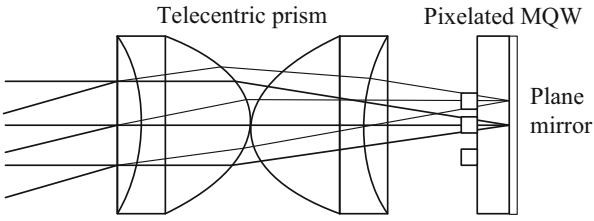

Fig. 5.8 Schematic diagram of multi-quantum-well cat's-eye reverse-modulation optical communication [63]

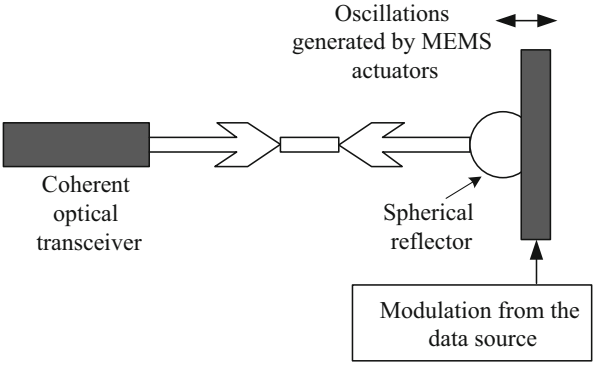

Fig. 5.9 Schematic diagram of microelectromechanical MRR optical communication [63]

The MQW device has the advantages of stability, all-solid-state structure, low driving voltage, low power, and a 40-Gbit/s switching speed. Therefore, in 1998, the US Naval Research Office applied an MQW device to an FSO system and extensively researched its characteristics [64]. The power consumption of the MQW modulator is as shown in Eq. (5.28):

$$P_{\mathrm{MOD}} = \eta C V^2 S, \tag{5.28}$$

where η is the charging circuit, C is the capacitance, V is the driving voltage, and S is the data rate. The charging circuit and communication mode determine the factors. When the charging circuit and communication mode are fixed, the power consumption of an MQW modulator mainly depends on V, followed by C and S.

In addition, the relationship between the maximum modulation rate of the MQW modulator, body resistance, and diameter is shown in Eq. (5.29):

$$S \propto \frac{1}{R_{\mathrm{MOD}} D_{\mathrm{MOD}}^2}, \tag{5.29}$$

where R_{MOD} is the MQW modulator resistor and D_{MOD} is the MQW modulator diameter.

From this formula, the smaller the modulator resistance and diameter, the higher the maximum modulation rate. The modulation rate is an important parameter of the MQW modulator, which directly affects the performance of the inverse modulator. By analyzing the characteristics of the MQW modulator, the key factors of the MQW modulator used in an MRR system are revealed: high switching rate, low power consumption, large field of view, and high modulation efficiency [20].

MRR FSO Application Prospects and Development Trends

Applications

Table 5.1 shows a detailed comparison of the angular-reflector MRR and cat's-eye MRR, according to a study of the system characteristics and communication performance.

MRR FSO communication technology is suitable for high-load satellites, unmanned aerial vehicles, and other platforms. It has been widely used in various fields, such as aerospace communication, maritime-ship communication, atmospheric monitoring, underwater submarine communication, target rendezvous, docking, and identification, and complex electromagnetic-interference environments, making end-to-end communication more reliable. In an MRR optical wireless

Table 5.1 Comparison of two reverse modulators

Angular-reflector MRR	1. Because the angular cone prism is composed of three highly reflective perpendicular planes, it has good reflection characteristics. If the reflectance of one plane is changed, the echo intensity can be changed 2. The attenuated total reflection can be used to fabricate optical MRRs based on angular cone prisms
Cat's-eye MRR	1. The cat's-eye MRR has a strong resistance to electromagnetic interference and can replace a microwave communication link in electromagnetic interference environments 2. Owing to its small size and high capacity, the cat's-eye MRR can monitor the attitude of a target platform and remotely identify the target during rendezvous and docking 3. The directivity of the cat's-eye MRR is very precise, so the communication-safety performance can be guaranteed 4. The transmission rate of a cat's-eye MRR system can reach Gbit/s or even higher, and it can transmit large amounts of multimedia data at the microwave-frequency limit

communication system, this technology plays an important role in the following aspects:

1. Small-platform communication. MRR FSO can minimize the architecture of a terminal on the premise of ensuring the angle of the field of view, and it has the backtrack feature. It has great application prospects in space satellites, space-based unmanned aerial vehicles, underwater vehicles, and other small platforms, as well as communication with ground systems. In addition, by optimizing the terminal architecture, multi-user collaborative communication can be achieved, which is especially suitable for small platforms. This can establish a full-coverage communication network and provide an important foundation for the future development of communication technology.
2. Identity and posture recognition. By transmitting signals outward through MRR, or combining MRRs into an MRR array according to a certain arrangement, remote targets can be identified through a communication link between a micro-MRR terminal and the remote drive end. This method is used to transfer position-feature information during rendezvous and docking. By establishing communication links between MRRs in various characteristic positions, an actively docking aircraft can obtain the attitude information of the docking object and adjust its attitude to dock accurately.
3. Because MRR wireless laser communication has a strong resistance to electromagnetic interference (EMI), MRR FSO can be used to replace the radio-frequency (RF) link in strong EMI environments with explosions and other complex signals. In addition, the transmitting beam-divergence angle is small, difficult to intercept, has good security, and can be used for confidential communications.

Development Tendencies

Because MRR is a rapid-targeting wireless laser-communication technology [65], it can effectively avoid technical problems, such as following and pointing between communication parties. However, traditional MRR technology can only load unilateral information and communicate in one direction. In recent years, many foreign research institutions have been studying the new MRR full-duplex transmission technology (FDX) [66], trying to find a lower power and lightweight FDX transmission scheme.

Based on domestic and foreign achievements in space laser-communication MRR research, it is believed that the future development of space laser communication under MRR will be as follows:

1. Higher speeds. Multi-quantum-well devices are some of the most important devices that can truly realize high-speed MRR spatial optical communication at present. Although it is reported that optical-fiber devices can be used for gigabit data transmissions, this form of MRR is inferior to MRR based on quantum wells because it loses the characteristic of original MRR that required less ATP.

   Furthermore, although the modulation rate of the multi-quantum-well device itself can be tens of gigahertz, the current maximum rate of systems based on multi-quantum-well MRR spatial optical communication systems is only 200 Mbit/s, which leaves extensive room for development.
2. The focal plane can be pixelated. MRRs based on multi-quantum-well devices mainly adopt the cat's-eye structure, which has a relatively small field-of-view angle. Expanding the field-of-view angle has become the focus of attention in various countries. One direct method is to increase the area of multi-quantum-well devices; however, the modulation rate decreases significantly with the increase of area.

   Thus, the single multi-quantum-well device at the focal point of the lens can be expanded into several devices. This forms a pixelated multi-quantum-well focal plane to achieve a large field-of-view angle while keeping the modulation rate constant. However, there is less research in this area. Another future direction of study involves separately controlling each pixel to only work under light irradiation, to reduce the power consumption.
3. Two-way communication. The traditional MRR space optical communication system has unidirectional characteristics; that is, the MRR terminal data are sent to the inquiry terminal. In some cases, two-way communication is required, and traditional MRR technology cannot meet the requirement. Therefore, the MRR terminal is equipped with both the receiving and inquiring ends; thus, two-way data communication can be achieved by a simple modification.

   For example, Changchun University of Science and Technology in China uses dual wavelengths to accomplish two-way MRR data communication. Moreover, the PLA University of Science and Technology suggests using different modulation methods to carry out two-way MRR communication.

4. Coherent detection. Because the beam of an MRR space optical communication system must pass through two optical paths, the system loss multiplies, compared with the traditional space laser communication link, and becomes an important reason to restrict the communication distance. Coherence-detection technology can significantly improve the sensitivity of the interrogator signal and improve the communication distance of MRR spatial optical communication systems.

Summary

This chapter introduced the principle of passive-modulation optical wireless communication technology, explained the structure and working principle of the core part of the MRR passive-modulation system, and analyzed the main parameters. It introduced the angular-reflector MRR and cat's-eye MRR, analyzed the different types of MRR and their principles, and summarized the domestic and foreign research statuses.

In the course of introducing the angular reflector MRR, the MRR system that changed the reflection characteristics of the reflector and the transmission-switch MRR system were introduced. In the course of introducing the cat's-eye MRR, the defocusing cat's-eye MRR and electro-absorption cat's-eye MRR were introduced.

This chapter discussed the main existing problems and possible solutions of MRR optical wireless communication systems. In addition, the MRR development trends in optical wireless communications were discussed. It is believed that MRR FSO will receive increasing attention and play an important role in future communication networks.

Abstract

In optical wireless communication system, photoelectric conversion is realized by photodetector at the receiver, and the noise in the detector will directly affect the photoelectric conversion efficiency. Based on the background of optical wireless communication, according to the generation mechanism of photodetector noise, this chapter describes the shot noise, multiple generation compound noise, 1/f noise, and thermal noise of the detector, in this order, and gives the corresponding mathematical models. The noise models of avalanche photodetector, original negative signature detector, photomultiplier tube, four quadrant detector, quantum dot infrared detector, and balance detector are analyzed, in this order. Finally, the direction of further research in this field is pointed out.

Optical wireless communication · Photodetector · Noise model

Introduction

In an optical wireless communication system, the photoelectric signal is converted by a photodetector at the receiving end, and the noise in the detector directly affects the photoelectric-conversion efficiency. In this chapter, the photodetector noise-generation mechanisms are described, and the corresponding mathematical models are presented. The mechanisms include scattered-particle noise, generation-compound noise, 1/f noise, and thermal-detector noise. The noise models of the avalanche photodetector, original negative detector, photomultiplier tube, four-quadrant detector, quantum-dot infrared detector, and balanced detector are analyzed.

Photodetectors are key devices that convert optical signals into electrical signals, and the effectiveness and stability of their output signals are important indicators of their working performance. In this chapter, detectors commonly used in optical wireless communication systems are summarized, including the detector's working principle, performance indicators, application scenarios, and noise models. Finally, the directions and challenges worthy of further study and discussion in this field are discussed.

Photodetectors

An optical wireless communication system includes channel coding and decoding, signal modulation and demodulation, optical amplification and coupling, optical transceiver antennas, and acquisition, alignment, and tracking systems. A laser or light-emitting diode is used as the signal light source, and the signal is modulated after channel coding.

Modulation is divided into active and passive, and active modulation can be divided into direct and indirect. A laser is directly output or amplified by an optical amplifier, which includes semiconductor optical amplifiers and optical-fiber amplifiers. A single or multiple antennas are used for transmission in free space. The transmission channels can be atmospheric, indoor-scattering, ultraviolet-scattering, and underwater.

The receiving end uses a single or multiple antennas for optical-signal reception. The optical-coupling module couples the signal into a single-mode fiber, after preamplification. It uses direct or coherent detection to convert the optical signal to an electrical signal, and then after demodulation and decoding, it delivers the information to the destination. The photoelectric detector is the core of the receiving end.

Photodetector Classification

Photodetectors are a class of devices that can convert optical-radiation signals into electrical signals. Photodetectors commonly used in the field of optical wireless communication can be divided into two categories, based on their physical-mechanism characteristics: photon detectors, based on the photoelectric effect, and thermal detectors, based on the temperature-change effect [1]. Figure 6.1 shows the classifications of some of the photodetectors commonly used in the field of optical wireless communication, based on their external and internal photoelectric effects.

When incident light illuminates the surface of a photoelectric-based detector, a photon of the incident light collides with the electrons in the material to produce new photoelectrons, which overflow from the detector surface, resulting in an external photoelectric effect. If the charge carriers generated inside the detector material do not overflow from the surface, but are bound to the inside of the detector material, it is called an internal photoelectric effect.

The external photoelectric effect generally includes photoconductive, photovoltaic, and magneto-optical effects. The internal photoelectric effect includes the photon-emission effect. The quantum-well and the quantum-dot infrared detectors use the photoconductive effect. For photocells, the positive–intrinsic–negative detector (PIN photodetector) and avalanche photodetector are photovoltaic-effect detectors. Photoresistors belong to detectors using the photoconductive effect. Vacuum photocells, gas-filled photocells, and photomultiplier tubes take advantage of the photon-emission effect.

In a thermal detector, a detector material that absorbs incident light will produce a thermoelectric effect, resulting in a change in resistivity. Commonly used thermal detectors include thermistors and thermopiles.

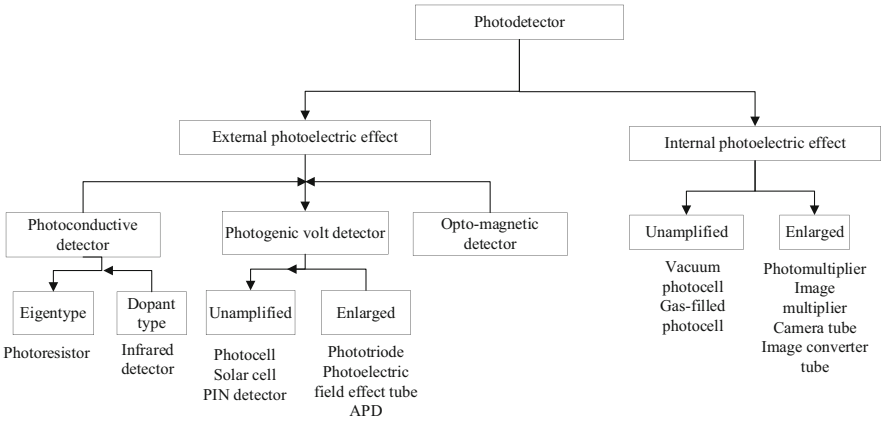

Fig. 6.1 Photodetector classification

Photoconductive Effect

When incident light irradiates the surface of a semiconductor material, the material absorbs energy. At this time, the carrier concentration gradually increases, the conductivity increases, and the resistance decreases; this is the photoconductive effect.

A photoconductive detector, which is a uniform intrinsic semiconductor with a photoconductive effect, can be represented by the model shown in Fig. 6.2. A voltage U is applied to both ends of the semiconductor to form electrodes. The current generated by the circuit can be detected by a galvanometer. When the optical metric is changed, the current of the circuit changes, that is, the resistance of the detector reverses.

Photovoltaic Effect

Figure 6.3 shows a schematic diagram of the photovoltaic effect with the presence of charge carriers in the P-N junction, with two types of carriers, majority and minority. Most carriers will constantly drift in the interior of the P-N junction, forming a self-established electric field E inside the P-N junction. When the P-N junction and the area around it are irradiated with light, a few charge carriers will be present near the P-N junction.

Under the action of the self-built electric field E, the electrons drift to the N region and the holes drift to the P region. The N region, where electrons drift, carries a negative charge. The P region, to which the holes drift, has a positive charge. The electric field generated by the control of a few carriers is an additional electric field, that is, the photogenerated electric field.

When a reverse voltage is applied to the P-N junction, the resulting reverse current gradually increases as the reverse voltage increases. The resulting photoelectric signal can be observed using photocurrent I.

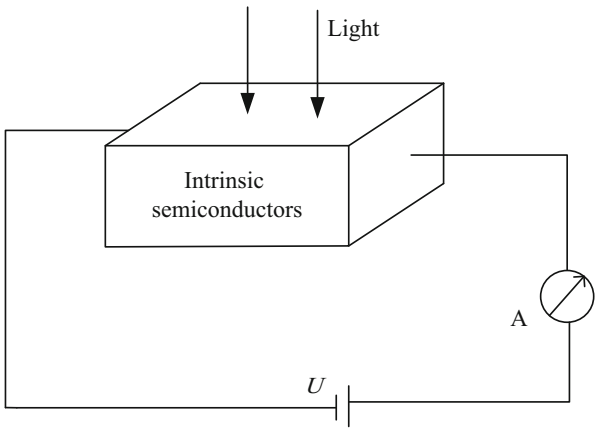

Fig. 6.2 Simple model of a photoconductive detector

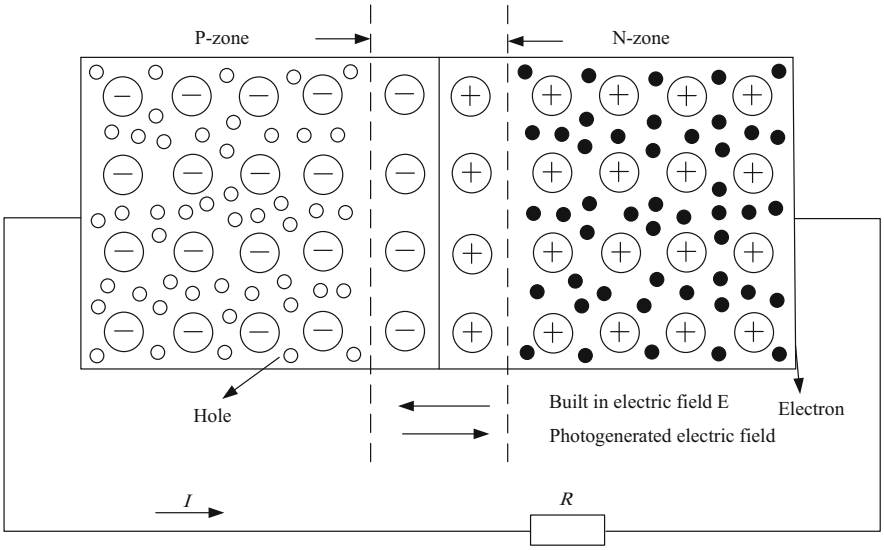

Fig. 6.3 Photogenerated voltage effect of a P-N junction

Photoelectron-Emission Effect

According to the quantum theory of light, when incident light strikes the surface of the device material, if the frequency of the incident light increases, the energy absorbed by the electron increases, and part of the energy is used for collision loss. If the remaining energy is sufficient to overcome the barrier on the surface of the material, the electrons overcoming the barrier will overflow from the surface of the material and enter the space environment.

The photoelectron energy-level transitions are shown in Fig. 6.4. The maximum kinetic energy of the photoelectrons that overflow the surface of the material is described by Einstein's equation:

$$E_k = hv - w, \tag{6.1}$$

where w is the work function of the material in joules, h is Planck's constant, and $E_k = 1/2^{mv^2}$ is the kinetic energy of a photoelectron spilling over the surface of the material. The mass of the photoelectron is represented by m, and its velocity is represented by v.

When the incident light irradiates the surface of the material, the kinetic energy of the photoelectrons does not change with the change in light intensity but is only related to the frequency of the incident light. When the incident-light frequency increases, the kinetic energy increases; when the incident-light frequency decreases, the kinetic energy decreases. When photoelectrons leak from the surface of the material, there is a critical threshold value, that is, when the kinetic energy is 0, the photoelectrons simply reach the surface of the material. In this case, the frequency of the incident light is the limiting frequency.

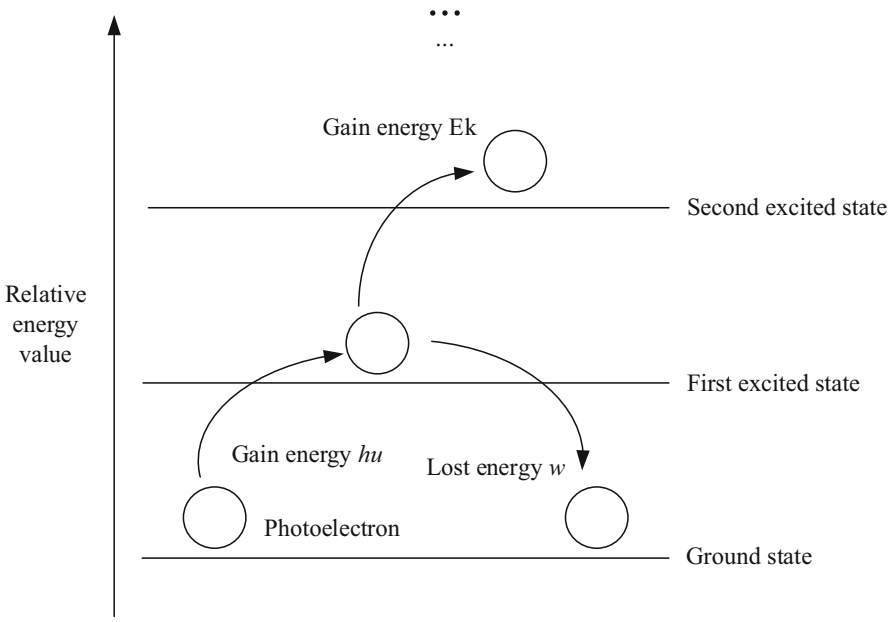

Fig. 6.4 Photoelectron energy-level transition diagram

Photodetector Performance Indicators

Quantum Efficiency

The quantum efficiency is defined as the average number of electrons released by an incident photon, η, and is expressed as

$$\eta = \frac{Ih\nu}{Pe}, \tag{6.2}$$

where η is the quantum efficiency, I is the average value of the photocurrent, e is the electron charge, P is the optical power, h is Planck's constant, and ν is the frequency of the incident light. Detectors with higher quantum efficiencies have better performance.

Noise-Equivalent Power

The noise-equivalent power (NEP) reflects the detection capability of the detector and is generally described under the premise of a unit signal-to-noise ratio, that is,

$$\text{NEP} = \frac{PV_s}{V_n}, \tag{6.3}$$

where NEP is the noise-equivalent power, V_s is the voltage intensity of the signal, V_n is the voltage intensity of the noise, and P is the incident light power. The larger the

NEP, the weaker the detection ability; the smaller the NEP, the stronger the detection ability.

Responsivity

The ratio of the output optical power to the input optical power of the detector is the responsivity R, which can be subdivided into voltage and current responsivities. The voltage responsivity R_u is defined as the ratio of the output voltage to the incident light power, that is,

$$R_u = \frac{U_s}{P}, \tag{6.4}$$

where R_u is the voltage responsivity, U_s is the output voltage of the photodetector, and P is the incident-light power.

The current responsivity R_i is defined as the ratio of the output current of the photodetector to the incident-light power, as follows:

$$R_i = \frac{I_s}{P}, \tag{6.5}$$

where R_i is the current responsivity, I_s is the output current of the photodetector, and P is the incident-light power.

Spectral Responsivity

The spectral responsivity $R(\lambda)$ is defined as the ratio of the output voltage or current of the detector to the incident light power, when it is illuminated by monochromatic light of wavelength λ.

$$R_V(\lambda) = \frac{V_S(\lambda)}{P(\lambda)} \tag{6.6}$$

$$R_I(\lambda) = \frac{I_S(\lambda)}{P(\lambda)}, \tag{6.7}$$

where $R_V(\lambda)$ and $R_I(\lambda)$ are the spectral responsivities, $V_S(\lambda)$ is the output voltage, $I_S(\lambda)$ is the output current, and $P(\lambda)$ is the power of the incident light.

Frequency Responsivity

The frequency responsivity $R(f)$ is affected by the incident-light frequency and is defined as

$$R(f_\tau) = \frac{R_0}{\left[1 + (2\pi f_\tau)^2\right]^{1/2}}, \tag{6.8}$$

where $R(f_\tau)$ is the responsivity when the frequency is f_τ, and R_0 is the responsivity when the frequency is 0. The time constant τ of the detector is a fixed value, usually determined by the material of the detector and the external circuit.

Detectivity and Normalized Geochemical-Exploration Measures

The detectivity D reflects the sensitivity of the detector and is the reciprocal of NEP:

$$D = \frac{1}{\text{NEP}}, \tag{6.9}$$

where D is the detection degree and NEP is the noise-equivalent power of the detector. The normalized geochemical exploration measure D^* is defined as follows:

$$D^* = D \cdot (A_d \Delta f)^{1/2}, \tag{6.10}$$

where D^* is the normalized geochemical-exploration measure, D is the detectivity, A_d is the area of the detector, and Δf is the amplifier bandwidth.

Photodetector Types

Source Noises

According to the different emission and modulation mechanisms of the system, source noise can be divided into laser light source noise and noise in LED-modulated signal light in visible light communication using LED as the light source. When the communication signal modulates the laser emission, the source noise can be roughly divided into two parts: the inherent thermal noise of the laser itself, and the distortion of the laser emission compared to the modulated signal. The study of the above noise/distortion of lasers has started since the invention of lasers in the 1960s. In 1966, Pauwels derived the series expressions for the amplitude and phase noise of lasers from the Van del Pol equation of quantum mechanics, but their expressions were too complex [2]. In the same year, Leeson obtained the spectral approximation to 1/f noise from a simpler spectral model [3]. In 1970, Ziel investigated the scattering grain noise model for GaAs lasers [4], and the results were widely quoted. In 1982, Harder et al. [5] solved the semiconductor rate equation to obtain the light intensity and spectral undulation of a semiconductor laser and obtained the laser's general equivalent circuit of the lase. In 1989, Petermann gave an exhaustive summary of the various types of noise in lasers [6]. Due to the complex form of the solution of the rate equation, it is often necessary to describe it by the series method, and this signal nonlinear distortion is also a kind of noise affecting the communication system. In 1992, Kuo conducted theoretical analysis and experimental research on the influence of gain saturation, relaxation oscillation, spatial hole burning, and other factors on the nonlinear noise of LD [7]. In 1994, Bihan et al. [8] used perturbation method and Bessel function method to solve the rate equation

and derived the expression of LD nonlinear intermodulation distortion, and the results show that the FM signal distortion is more obvious than the AM signal. In 1997, Chai et al. [9] analyzed the effect of phase noise of semiconductor laser on the characteristics of high-speed optical fiber communication system, the results show that the dispersion characteristics of optical fiber make the phase noise of laser will be transformed into intensity noise at the receiving end, and the sensitivity of the optical receiver deteriorates and shows the "saturation" phenomenon on the BER curve. In 2002, Fukuda et al. [10] elucidated experimentally and theoretically the reason for the increase of the residual spectral linewidth during the degradation of the device, based on the multi-quantum-well-distributed feedback lasers, and proposed a correlation between the 1/f noise and the degradation of the semiconductor lasers. In the same year, Lawrence conducted a detailed study on nonlinear distortion in LDs driven by FM signals and showed that factors such as the modulation regime, the modulation frequency, the magnitude of the injected current, and the length of the external cavity affect the nonlinear dynamic distortion of the lasers [11].

In 2006, Yu et al. [12] designed a new type of low-noise fiber laser using a composite cavity structure, which effectively suppressed the intensity noise of the light source. In 2010, Domenico et al. [13] proposed an approximate formula to handle the relationship between laser frequency noise spectrum and laser linear, which can be applied to any noise spectral density. In 2012, Liu et al. [14] studied the effects of laser phase noise on modulation format selection, parameter optimization, and carrier phase estimation performance in coherent fiber optic communication systems. Simulation results showed that when the carrier phase estimation method is used in coherent fiber optic communication systems, the optimal average length of the symbol sequence in the algorithm is inversely proportional to the laser phase noise. In 2015, Mahmoud conducted a detailed study on the impact of LD noise and distortion in Radio Over Fiber on the system, pointing out that intermodulation distortion is more severe than harmonic distortion during laser modulation [15]. In 2016, Chen et al. [16] derived the expression of nonlinear intermodulation distortion in lasers using the Bessel function, studied the impact of nonlinear intermodulation distortion on the carrier intermodulation noise ratio and bit error rate performance of the system, and provided the selection of the optimal modulation index of the system and the corresponding relationship with the nonlinear coefficient. In 2016, Chen proposed a novel nonoptical heterodyne detection method based on subcarrier modulation and conducted system simulation experiments under additive noise, multiplicative noise, and mixed noise, providing experimental basis for the application of this nonoptical heterodyne detection method [17]. In 2017, Song et al. [18] qualitatively analyzed the phase noise of fiber lasers with different pump powers, seed source powers, and wavelengths using power spectra and integral spectra. The results showed that the higher the pump power, the greater the proportion of low-frequency phase noise; for different seed source powers, the proportion of phase noise in the test frequency band is basically at the same level; and the proportion of phase noise in the high-frequency range varies for different seed wavelengths tested, with the highest proportion occurring when the seed wavelength is 1560.48 nm. In 2019, Bai derived the relationship between laser linewidth,

frequency noise power spectral density, and phase noise power spectral density. A method for calculating laser linewidth by measuring laser phase noise was obtained, and numerical simulation and characteristic analysis were conducted on the output laser spectral line of the laser [19]. In 2022, Du et al. [20] proposed and conducted a theoretical study aimed at exploring the noise codriving chaotic synchronization phenomenon based on a three-stage-distributed Bragg reflection semiconductor laser.

Photomultiplier Tubes

Working Principle

The principle of the photomultiplier tube is illustrated in Fig. 6.5. The electron-focusing system includes a focusing pole D, photocathode K, and anode a, from which the incident light enters into the interior of the photomultiplier tube. Under the action of the photocathode, the incident light will converge to form a beam of light that strikes the first multiplier pole. Under the excitation of the first multiplier pole, the reflected beam produces a large number of secondary electrons, which are driven by an electric field to the second multiplier pole, producing more secondary electrons; this continues to D_{10}.The last incident beam passes through D_{10}. The pole multiplication reaches the anode, and the output photocurrent at load $R_L V$ is formed on V_0.

Research Progress

In 1972, Shun et al. [21] developed several new types of photocathode materials and analyzed the corresponding processing technology. A new secondary-emission technology was used in the photomultiplier, which improved its gain characteristics.

In 1989, Li [22] discovered how the polarization effects of the grating and photomultiplier tubes varied with the wavelength. The experimental results showed

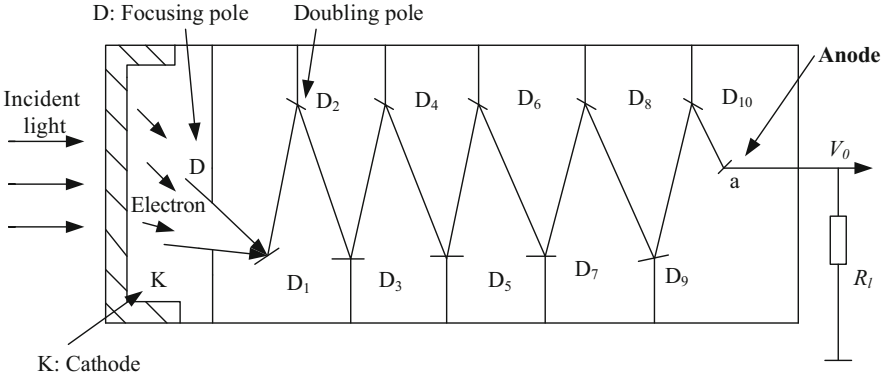

Fig. 6.5 Schematic diagram of a photomultiplier tube

that the polarization effect of the grating was greatly affected by the change in wavelength, in the range of 420–740 nm. Therefore, the polarization effect of the grating must be considered when measuring the polarization.

In 2000, Chow [23] analyzed basic photomultiplier-control technology and its improvements. Through the continuous improvement of basic devices, a photomultiplier tube can be used as a weak light-detection device.

In 2004, Guo et al. [24] discussed the noise sources of photomultiplier tubes, including loose-particle, thermal, generation-compound, and 1/f noise, and established the corresponding noise model.

In 2014, Chowdhuri et al. [25] analyzed the spectral detection based on a photomultiplier array; the detection method had a fast time response of 10 μs and a spatial resolution of 3 cm.

In 2015, Maltseva et al. [26] used photomultiplier tubes to detect Cherenkov light; the detector's spatial resolution reached 3 m for 20 m long fibers. In addition, the resolution could be improved by optimizing the parameters of the optical fiber and photomultiplier, and the spatial resolution of the detector reached 0.5 m.

In 2016, Chen et al. [27] analyzed the performance of a silicon photomultiplier tube, designed a nuclear-radiation detector, developed a radiation-measurement probe, and tested its radiation performance. This detector has some reference value for the design of nuclear-radiation detectors.

In 2017, Zhao et al. [28] developed a one-dimensional single-photon position-sensitive silicon photomultiplier tube, with a single-photon position resolution of 393.4 μm. It improved from 393.4 μm to 56.2 μm when the number of photoelectrons was increased from one to seven.

In 2018, Takahashi et al. [29] analyzed the detection principle of low-intensity light and estimated the average signal generated by a single photoelectron, using the fact that photoelectrons conform to the Poisson distribution.

In 2019, Elorrieta et al. [30] described the detailed characteristics of a 3-inch photomultiplier, including the dark count rate, probability of associated pulses, timing characteristics, gain, and temperature dependence of the peaks and valleys. The effect of conductive objects near the photocathode on photomultiplier noise was also shown.

In 2020, Sun et al. [31] designed a system consisting of ultraviolet (UV) light and highly sensitive photomultiplier tubes to simulate very cloudy harbor water. It transmitted data at a rate of 85 Mbit/s using on–off control modulation and established a non-direct-looking link with a transmission distance of 30 cm.

In 2021, Ning et al. [32] investigated the performance of devices under various light intensities and photomultiplier-tube gains and proposed a small-volume receiver-control system and related adaptive-control strategy to improve stability and reliability.

Table 6.1 summarizes the relevant properties of photomultiplier tubes. Photomultiplier tubes have applications in the ultraviolet communication field, as well as weak optical-signal detection.

Table 6.1 Research progress of photomultiplier tubes

Researcher	Year	Development
Shun	1972	Improved the gain characteristics of photomultiplier tubes
Li	1989	Grating polarization effect must be considered in polarization measurement
Zhou	2000	Photomultiplier tubes can be used as weak light-detection devices
Guo	2004	Discussed the sources of noise and built a noise model
Maltseva	2015	Detector spatial resolution reached 3 m
Chen	2016	Developed nuclear-radiation detector
Zhao	2017	Single-photon position resolution is 393.4 μm
Takahashi	2018	Conversion of photons to photoelectrons
Elorrieta	2019	Effect of conductive objects near the photocathode
Sun	2020	Non-direct-looking link with a data rate of 85 Mbit/s
Ning	2021	Small-volume receiver-control system

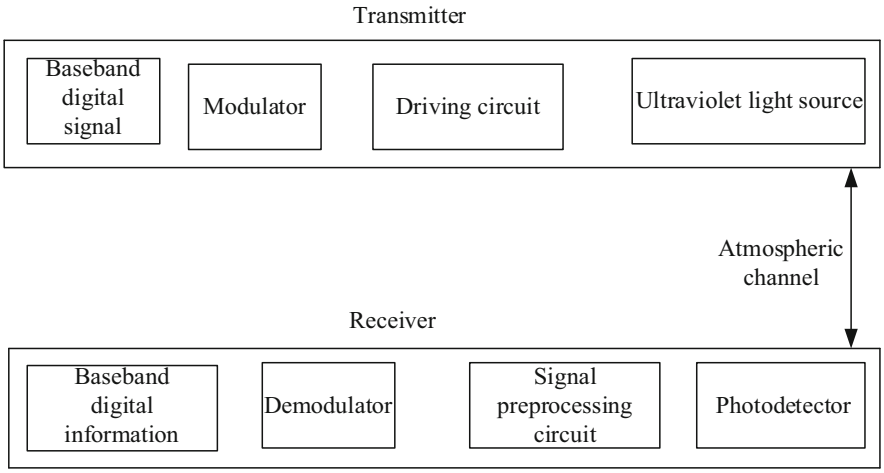

Fig. 6.6 Structure of a UV communication system [33]

Typical Application Scenarios

Figure 6.6 shows the structure of a UV communication system that consists of transmitting, receiving, and atmospheric channels [33]. The transmitting component modulates the original electrical signal and transforms it into a signal suitable for transmission in the channel. The signal is disrupted by interference in the atmospheric channel, and the receiving part must recover the original signal from the received disrupted signal.

The receiving part is composed of an ultraviolet photomultiplier tube, preprocessing circuit, demodulation module, and beacon module. The ultraviolet detector collects the ultraviolet signal and converts the corresponding optical signal into an electrical signal. The preprocessing circuit amplifies and filters the electrical signal, and the demodulation module demodulates it and converts it into a baseband

digital signal. The UV photomultiplier is currently the most ideal UV detector. It has been widely used for nondirect UV communication because of its large detection area, high gain, and low dark current.

Avalanche Photodetector

Working Principle

An avalanche photodetector is based on an avalanche photodiode (APD). Figure 6.7 shows a schematic diagram of the avalanche breakdown. When incident light illuminates the diode surface, the light is absorbed by the P-N junction to form a photocurrent. The photocurrent is affected by the reverse bias and increases with the increase in reverse bias. When the reverse bias is continuously increased, the photocurrent exponentially increases. At this time, the so-called "avalanche" phenomenon occurs.

Research Progress

In 1980, Yang et al. [34] studied avalanche-photodiode technology and proposed a new avalanche photodiode that had high gain and low noise and could be used for long-wavelength detection.

In 1990, Watkins et al. [35] observed the characteristics of laser-induced electrical failures in biased silicon avalanche photodiodes. When monitoring current–voltage characteristic changes, two types of changes were observed: The first was a large increase in leakage current, which can be modeled by introducing defects into the depletion region through deep melting transients. The second type was a catastrophic failure, in which an electrical short circuit occurred in the device after irradiation; it can be modeled by excessive current density in the photodiode junction.

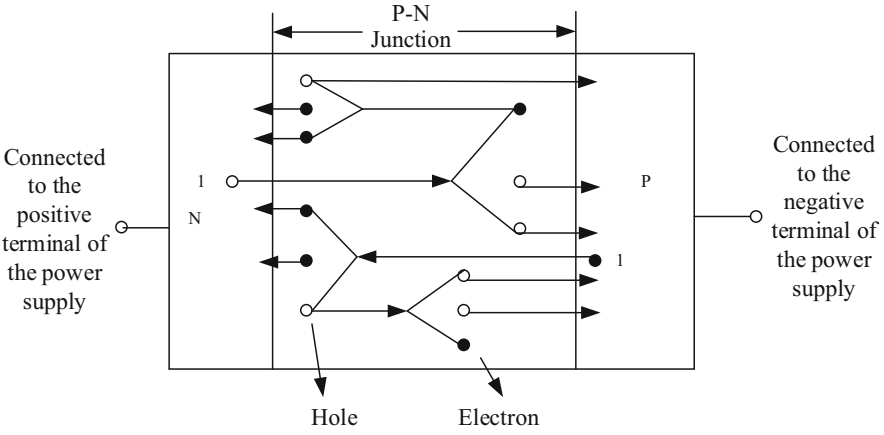

Fig. 6.7 Schematic diagram of the avalanche breakdown

In 1996, Li et al. [36] designed a superlattice avalanche photodetector. The optimal structural parameters were obtained as follows: The thickness of the i-Si avalanche zone was 1.8 μm–2 μm. The carrier concentration in the p-Si zone was 1.018 cm^{-3}, and the thickness was 17 nm. The total thickness of the superlattice was 340 nm. The detector could operate in the range of 1.3 μm–1.6 μm.

In 2005, Ng et al. [37] concluded that collision ionization in the InGaAs absorption layer increased the excess noise in the InP avalanche photodiode. Moreover, strict limits needed to be imposed on the doping in the charge-control layer if the avalanche noise was to be minimized.

In 2009, Guo et al. [38] used passive-suppression technology to determine that dark current does not reflect Pass-through characteristics, which is an obvious difference between photocurrent and dark current. Through the above research, it was concluded that to improve the signal-to-noise ratio of a single-photon detector, the through-through characteristics could be used to properly select the reverse-bias voltage of an avalanche photodiode in Geiger mode.

In 2010, Chitnis et al. [39] investigated a compact readout circuit that could be integrated within a single single-photon avalanche detector. The avalanche process in photodetectors can be suppressed by using the smallest transistor size.

In 2011, Zhang et al. [40] analyzed the scattered-particle noise and 1/f noise of avalanche photodiodes and established their signal-to-noise ratio (SNR) model.

In 2012, Guo et al. [41] studied the relationship between dark noise and the detector temperature. The results showed that when the temperature was reduced from 60 °C to −40 °C, the noise-equivalent power decreased by one order of magnitude. If the cooling, spatial filtering, and spectral filtering methods were combined, the sensitivity of the detector increased by 7.7 times.

In 2013, Adamo et al. [42] analyzed novel silicon photomultiplier tubes manufactured on silicon p-type substrates; they could be used as sensitive power meters for low-photon fluxes.

In 2014, Youn et al. [43] studied an 850 nm photoelectric integrated-circuit receiver and found that the signal-to-noise characteristics of avalanche photodiodes depended on the reverse-bias voltage.

In 2015, Chen et al. [44] studied a low-voltage germanium-waveguide avalanche photodetector with a gain × bandwidth product higher than 100 GHz and developed a photon receiver based on this photodetector. Using the bit-error rate measurement, the avalanche gain was 6 and the sensitivity was improved by 5.8 dB at a −5.9 V bias.

In 2016, Goykhman et al. [45] studied a silicon plasma Schottky photodetector and achieved a responsivity of 0.37 A/W with a reverse bias of 3 V.

In 2017, Yin et al. [46] simulated an avalanche photodetector using benzocyclobutene as a bonding-layer material, with a detection efficiency of 96.7%.

In 2018, Jukic et al. [47] discovered that the excess noise of avalanche photodiodes was related to the avalanche gain. By analyzing the structure of the avalanche photodiode, it was found that this correlation could be suppressed by modulation doping.

In 2019, Huffaker [48] proposed a new avalanche photodiode consisting of a vertical InGaAs array that could be used for single-photon detection, greatly reducing the avalanche volume and number of filling traps.

In 2020, Zhou et al. [49] studied a linear array of 1 × 64 highly uniform 4H-SiC avalanche photodiodes for UV detection; it achieved a highly uniform breakdown voltage and a fluctuation of less than 0.5 V.

In 2021, Eid et al. [50] studied the pulse broadening and signal-fiber bandwidth of a silicon-doped germanium-fiber link in terms of the temperature variation and found that the bit-error rate of the silicon avalanche photodetector at the receiving point was related to the temperature.

In 2022, Li et al. [51] studied the excess noise of avalanche photodiodes, analyzed two noise-measuring methods, including the direct-power measurement method and phase-sensitive detection method, and also analyzed and discussed their advantages and disadvantages. On this basis, three methods of reducing the excess noise were obtained: selecting materials with a low impact-ionization coefficient ratio, reducing the thickness of the multiplier layer, and using APD impact-ionization engineering.

Table 6.2 shows the development of avalanche photodiodes. The gain and sensitivity of the detector are discussed in the above literature. A noise model of the avalanche photodetector was established by analyzing the source of the noise, noise-suppression techniques were studied, and the InGaAs/InAlAs detector as a mature material was further analyzed.

Table 6.2 Research progress on avalanche photodiodes

Researcher	Year	Development
Yang	1980	APDs can be used for long-wavelength detection
Watkins	1990	Observed the characteristics of laser-induced electrical failures
Li	1996	Superlattice avalanche photodetector is studied and optimized
Ng	2005	Strict restrictions on the doping of charge-control layers
Guo	2009	Proper selection of the reverse bias of an avalanche photodiode
Chitnis	2010	Avalanche process in the photodetector is suppressed
Zhang	2011	SNR models of granular noise and 1/f noise are established
Guo	2012	Sensitivity of the detector is improved by 7.7 times
Adamo	2013	Used as a sensitive power meter for low photon flux
Youn	2014	SNR depends on the reverse bias voltage
Chen	2015	Sensitivity is improved by 5.8 dB
Goykhman	2016	Responsivity of 0.37 A/W was achieved
Yin D	2017	Detection efficiency reached 96.7%
Jukic	2018	Excess noise can be suppressed by modulation doping
Huffaker	2019	Vertical InGaAs arrays can be used for single-photon detection
Zhou	2010	High uniform breakdown voltage is achieved
Eid	2021	Bit-error rate is temperature-dependent
Li	2022	Excess noise of avalanche photodiodes is studied

Typical Application Scenarios

Figure 6.8 shows the principle block diagram of a detection and receiving system. A weak optical signal that is diffusely reflected back is converted into an electrical signal by an avalanche photodetector and amplified by an amplifier. Then, it enters a comparator for comparison. The bias control circuit provides the avalanche photodetector with the corresponding bias voltage, giving the detector an optimal multiplier factor under the optimal bias voltage. The voltage amplitude control adjusts the output-signal amplitude. Adjusting to the optimal amplitude can reduce the blind area of the ranging system. The threshold-circuit comparison voltage is discriminated to output a useful signal level. The comparison voltage must be simultaneously lower than the signal voltage and higher than the noise voltage. Finally, further processing is conducted using the oscilloscope.

PIN Photodetectors

Working Principle

The PIN detector separates the p-type region from the n-type region by adding a lightly doped thin layer in the middle of the P-N junction. The structural diagram of the PIN diode is shown in Fig. 6.9. The junction capacitance of the PIN detector is very small, and the depletion-layer width of the P-N junction is directly related to the

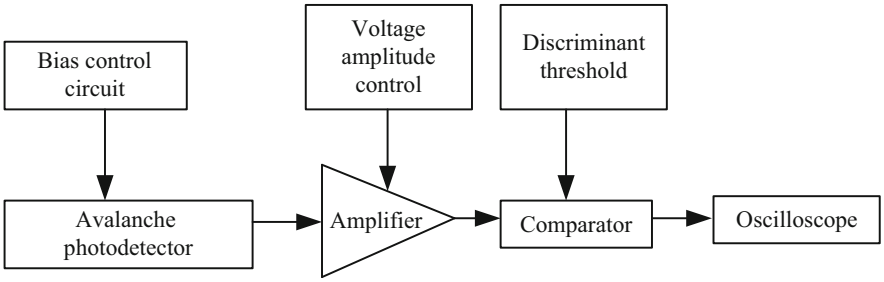

Fig. 6.8 Block diagram of the receiving system

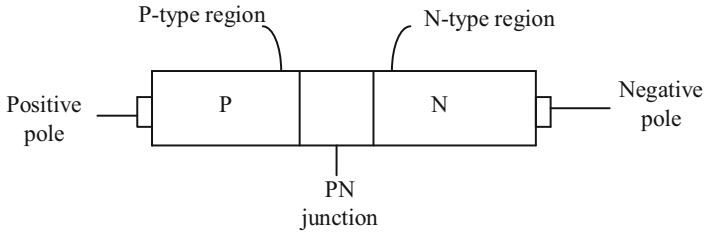

Fig. 6.9 Structural diagram of a PIN diode

reverse bias. When the reverse bias increases or decreases, the depletion-layer width increases or decreases correspondingly. The PIN detector structure is simple.

Research Progress

In 1986, Shu B researchers [52] successfully manufactured a silicon PIN photodetector based on high-resistance monocrystalline silicon using a mature semiconductor planar process.

In 1992, Zhang et al. [53] developed a state-space model for PIN photodetectors. This model produced the detector's time-domain and frequency-domain responses to any form of optical excitation, including terminal, uniform, and exponential illumination. Transmission time limits and circuit RC time constants were included in the model.

In 1997, Zhang et al. [54] used a coaxial package for the InGaAs PIN photodetector chip to measure the C–V characteristics and transient response of the coaxial package device. The results showed that the transient response of the device was greatly improved; the rise time was reduced from 85 ps to less than 25 ps, the half-height width was reduced from 210 ps to 85 ps, the capacitance was reduced by approximately 0.4 pF, and the bandwidth was increased to more than 6 GHz.

In 2004, Jutzi et al. [55] investigated a SiGe PIN photodetector and achieved an optical responsiveness of 160 mA/W at 1300 nm.

In 2010, Giannopolous et al. [56] designed a vertical-cavity surface-emitting laser that was integrated with a PIN photodetector monolith for optical-position sensing. The design was integrated into a silicon platform to form a microsystem. By using a metal grating as a position meter, the sensor microsystem could measure the difference in the reflected power of the grating as it traveled parallel to the sensor.

In 2011, Shao et al. [57] studied the growth and preparation of a back-lit AlGaN/GaN PIN solar blind UV photoelectron detector. The peak responsivity of the photodetector was about 0.055 A/W at 270 nm at a 2.5 V reverse bias, and the dark-current measurement of a 1500 μm diameter device was approximately 25 pA at a 0.3 V bias.

In 2012, Guan et al. [58] analyzed various photoelectric-conversion circuit noises where the PIN detector was located and proposed a method to reduce the noise in the photoelectric conversion circuit to improve the signal-to-noise ratio and measurement accuracy.

In 2014, Wu et al. [59] studied the threshold characteristics of a PIN detector in optical wireless communication. The experiment showed that the detector reached the depth saturation at a 1064 nm wavelength, resulting in serious intercode crosstalk; thus, it could not meet the communication indicators.

In 2015, Chaudhari et al. [60] proposed a low-cost, low-temperature process with precise-thickness films, which was suitable for the low-cost industrial manufacturing of PIN-based detectors.

In 2016, Rouse et al. [61] manufactured a Ge-based PIN detection device on 300 mm silicon wafers using high-throughput, large-area complementary metal-oxide semiconductor technology.

In 2018, Xu et al. [62] used a laser light source with a 10 ns pulse width and a PIN detector for photoelectric conversion. When the applied bias voltage was 89.449 V, the output current signal needed to be amplified by a transresistance amplifier, and the amplified voltage amplitude reached −3.7 V.

In 2019, Shu et al. [63] studied the influence of the main noise sources of a 10 Gbit/s PIN photodetector circuit on the output current signal using an adaptive-filtering algorithm and a peak-pulse median removal algorithm. The results showed that the above denoising method could effectively reduce the measurement error of the output current, improve the measurement accuracy, and increase the stability.

In 2021, Wang et al. [64] designed a highly responsive silicon-based PIN detector with a 4.1 mm × 13.8 mm surface area and a 420 μm thickness. The photocurrent signal was extracted through a ring aluminum electrode, and the detector had a response of 0.6 A/W at a constant laser light source with an 860 nm wavelength.

In 2022, Xiao et al. [65] designed a high-speed monolithic PIN photodetector based on InP and integrated it with a multi-quantum-well semiconductor optical amplifier. The chip allowed for the separate design of the multi-quantum-well semiconductor optical amplifier and PIN photodetector. The PIN photodetector was manufactured with a 300 pA dark current at 3 V.

Table 6.3 illustrates the development of the PIN detector. The above literature mainly discusses the industrial structure and preparation of PIN detectors and their corresponding noise models, as well as the related applications of PIN detectors in optical wireless communication.

Typical Application Scenarios

Owing to the small dynamic range of traditional optical-power detection and the errors in amplification and switching, a weak optical signal is amplified according to

Table 6.3 Research progress of PIN photodetectors (PD)

Researcher	Year	Development
Zhang	1992	Established a state-space model of the PIN photodetector

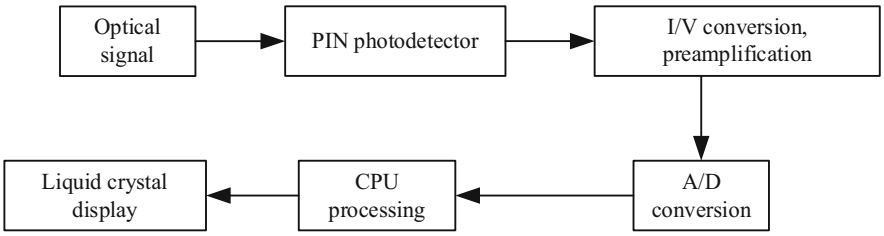

Fig. 6.10 Schematic diagram of an optical power meter

the response characteristics of a PIN photodiode, and a single-chip microcomputer is used for data-correction processing. When it is finally combined with liquid-crystal display (LCD) technology, an optical power-detection meter can be produced.

The basic working-principle block diagram of the optical power meter is shown in Fig. 6.10. The optical signal first passes through the PIN photodetector, which converts the optical signal into an electrical signal; then, the electrical signal goes through an I/V transformation and preamplification processing. The analog signal obtained after processing is converted to digital; the digital signal represents the power size. Then, the CPU processes and analyzes the data. Finally, the power size is displayed on the LCD.

Four-Quadrant Detectors

Working Principle

Following Cartesian-coordinate requirements, diodes with the same performance are placed in the four quadrants, and the detector formed by such a combination is called a four-quadrant detector. A very narrow interval exists between the four quadrants, which is called the dead zone. The detector's detection ability is affected by the dead zone; therefore, the dead-zone area should be reduced as much as possible when making the detector.

Figure 6.11 shows the surface structure of the four-quadrant photodetector. The incident light irradiates the surface of the circular area in the figure, which is called the sensitive surface. The sensitive surface is divided into four parts, namely, A, B, C, and D, and the corresponding areas of these four parts are S_A, S_B, S_C, and S_D, respectively. The corresponding electrodes inside each of these four parts will generate impedance currents I_A, I_B, I_C, and I_D, respectively.

As the incident beam moves, the spot on the detector's surface moves with it, so the true area of light in each quadrant changes, as does the intensity of the light received. The lateral and longitudinal offsets of the light can be determined by the amount of current generated. The formulas for determining the spot position by the area of light received are as follows:

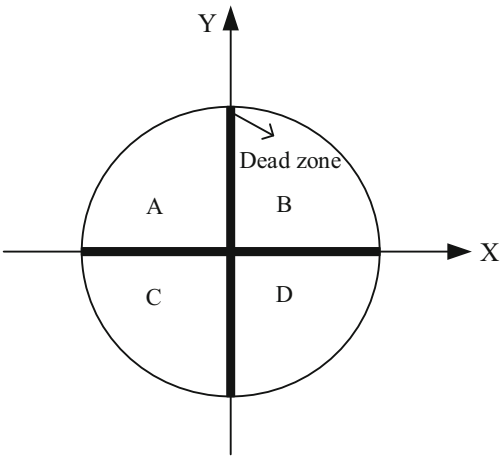

Fig. 6.11 Four-quadrant detector surface-structure diagram

$$\sigma_{\mathrm{x}} = \frac{(S_A + S_D) - (S_B + S_C)}{S_A + S_B + S_C + S_D} = \frac{(I_A + I_D) - (I_B + I_C)}{I_A + I_B + I_C + I_D} \tag{6.11}$$

$$\sigma_y = \frac{(S_A + S_B) - (S_C + S_D)}{S_A + S_B + S_C + S_D} = \frac{(I_A + I_B) - (I_V + I_D)}{I_A + I_B + I_C + I_D}, \tag{6.12}$$

where S_A, S_B, S_C, and S_D are, respectively, the corresponding spot areas of the four quadrants; I_A, I_B, I_C, and I_D are, respectively, the impedance currents generated by the corresponding four quadrant electrodes. σ_x and σ_y are the calculated values for the X and Y axes, respectively, which can be used to analyze the position information of the light spot on the target plane.

Research Progress

In 1979, researchers [66] designed a quadrant detector with a new structure. A P-N junction was used for isolation on the same silicon chip. In addition, a quadrant detector was successfully developed using a four-quadrant patterned oxidation-mask diffusion process.

In 1996, Feng et al. [67] discussed some of the key factors involved in optical roaming using a four-quadrant photodetector, such as the error-data extraction and target-spot size on the active quadrant of the photodetector, in search of more flexible software and hardware design methods.

In 2002, Wang et al. [68] proposed a method to improve the detection accuracy of the high-point position. A Gaussian spot was used as the incident-light model to analyze the solution relationship between the actual position of the spot and the output signal of the four-quadrant detector. Then, the output current signal of the detector was amplified through an analog circuit, and the output voltage signal with noise was digitally filtered. The results showed that the maximum spot-position detection error of this method was only 0.0277 mm, and the root mean square error

was 0.0065 mm, when the four-quadrant detector was in a high-background noise environment.

In 2004, Kuang et al. [69] determined the offset of the two directions of the light spot by measuring the change in the position of its centroid from the laser beam.

In 2005, Chi et al. [70] analyzed the noise of a four-quadrant infrared detector, including loose-particle noise, thermal noise, generation-compound noise, 1/f noise, and the cause of the noise formation.

In 2010, Xin et al. [71] analyzed the factors affecting the tracking accuracy of a four-quadrant detector, including spot size, spot location, and detector noise. The analysis results showed that when using the commonly used four-quadrant centroid algorithm, it was necessary to adopt an appropriate optical system and signal-detection circuit to achieve high-precision tracking-error detection.

In 2013, Yang et al. [72] made a detailed analysis of the dead zone of a four-quadrant detector and showed the influence of the dead zone on the detection sensitivity; the larger the dead zone area, the greater the impact.

In 2014, Schalkwyk et al. [73] made a forward-looking intrinsic day-blind UV four-quadrant Schottky detector based on AlGaN with a Schottky barrier height of 1.22 ± 0.07 eV.

In 2016, Tian et al. [74] proposed an optical-system design method that controlled the spot-size design on a four-quadrant detector by adjusting the entry/exit pupil ratio of the nonfocal system, according to the characteristics of inter-satellite laser communication. The optical distortion, spot pattern, and circumferential energy were analyzed and evaluated. The focal-free system was proved to be applicable to a beacon system for tracking and detection.

In 2018, Grajower et al. [75] used a new silicon-based plasma four-quadrant photodetector to operate in the short-wave infrared band; it could accurately track various waist beams at telecommunication wavelengths.

In 2019, Wang et al. [76] proposed a new polynomial-fitting algorithm, using a circular spot with Gaussian energy as the incident-light model. When the radius of the incident spot was 0.5 mm, within a [−0.5 mm, 0.5 mm] detection range, the new fifth-order polynomial-fitting algorithm was adopted, and the maximum error was 1.353 μm. The root-mean-square error was 0.4596 μm, which improved the accuracy of the four-quadrant detector.

In 2020, Liu et al. [77] designed a four-quadrant detector with a five-level amplifier circuit that could be used for low-light detection. The magnification could be adjusted according to the power of the incident light, and the centroid position of the light spot could be intuitively judged. The results showed that the four-quadrant detector had a high resolution, low static noise, and a simple design.

In 2021, Safi et al. [78] studied a surface-to-air free-space optical link for hovering unmanned aerial vehicles (UAVs), and a four-quadrant photodetector array was used at the optical receiver to mitigate the adverse effects of hovering fluctuations by expanding the receiver's field of view.

Table 6.4 shows the development of the four-quadrant photodetector. The above literature introduces the application of the four-quadrant detector to position

Table 6.4 Research progress of four-quadrant detectors

Researcher	Year	Development

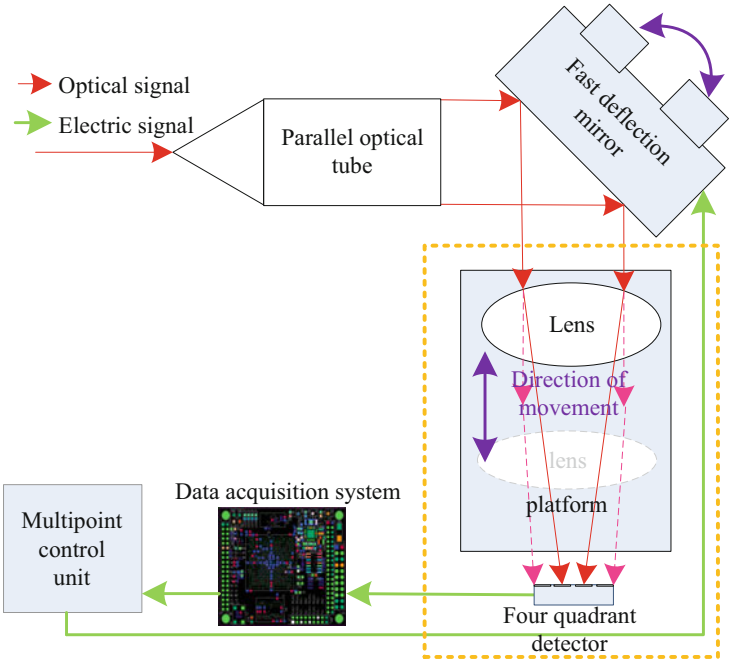

Fig. 6.12 Block diagram of a spot-tracking system

detection and laser collimation, further analyzes the factors that affect the detection accuracy and the causes of related noise, and expounds the improvement in sensitivity of the four-quadrant detector.

Typical Application Scenarios

Figure 6.12 shows a block diagram of a spot-tracking system, based on a four-quadrant detector and fast deflection mirror. The light signal first passes through the

parallel optical tube, and the fast deflection mirror reflects the beacon light from there onto the lens. The lens, with an entry pupil diameter of H, projects the light spot onto the four-quadrant detector used for defocusing.

The data-acquisition system processes the electrical signal and sends it to the multipoint control unit, which controls the deflection angle of the fast deflecting mirror to adjust the incident direction of the optical path, forming a closed-loop tracking system. The mobile electric platform under the lens can control the size of the light spots, and then detect the root mean square error of the infinite integral algorithm under different light spots.

Quantum-Dot Infrared Detectors

Working Principle

The quantum-dot infrared detector is composed of periodic composite layers of quantum dots. Figure 6.13 shows a schematic diagram of the structure of the quantum-dot infrared detector. Each quantum dot in the composite layer has a large number of boundary states, which can receive more electrons. When infrared light is incident on the photosensitive region of the detector, electrons transition from the ground state to the excited or continuous states, which changes the conductivity of the detector, which finally detects the infrared light.

Research Progress

In 1999, Sheng et al. [79] analyzed the noise of a quantum-well infrared detector, including loose-particle noise, thermal noise, generation-compound noise, and 1/f noise, and explored the negative impact of each noise on the detector.

In 2006, Zhao et al. [80] experimentally verified an AlGaAs/GaAs multi-quantum-well infrared detector and showed that the dark current did not appear to change with the temperature when the temperature was less than 40 K. When the

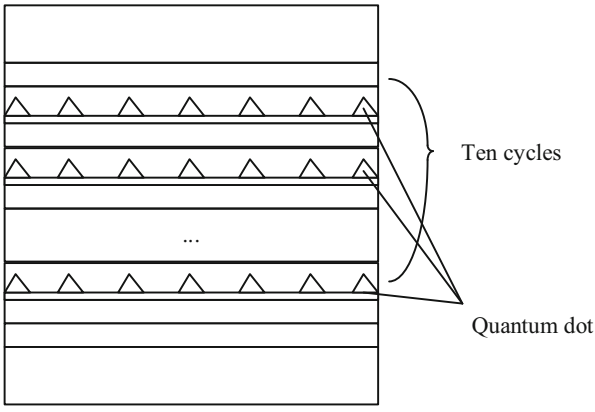

Fig. 6.13 Schematic diagram of the structure of a quantum-dot infrared detector

temperature was higher than 40 K, the dark current increased rapidly with an increase in temperature.

In 2010, Hill et al. [81] proposed a method to extend the detector-cutoff wavelength by combining self-assembled InSb quantum dots with the detector's active region. This extended the cutoff wavelength from 4.2 m to 6 m and exhibited an infrared response at temperatures up to 225 K.

In 2011, Chien [82] developed a model using a quadrant detector at room temperature to optimize a photodetector based on its structure, and the photoelectron capture and transit processes were studied using Monte Carlo simulations.

In 2012, Gustafsson et al. [83] studied quantum dots based on InSb. These quantum dots were used as active materials for a photon detector, which reduced the detector noise.

In 2013, Liu et al. [84] proposed a noise model for a quantum-dot infrared detector. They studied the dark current of the detector, considering the influence of micron-scale and nanoscale electron transports on the excitation energy, and then deduced the noise model.

In 2014, Kim et al. [85] proposed and analyzed a novel detector structure for pixel-level multispectral infrared imaging and then studied the device performance of a raster-integrated quantum-dot well photodetector under back-illumination. By adjusting the grating parameters, a wide range of spectral responses was obtained.

In 2015, Srinivasan et al. [86] used molecular-beam epitaxy to investigate the fabrication of 20-layer silica-doped InAs dots in the structure of quantum-dot infrared photodetector devices.

In 2016, Karow et al. [87] realized a monolithic integrated circuit of a laser and detector, pushed the research on microscale sensor technology to the low-photon quantum limit, and paved the way for on-chip photoelectric-feedback experiments.

In 2017, Kim [88] studied the effects of micron and nanoscale external electrons and electron transport on the noise of quantum-dot infrared detectors by computational simulation. The results showed that under a 2545 kV/cm applied electric field, the noise increased with an increase in the applied electric field and temperature. When the control temperature was less than 80 K, the noise increased very quickly. When the control temperature was greater than 80 K, the noise increased more slowly. Thus, it could be concluded that the lower the temperature, the more obvious the impact of noise on an applied electric field.

In 2018, Wang [89] established a model and algorithm that could represent the dark current of quantum-dot infrared detectors. The model was simplified by combining the actual detector situation. It was found that the temperature, quantum-dot density, and side dimension affected the dark current of the detector.

In 2019, Baira et al. [90] evaluated the size and shape of self-organizing GeSn/Ge quantum dots and found that larger quantum dots with higher aspect ratios might have higher oscillator strengths and longer radiation lifetimes.

In 2020, Gansen et al. [91] investigated a 1/f noise source in a quantum-dot field-effect transistor and produced a 1/f noise model.

Table 6.5 shows some of the progress in quantum-dot infrared detectors. The above studies investigated the influence of the dark current and temperature on noise

Table 6.5 Research progress of quantum-dot infrared detectors

Researcher	Year	Development
Sheng	1999	Loose-particle noise and thermal noise were analyzed
Zhao	2006	Dark current increases rapidly with the increase of temperature
Hill	2010	Extended the detector cutoff wavelength
Chien	2011	Investigated photoelectron capture and transit processes
Lau	2013	Noise model of a quantum-dot infrared detector is proposed
Kim	2014	Wide range of spectral responses was obtained
Karow	2016	Realized a monolithic integrated circuit of laser and detector

Gansen	2020	Noise model of 1/f noise is derived

generation and the influence of noise on detector performance by analyzing the quantum-dot junctions of quantum-dot infrared detectors.

Bottlenecks and Breakthroughs

Although gallium nitride (GaN), indium antimonide (InSb), mercury cadmium telluride (HgCdTe), and other bulk semiconductor materials can broaden the spectral detection range of CMOS detectors, these bulk semiconductor materials are not compatible with silicon-based CMOS detectors and require flip bonding and other complex processes. This results in a high cost and low pass rate in the detector-manufacturing process. In addition, ultraviolet and infrared photon energies are very different, and cross-band coupling is extremely difficult.

The solution properties of colloidal quantum-dot materials can be used to pattern a quantum-dot thin film after the quantum-dot infrared material is coupled to a CMOS readout circuit. This allows direct lithography to be used in the fabrication of multiband wide-spectrum detectors from ultraviolet to infrared by plane coupling. Using lead sulfide (PbS) quantum dots, the team of Professor Jiang Tang from Huazhong University of Science and Technology has fabricated near-infrared quantum-dot chips and demonstrated good imaging performance under 970 nm infrared irradiation.

To overcome the band bottleneck, Professor Xin Tang from the Beijing Institute of Technology proposed the use of mercury telluride (HgTe) and perovskite colloidal quantum-dot materials to broaden the CMOS detection range, improve the detector-manufacturing scale, realize wafer-level processing, greatly reduce the detector production cost, and improve the process pass rate. Because the bulk material band gap is zero, mercury telluride (HgTe) colloidal quantum dots can be used in short-wave infrared, medium-wave infrared, and long-wave infrared detectors.

This breakthrough greatly simplified the complexity of the optical hardware and software of multiband cameras, reduced the cameras' size and weight, and helped realize the microplatform design of multiband cameras. The team used a direct-photolithography process to form colloid quantum dots into a two-color or

multicolor focal plane array and broke through the traditional block semiconductor-material flip-bonding process to complete multicolor detection and detector coupling. In addition, they realized multiband detection and multicolor imaging capabilities in one detector, greatly reduced the production cost of multicolor detectors, and improved the production-process scale and product pass rate.

Typical Application Scenarios

To better use space resources, countries constantly launch satellites and space stations to establish detection sites, all competing to occupy the optimal positions. Space photoelectric systems play a very important role in this respect, because the new quantum-dot infrared detectors have high detection sensitivity, high working temperature, and antiradiation ability. It would be extremely beneficial to apply quantum-dot infrared detectors to space photoelectric systems.

During laser communications between satellite and ground or satellite and satellite, the space environment is complicated because of the long transmission distance, which mainly causes two problems: The first is that the intensity attenuation intensifies as the communication distance increases. The second is the harsh space environment, which requires photoelectric devices to have better temperature characteristics and radiation-resistance performance. A quantum-dot infrared detector not only has a high working temperature and radiation resistance but also has advantages in structure and volume. Therefore, it has broad application prospects in space environments.

Balanced Detectors

Working Principle

Figure 6.14 shows the principle diagram of a balanced detector receiving coherent light [92]. When the local light and signal light fully meet the coherence conditions, the light field interferes and the photodetector converts the light to an electrical

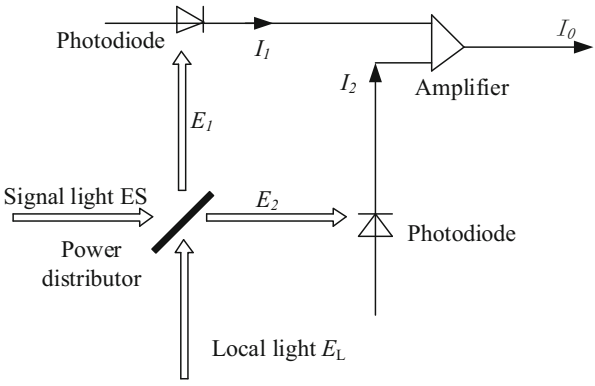

Fig. 6.14 Block diagram of a coherent-light-receiving balanced detector [92]

signal. The signal light is represented by E_S, and the local oscillator light is represented by E_L. Assume that the power divider is an ideal device, that is, linear, symmetrical, and lossless:

$$\begin{bmatrix} E_1 \\ E_2 \end{bmatrix} = \exp(j\psi_r) \begin{bmatrix} 1 & \exp\left(j\frac{\pi}{2}\right) \\ \exp\left(j\frac{\pi}{2}\right) & 1 \end{bmatrix} \begin{bmatrix} E_S \\ E_L \end{bmatrix}, \tag{6.13}$$

where w_{IF} denotes the reflected phase shift of the power divider, E_S denotes the signal light, and E_L denotes the local oscillator light.

$$I_1(\mathrm{t}) - I_2(\mathrm{t}) = 2\frac{\eta e}{h\nu}\sqrt{P_S P_L}\cos(w_{IF}t + \phi_S - \phi_L), \tag{6.14}$$

where w_{IF} is the frequency of the intermediate frequency signal; ϕ_S and ϕ_L are the phases of the signal light and local oscillator light, respectively; P_S and P_L are the optical powers of the signal light and local oscillator light, respectively; η is the quantum efficiency of the photodetector; e is the amount of charge; h is Planck's constant; ν is the optical frequency; and I_0 is amplified by the amplifier to generate the current. Because the balanced detector can suppress the common-mode signal, the noise is reduced, and the detector sensitivity is improved.

Research Progress

In 2014, Dai et al. [93] designed a set of high-speed balanced-detection systems that achieved coherent detection at different rates. For a 2.5-Gbit/s signal rate, the direct-detection sensitivity reached −26 dBm and the dynamic range was −26–3 dBm. When the local oscillator light was 3 dBm, the sensitivity reached −46.5 dBm and the dynamic range was −46.5–3 dBm.

In 2015, Guo et al. [94] analyzed the output noise of balanced heterodyne detection and established a relevant noise model. The simulation results showed that, compared with the signal-to-noise ratio of common coherent detection, the signal-to-noise ratio of a balanced heterodyne-detection method could be improved by reasonably setting the structural parameters of the detector.

In 2016, Shi et al. [95] designed a coherent-detection test scheme based on the composition of a balanced detector. When the communication rate was 5 Gbit/s, the common-mode rejection ratio was higher than 27 dB. Balanced detection was adopted to achieve coherent demodulation, and the minimum signal optical power was improved by 8 dB compared with single-tube detection.

In 2017, Munshid [96] designed and constructed a heterodyne detector based on photonic crystal fiber and found that the relationship between the wavelength shift and temperature change was linear.

In 2018, Yong et al. [97] estimated the dispersion of coherent optical communication systems based on heterodyne detection and investigated the nonlinear limitations of 10-Gbit/s nonreturn to zero electron predistortion systems by simulation.

In 2019, Zhang et al. [98] designed a balanced detector in a high-speed terahertz time-domain spectroscopy system. Two low-noise photodiodes in series were used

to directly detect the difference in the photocurrents of two laser beams and reduce the detector noise.

In 2021, Hu et al. [99] studied a novel heterodyne detection scheme and compared it to the heterodyne detection of a single-ended photodetector. The new scheme allowed for the use of a simple transmitter structure, reducing the receiver bandwidth to a value far below the sign rate, while preserving the ability to compensate for digital dispersion.

As shown in Table 6.6, the aforementioned literature focuses on the application of balanced detectors in coherent optical communication systems based on heterodyne detection. The structure can suppress the noise, and the noise model of the detectors is obtained simultaneously.

Typical Application Scenarios

The principle of coherent detection is illustrated in Fig. 6.15. The light emitted from the laser acts as a carrier and is modulated by the signal either directly or externally. At the receiving end, the spatial optical signal W_s is coupled into the fiber via a fiber coupler, and the lightwave generated by the local oscillator W_L is superimposed on the received signal in the mixer, producing an intermediate frequency (IF) signal at the output end of the balanced detector. Zero-difference detection can be directly obtained from the baseband signal and balanced-detector output signal after IF amplification, filtering, demodulation, and restoration of the digital signal to the sending end.

Table 6.6 Research progress of balanced detectors

Researcher	Year	Development
Bae	1993	Excess intensity noise of local vibration light is suppressed
Dai	2014	Sensitivity can reach −46.5 dBm
Guo	2015	Improved SNR ratio of the balanced heterodyne detection method
Shi	2016	Common-mode rejection ratio is higher than 27 dB
Munshid	2017	Relationship between wavelength shift and temperature is linear
Yong	2018	Ten Gbit/s non-return-zero electron predistortion systems

Double Balanced Probes

Working Principle

Double-balanced detection is based on the structural composition of a balanced heterodyne detection system. The double-channel balanced receiving technology is shown in Fig. 6.16, which uses four photodetectors that are almost identical. The two detectors at the receiving end are a group, forming two groups of balanced heterodyne detectors [100].

The signal light and local light enter the port at the input end of a 90° optical mixer. After a quarter of the waveplate, the local light can be converted into circularly polarized light. At this time, the two present a 45° angle. Through the beam-splitting prism, the signal and local lights can be shot into half of the wave plate after the mixed-beam splitting; at this time, the two will present a 22.5° angle. Finally, four light beams are obtained, based on the polarization beam splitter. Two orthogonal IF current signals can be obtained by combining two beams of light with opposite phases and inputting them into a balanced detector.

$$\begin{cases} I : I_0 - I_{180} = 2k_1k_4 \cos\left[\omega_{IF} - \left(\varphi + \frac{\pi}{4}\right)\right] \\ Q : I_{90} - I_{270} = 2k_2k_3 \sin\left[\omega_{IF} - \left(\varphi + \frac{\pi}{4}\right)\right] \end{cases}, \tag{6.15}$$

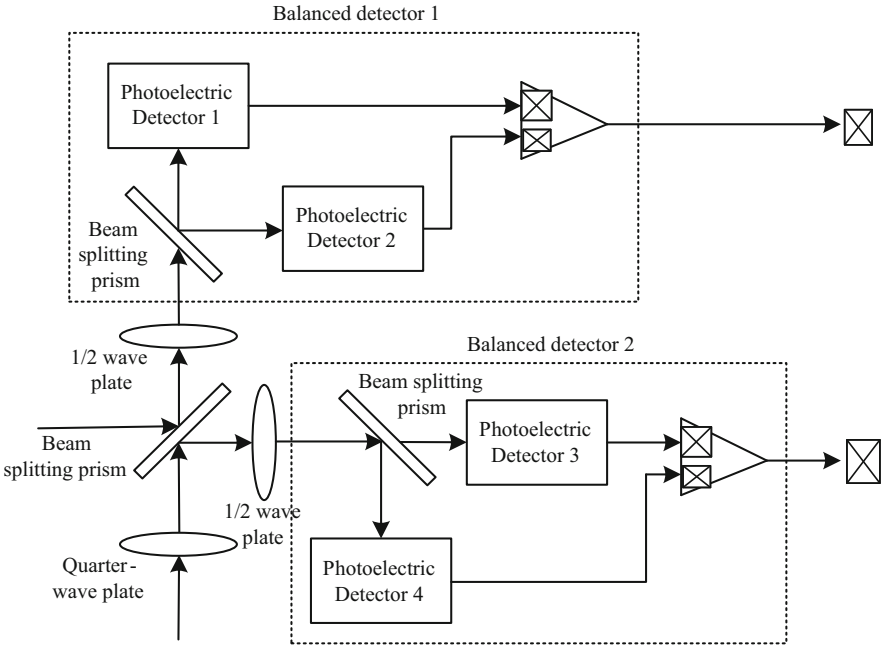

Fig. 6.16 Double-balanced probe

where I and Q are the 90° phase difference between the two channels, that is, the in-phase component and the orthogonal component required by the demodulation information. I_0, I_{180}, I_{90}, and I_{270} are the four optical-mixer outputs obtained through the polarization splitter prism; k_1, k_2, k_3, and k_4 represent the local light and signal light in the directions of the component, φ is the phase difference, and ω_{IF} represents the intermediate frequency. When the two subtracted photocurrents after the DC component are completely offset, and the intensity noise related to the DC component is also eliminated, the AC term is proportional to the square root of the local light power. Therefore, the noise intensity has a much smaller influence.

Research Progress

In 2003, Li et al. [101] verified the physical mechanism of the balanced detector and built a 1550 nm balanced heterodyne detection system. The results showed that the signal-to-noise ratio performance of the double-balanced detector was much better than that of the single-ended detector.

In 2010, Gao et al. [102] applied dual-balanced detection technology to a weak signal-detection field, for example, in Lidar, the polarization factor of incident light will cause a polarization mixing error, and the error of the dual-balanced detection system was discussed. The results showed that the vertical orthogonal factor of the ellipse formed by polarized light on the polarization splitter was 0.523, when the polarization degree was in the range of (0, 0.02).

In 2013, Zhu [103] established a dual optical-path-balanced detection system using 3 × 3 couplers to solve the corrosion and electromagnetic-interference problems of traditional acoustic microphones. This enabled the differential processing of two equal-amplitude signals. Experiments showed that the system was stable and the waveform distortion was small. It extracted and recovered speech signals in the 300–3400 Hz range.

In 2013, Huan [104] studied the weak laser-signal detection of a double-balanced heterodyne detection system, starting from the aspects of the system structure and a mathematical model. Through simulation analysis, they deduced a conclusion that conformed to the mathematical model, which laid the foundation for research on weak laser-detection technology.

In 2015, Zheng et al. [105] proposed a new dual-balanced differential configuration method with a photon-detection efficiency of 10% for a 1550 nm laser at 10 MHz. The results showed that this configuration effectively resolved ultraweak avalanche signals.

In 2015, Peng et al. [106] introduced a new photoelectric heterodyne-receiving technology based on double-balanced coherent detection, explained the working principle of double-balanced coherent detection, and further analyzed double-balanced and balanced coherent-detection systems.

In 2016, Li et al. [107] designed a double-balanced sound-receiving system based on the Mach–Zehnder ring structure to increase the measuring distance of a laser Doppler velocimeter. The SNR expression of the double-balanced sounding system was derived. Simulation results showed that the signal-to-noise ratio of the double-balanced detection system was higher than that of common coherent detection.

In 2017, Huang et al. [108] considered the shortcomings of common ground-fault detection methods and proposed a new two-bridge detection method. This method can be used for fault detection, which not only solves the problem caused by the dead zone but also does not affect the distributed capacitance. The feasibility of this method was experimentally verified.

Table 6.7 shows the development of the dual-balanced detector. The above literature describes the working principle of double-balanced detection technology and analyzes whether it can be applied to the detection of weak signals and other fields. A comparison with common coherent detection technology shows that double-balanced detection technology can improve the system signal-to-noise ratio.

Typical Application Scenarios

Figure 6.17 presents a simulation block diagram of a coherent-optical communication system. In the simulation, a pseudorandom bit sequence forms the modulated signal, and the signal light is modulated by quaternary phase-shift keying (QPSK). In the experiment, the oscillator light and signal light are introduced into the mixer for mixing. The mixer signal is output to the double-balanced detection system, and its signal is converted to analog after digital signal processing. The receiver decision circuit measures the signal-to-noise ratio to determine whether the system performance is good or bad by observing the bit-error rate.

Table 6.7 Research progress on double-balanced detectors

Researcher	Year	Development
Li	2003	Improved the SNR performance of double-balanced detectors
Gao	2010	Applied dual-balanced technology to weak signal detection

Huan	2013	Weak laser-signal detection in a double-balanced detection system
Zheng	2015	Proposed a double-balanced differential configuration method
Peng	2015	Studied double-balanced coherent detection
Li	2016	Created a DB detection system based on the Mach–Zehnder ring structure
Huang	2017	Proposed a new two-bridge detection method

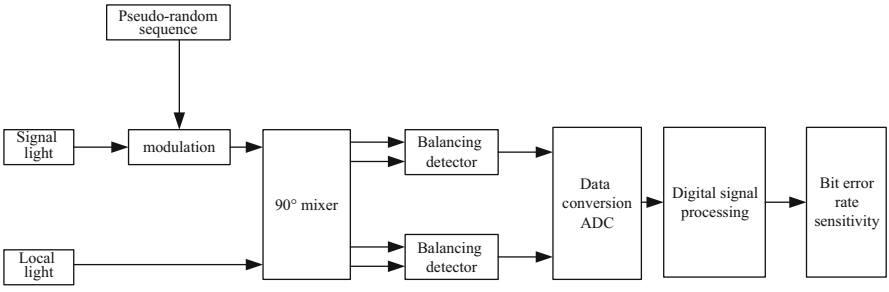

Fig. 6.17 Schematic diagram of a coherent-optical communication-system simulation

Photodetector Noise

Sources of Photodetector Noise

Loose-Particle Noise

When incident light irradiates a detector surface, the photoelectrons oscillate randomly, and scattered noise is generated. The electrons emitted by the electron tube in any short time τ will fluctuate near the mean value. From the perspective of the mean-square deviation of the fluctuation, the power of the scattered particle noise is

$$i_n^2 = 2eI\Delta f, \tag{6.16}$$

where i_n^2 represents the power of the scattered particle noise, e represents the electron charge, Δf represents the noise bandwidth, and I is the average photocurrent generated by the detector.

For the cases of incident light and no incident light, the dark-current noise power and light-radiated scattered-particle noise power are, respectively,

$$i_{nd}^2 = 2eI_d\Delta f \tag{6.17}$$

$$i_{np}^2 = 2eI_p\Delta f, \tag{6.18}$$

where i_{nd}^2 denotes the dark-current noise power, i_{np}^2 denotes the light-radiated scattered-particle noise power, e denotes the amount of charge in an electron, and Δf represents the noise bandwidth of the detector. The average photocurrent without incident light is represented by I_d, and the average photocurrent with incident light is represented by I_p.

Generation-Compound Noise

The constant movement of charge carriers in a semiconductor leads to the random generation and recombination of electrons and holes; hence, the average carrier concentration will fluctuate continuously. The noise generated at this time is called generation-compound noise, and the expression is

$$i_{ng-r}^2 = 4eIM\Delta f, \tag{6.19}$$

where the power generating the generation-compound noise is represented by i_{ng-r}^2, I represents the average photocurrent, Δf represents the noise bandwidth of the detector, and M represents the gain.

Thermal Noise

The random motion of the charge carriers in the dissipative element produces thermal noise. For resistances, these electrons produce thermal noise as long as the resistance is in thermal equilibrium, even if no voltage is applied.

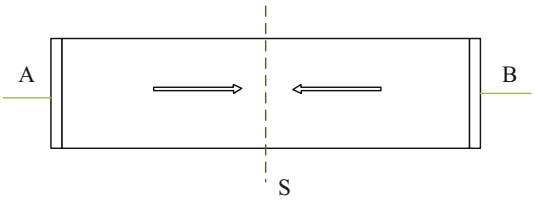

Fig. 6.18 Equivalent diagram of an AB electrode

An AB-electrode equivalent diagram is shown in Fig. 6.18. The resistance between the poles of AB is denoted by R. At an absolute temperature T, the electrons between the poles of AB are in constant random thermal motion.

Because there are voltage fluctuations at both ends of AB, the average power of the thermal noise obtained is

$$U_{nJ}^2 = 4KT\Delta fR, \tag{6.20}$$

where U_{nJ}^2 denotes the average power of thermal noise, the Boltzmann constant is denoted by k, the measurement bandwidth is denoted by Δf, the absolute temperature is denoted by T, and R is the resistance between the AB electrodes. If the noise is caused by the current,

$$i_{nJ}^2 = \frac{4KT\Delta f}{R}, \tag{6.21}$$

where i_{nJ}^2 represents the average power of the thermal noise.

The root-mean-square values of the thermal-noise current and voltage are typically calculated as follows:

$$\sqrt{i_{nJ}^2} = \left(\frac{4KT\Delta f}{R}\right)^{1/2} \tag{6.22}$$

$$\sqrt{U_{nJ}^2} = (4KT\Delta fR)^{1/2}, \tag{6.23}$$

where $\sqrt{i_{nJ}^2}$ is the root mean square value of the thermal noise current and $\sqrt{U_{nJ}^2}$ is the root mean square value of the thermal noise voltage.

1/f Noise

The detector-manufacturing process introduces unnecessary trace impurities or small nonuniform particles into the sensitive layer. Under the action of current, microburst pulses are generated between these particles, resulting in 1/f noise.

The current mean-square value of 1/f noise can be expressed as

$$i_{nf}^2 = k_1 \frac{I^b \Delta f}{f^a}, \tag{6.24}$$

where i_{nf}^2 represents the current mean square value of 1/f noise, and the proportionality coefficient is k_1. k_1 is affected by various factors, including the detector manufacturing process, electrode contact, and size of the detector. Δf is the working bandwidth, a is a constant related to the material of the detector, usually between 0.8 and 1.3. Current I is in the device; b is related to I, b usually taking the value 2.

Typical Photodetector-Noise Models

Noise Model of an Avalanche Photodetector

Thermal Noise

For an avalanche photodiode, the thermal noise current satisfies Eq. (6.18), if the resistance inside the diode is ignored, and only the effect of the load of the current in which the diode is located is considered.

Loose-Particle Noise Generated by the Dark Current

The continuous random movement of carriers in the P-N junction generates loose particle noise. Then [109]

$$i = i_p + i_s, \tag{6.25}$$

where i is the total current flowing through the P-N junction. The scattered-particle noise current is represented by i_s and the average value of the current is i_p. If the bandwidth of the receiving system is B, the effective value of the scattered noise can be expressed as

$$i_s = \sqrt{2ei_pB}, \tag{6.26}$$

where i_s is the effective value of the scattered particle noise, e is the electronic charge, and the average current value is i_p. In a dark environment, for an avalanche photodiode with a multiplication factor M, the dark current is

$$i_d = i_b + Mi_t, \tag{6.27}$$

where i_d is the dark current, i_b is the surface leakage current, i_t is the volume leakage current, and M is the multiplication factor. The dark current of the detector causes loose-particle noise, and the effective value of the noise current is expressed as [109]

$$i_s' = \sqrt{2ei_tBM^2 + 2ei_bB}, \tag{6.28}$$

where i_s' is the effective value of the noise current.

Excess Noise

The gain of an avalanche photodiode represents the ratio of the output photocurrent to the incoming photocurrent [109]:

$$M = \frac{I_p - I_d}{I_{p0} - I_{d0}}, \tag{6.29}$$

where the multiplication factor is M, I_p is the photocurrent of the avalanche photodiode, I_d is the dark current of the avalanche photodiode, I_{p0} represents the photocurrent at unit gain, and I_{d0} represents the dark current at unit gain.

Assuming that the avalanche multiplication region is uniform, the overnoise factor is related to the gain and ionization coefficient, that is,

$$F(M) = kM + (1-k)\left(1 - \frac{1}{M}\right), \tag{6.30}$$

where $F(M)$ is the overnoise factor, k is the ionization coefficient, and M is the multiplication factor. In device design, materials with smaller k values should be selected for the multiplication region as much as possible.

PIN Photodetectors

Thermal Noise

Thermal noise is the current or voltage fluctuation caused by the random movement of charge carriers in the material at a certain temperature. The thermal noise of a PIN detector satisfies Eq. (6.20).

Loose-Particle Noise

The expression for the scatter-noise current satisfies Eq. (6.14).

Generation-Compound Noise

The mean-square current of PIN-detector generation-compound noise is

$$i_{nf}^2 = \frac{cI^\alpha}{f^\beta}\Delta f, \tag{6.31}$$

where i_{nf}^2 is the mean square value of the current of generation-compound noise, the average value of the output current is expressed by I, the operating frequency is expressed by f, α is approximately 2, Δf is the operating bandwidth, and c is the proportionality constant. The values of α, β, and c can be measured empirically and are related to variations in the device surface.

1/f Noise

The mean-square current of the 1/f noise of a PIN detector is expressed as

$$i_{nf}^2 = \frac{cI^\alpha}{f^\beta}\Delta f, \tag{6.32}$$

where i_{nf}^2 is the mean square value of the current of 1/f noise, the working frequency is expressed by f, α is approximately 2, between 0.8 and 1.5., Δf is the operating bandwidth, c is a constant of proportionality, and the values of a α, b β, and c can be measured experimentally and are related to the surface undulation state of the device.

Photomultiplier Tubes

Signal-to-Noise Ratio

Suppose the photomultiplier is order K, and the average number of electrons collected by its anode is n_a. If each order of multipliers is the same and conforms to the Poisson distribution, [110]

$$\mathrm{SNR}_a \approx \left|\frac{\eta n_p(\delta-1)}{\delta}\right|^{1/2}, \tag{6.33}$$

where SNR_a is the signal-to-noise ratio of the photomultiplier tube, ηn_p is the average number of photoelectrons, and δ is the gain. If $\delta \gg 1$, then

$$\mathrm{SNR}_a \approx \sqrt{\eta n_p}. \tag{6.34}$$

Scattered-Particle Noise Current

The mean square current value of the scattered noise is [110]

$$I_{Npe}^2 = 2q^2\eta I_p \Delta f, \tag{6.35}$$

where the charge is q and forms a series of current pulses. The spectrum of the current pulse consists of many harmonics; Δf is the harmonic interval, I_p is the rate reached by the average photon, and η is the quantum efficiency. The mean-square current of the scattered-particle noise of the photomultiplier tube is

$$I_{N_a} = 2qI_{pe}\Delta f\left(1+\frac{1}{\delta 1}+\frac{1}{\delta 2}+\cdots+\frac{1}{\delta_1\delta_2\cdots\delta_k}\right)m_k, \tag{6.36}$$

where $m_k = \prod_{i=1}^{k}\delta_i$ is the total gain of the photomultiplier and I_{pe} is the photocathode current.

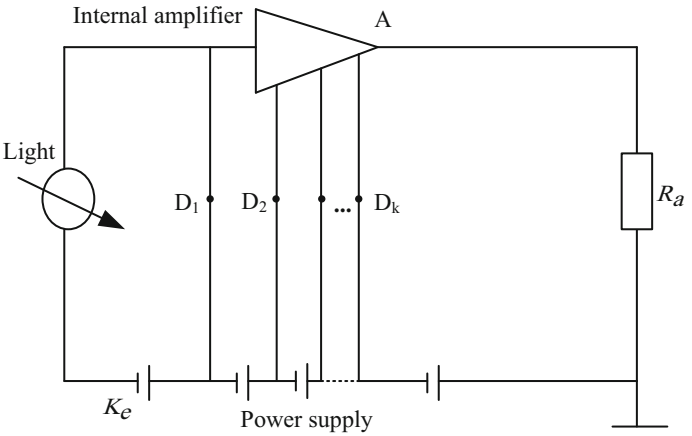

Fig. 6.19 Equivalent-circuit diagram of a photomultiplier

Simplified Photomultiplier Model

The simplified noise model of a photomultiplier consists of a photocathode, several secondary emission multipliers, and an anode. An equivalent circuit diagram of the photomultiplier is shown in Fig. 6.19.

In Fig. 6.19, D_1, D_2, ... D_k represent the first k multipliers, K_e is the photocathode, A is the output anode of the inner amplifier, and R_a is the anode load resistor.

The photomultiplier tube can also be viewed as a current source whose anode current is an m_k multiple of the photocathode current:

$$I_a = m_k I_{pe} = \left(\prod_{i=1}^{k} \delta_i \right) I_{pe}, \tag{6.37}$$

where I_{pe} is the cathode current and $\prod_{i=1}^{k} \delta_i$ is the total gain of the photomultiplier tube.

In Fig. 6.20 [110], R_a is the anode resistance, I_{pe} is the cathode current, $m_k = \prod_{i=1}^{k} \delta_i$ is the total gain of the photomultiplier, I_p is the average photon-arrival rate, C_a is the anode capacitance, R_p is the cathode resistance, C_p is the cathode capacitance, and U_a is the anode voltage source.

Four-Quadrant Detector

Thermal Noise

The thermal noise of the four-quadrant detector satisfies Eq. (6.20).

1/f Noise

The 1/f noise-voltage power-spectrum density in the four-quadrant detector is expressed as follows [111]:

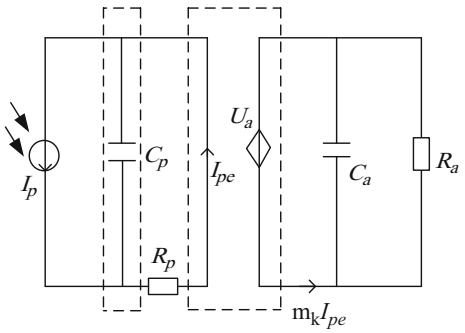

Fig. 6.20 Simplified photomultiplier noise model

$$S_V(f) = AV^{\beta}/f^{\gamma}, \tag{6.38}$$

where $S_V(f)$ is the power spectrum density of the 1/f noise voltage, A is related to the detector material and is a constant, β is the exponential factor, V is the noise voltage, f is the frequency, and γ is the frequency exponent.

In 1969, Hooge proposed his famous empirical formula and mobility fluctuation model:

$$\frac{S_I(f)}{I^2} = \frac{S_R(f)}{R^2} = \frac{S_v(f)}{V^2} = \frac{\alpha_H}{fN}, \tag{6.39}$$

where the power spectral density of the noise current is represented by $S_I(f)$, the power spectral density of the resistance is represented by $S_R(f)$, and the power spectral density of the voltage is represented by $S_v(f)$. The Hooge coefficient is α_H; it can be used to measure the 1/f device noise level, where f is the frequency and N is the total number of carriers.

Generation-Compound Noise

When generating four-quadrant detector generation-compound noise, the power spectral density is satisfied as follows [111]:

$$S_I(f) = \sum_{i=1}^{m} \frac{C_i \tau_i}{1 + \left(2\pi f_{\tau_i}\right)^2}, \tag{6.40}$$

where $S_I(f)$ is the power spectral density of generation-compound noise, τ_i is the characteristic time constant of generation-compound noise, m is the number of deep energy levels, C_i represents the amplitude of the generation-compound noise component of time constant τ_i, and f_{τ_i} is the frequency of the characteristic time constant.

The characteristic time constant τ_i can be expressed as

$$\frac{1}{\tau_i} = CT^2 \exp(-Ea/kT), \tag{6.41}$$

where k is Boltzmann's constant, C is a constant, Ea is the activation energy of the deep-level impurity, and T is the temperature.

Quantum-Dot Detector

Dark Current

The barrier has moving carriers, and the dark current can be calculated from the density of the carriers [84]:

$$I_{\text{dark}} = 2evuEA\left(1+\left(\frac{uE}{v_s}\right)^2\right)^{-1/2}\left(\frac{m_b kT}{2\pi h^2}\right)^{3/2}\exp\left(-\frac{E_{0,\text{micro}}\exp(-E/E_0)+E_{0,\text{nano}}-\beta E}{KT}\right) \tag{6.42}$$

where e is the electronic charge, v is the electron drift velocity, A is the area of the detector, E is the bias electric-field intensity and can be approximated by dividing the applied voltage by the thickness of the intrinsic region of the detector, μ is the electron mobility, v_s is the maximum moving velocity of an electron, m_b is the effective mass of an electron, k is Boltzmann's constant, T is the temperature, and h is a normalized Planck's constant. $E_{0,\text{micro}}$ is the excitation energy of a micron-scale electron transport under zero pressure bias, $E_{0,\text{nano}}$ is the excitation energy of a nanoscale electron transport under zero pressure bias, E_0 describes how fast or slow the excitation energy of the micron-scale electron transport varies with the electric field, and β describes how fast or slow the excitation energy of the nanoscale electron transport varies with the electric field.

Noise Gain

The noise gain can be calculated by the ratio of the electron recombination time τ_r to the electron transit time τ_d [84]:

$$g_n = \frac{\tau_r}{\tau_d}, \tag{6.43}$$

where g_n is the noise gain.

In general, the electron capture by quantum dots is considered to be symmetric, and the specific calculation form is as follows:

$$\frac{1}{\tau_T} = N_t(4\pi D R_t)\left\{1-\left[\frac{D}{V_t R_t^2}\tan h\left(\frac{V_t R_t^2}{D}\right)\right]^{1/2}\right\}, \tag{6.44}$$

where R_t is the effective radius of the quantum dot, V_t is the capture speed of a quantum dot capturing an electron, τ_T is the capture time of a quantum dot capturing an electron, N_t is the quantum number of points, and D is the band-diffusion coefficient, which is related to electron mobility μ:

$$\mu = \frac{eD}{kT}. \tag{6.45}$$

Equations (6.40) and (6.41) are substituted into Eq. (6.39) and sorted to obtain the noise gain, which can be written as

$$g_n = \frac{uE\left(1 + \left(\frac{uE}{v_s}\right)^2\right)^{-1/2}}{N_t(4\pi R_t ukT/e)\left\{1 - \left[\frac{ukT}{ev_t R_t^2}\tan h\left(\frac{ev_t R_t^2}{ukT}\right)\right]^{1/2}\right\}}, \tag{6.46}$$

where E is the bias electric-field intensity of the quantum-dot infrared detector, μ is the mobility of the electron, and v_s is the saturation movement speed of the electron.

Noise

The noise of quantum-dot detectors mainly comes from the electron production–recombination process and can be written as

$$i_n = \sqrt{4eg_n I_d} \tag{6.47}$$

where e is the basic electron charge and g_n is the noise gain, which is approximately equal to the photoconductance gain, and I_d is the dark current.

According to the dark-current and gain-calculation methods, Eqs. (6.39) and (6.43) are substituted into Eq. (6.44) to obtain the formula for calculating quantum-dot infrared detector noise [84]:

$$i_n = \sqrt{\frac{8e^2u^2E^2\left(1 + \left(\frac{uE}{v_s}\right)^2\right)^{-1}\left(\frac{m_b kT}{2\pi h^2}\right)^{3/2}\exp\left(-\frac{E_{0,\text{micro}}\exp(-E/E_0) + E_{0,\text{nano}} - \beta E}{KT}\right)}{N_t(4\pi R_t ukT/e)\left\{1 - \left[\frac{ukT}{ev_t R_t^2}\tan h\left(\frac{ev_t R_t^2}{\mu KT}\right)\right]^{1/2}\right\}}} \tag{6.48}$$

where the bias electric-field intensity is expressed by E, m_b is the effective mass of the electron, μ is the electron mobility under a zero voltage bias, $E_{0,\text{micro}}$ is the excitation energy generated with a micron-magnitude electron transmission, and $E_{0,\text{nano}}$ is the excitation energy generated with a nanometer-magnitude electron transmission. The size will be affected by the change of the electric field, β describes the change of the speed, and v_s represents the maximum speed that can be reached when the electron is moving.

Balanced Detector

Thermal Noise

The thermal noise of the balanced detector satisfies Eq. (6.20).

Loose-Particle Noise

The mean-square value of the scattered noise current is expressed as

$$i_{sn}{}^2 = 2eP_LB, \tag{6.49}$$

where e denotes the electron charge and B denotes the noise bandwidth.

Double-Balanced Detector

Loose-Particle Noise

The power spectral density of a single sideband of scattered noise is expressed as [112]

$$G_{\text{shot}}^2 = 2 \cdot q \cdot (\eta \cdot P + I_d) \cdot \Delta f, \tag{6.50}$$

where G_{shot}^2 is the single-sideband noise power spectral density, q is the electron charge, η is the device-response factor, I_d corresponds to the dark current, Δf is the single-sideband effective noise bandwidth, and P is the total received power.

Thermal Noise

The main source of thermal noise is cross-resistance amplification; the noise can be represented as follows [112]:

$$\sigma_{\text{thermal}}^2 = (i_{\text{TIA}})^2 \cdot \Delta f, \tag{6.51}$$

where $\sigma_{\text{thermal}}^2$ represents thermal noise, i_{TIA} is the single-side differential input noise current either, and Δf is the single-sideband effective noise bandwidth.

Relative-Intensity Noise

The relative-intensity noise caused by local vibration light can be expressed as [112]

$$\sigma_{\text{RIN}} = 2(\eta P_L)^2 \cdot \text{RIN} \cdot \Delta f, \tag{6.52}$$

where σ_{RIN} represents the relative intensity noise, P_L is the local vibration power, RIN is the relative-intensity noise coefficient, and η is the equipment-response coefficient.

Summary

In this chapter, specific detectors were analyzed, including the avalanche photodetector, PIN photodetector, photomultiplier, four-quadrant detector, quantum-dot infrared detector, and balanced detector. Their thermal noise, loose-particle noise, generation-compound noise, and 1/f noise were analyzed from the noise-generation mechanism, and the noise model of related detectors was established. This provided

a basis for studying the signal quality at the receiving end of an optical wireless communication system.

In the future, the following work is worthy of further study and discussion.

1. Develop new composite materials with a high carrier mobility, longer lifetime, and diffusion distance, as well as a large photoconductance gain, to improve the response speed and quantum efficiency of the detector.
2. Explore new integration methods to increase the photodetector integration and reduce the number of detectors and search time. In addition, the resolution of the detector-channel wavelength should be enhanced and the cost reduced.
3. Further reduce the carrier concentration, noise, and impact of the junction area and pressure-welding size on the dark current of the detector, and thereby improve the sensitivity of the photodetector.
4. Improve the detector-surface process state, avoid the existence of uneven particles or unnecessary trace impurities in the photosensitive layer, and reduce the 1/f noise of the detector.
5. Improve the detector structure, reduce the composite loss of photogenerated carriers in the dead zone of the device surface, and improve the detector detection efficiency.
6. Ultrahigh speed, low-voltage, low-loss lithium-niobate thin-film electro-optic modulators have introduced a new era in the sustainable and rapid development of information technology. Whether future optical-interconnection technology can transmit the massive amounts of information in sufficient time is a fundamental issue concerning the sustainability of information-technology development.

Abstract

Optical wireless communication has received widespread attention as a high-speed, high-bandwidth communication technology. However, noise is an important limiting factor in system performance and has a critical impact on optical wireless communication systems. This chapter reviews the research progress of noise modeling in optical wireless communication systems, summarizes the research results of Ke's model, the turbulence-noise model, thermal-noise model, background optical-noise model, etc., and further analyzes the performance of systems under the influence of turbulence. Finally, the shortcomings of current research are highlighted, and future development directions are discussed.

Introduction

With the increasing demand for wireless communication and the growing scarcity of spectrum resources, optical wireless communication systems have attracted widespread attention as an emerging high-speed, high-bandwidth communication technology. Optical wireless communication systems use light as a carrier for data transmissions. This has the advantages of high-capacity, low-latency, and interference resistance [1] and is widely used in high-density communication scenarios and special environments.

However, noise is a nonnegligible factor in optical wireless communication systems and has a critical impact on system performance. Noise sources include turbulence noise, background optical noise, and thermal noise. These noises introduce additional interference into the transmission, reception, and processing of optical signals and reduce the signals' quality and reliability. Therefore, the study of noise and noise modeling in optical wireless communication systems is critically important for improving the performance of communication systems.

This chapter reviews the research progress in noise modeling in optical wireless communication systems, outlines the current research results in noise modeling, and analyzes the system performance under the influence of noise. Finally, it summarizes the shortcomings of current research and discusses future development directions for noise-modeling research. This review improves the understanding of how noise affects system performance and provides guidance and insights for noise suppression and system optimization.

Noise Distribution in Optical Wireless Communication Systems

Optical wireless communication is a broadband wireless transmission and access technology that combines the optical and wireless communication technologies. It uses light waves as carriers and the atmosphere, water, or outer space as channels for information transfer. It is also known as free-space optical (FSO) communication.

In optical wireless communication, the information output by the source is first modulated to an optical carrier, and the carrier (light beam or field) is launched through an optical channel (atmosphere) using a transmitter. The optical transmitter includes source coding, channel coding, modulation, optical-signal amplification, and a transmitting antenna. The optical signal is then optically collected and processed at the receiver end. The optical receiver consists of an optical-signal collection antenna, spatial optical-fiber coupling unit, preamplifier, detector, and demodulator [2].

Typically, various noises are present in the optical-field transmission process, which causes the performance of the communication system to deteriorate. Therefore, it is crucial to model and analyze these noises. In this study, we individually analyze all types of typical noise introduced in the source, channel, and beacon of an optical wireless communication system. A typical optical wireless communication system and its corresponding noise are shown in Fig. 7.1.

Optical wireless communication typically uses lasers as light sources. The laser itself introduces noise, mainly laser-intensity and phase noise. Laser-intensity noise is caused by the randomness of the photons generated within the laser, which can lead to fluctuations in the optical power. Laser phase noise is mainly caused by factors such as the natural linewidth, technical noise, and environmental interference, which may affect the stability of the optical signal.

The channels of optical wireless communication systems include atmospheric, indoor, ultraviolet-light scattering, and underwater channels. Channel noise mainly includes turbulence, phase, aiming, and background-light noise. Turbulence noise is caused by turbulence phenomena in the channel, which can cause the received signal to fade or distort. Phase noise is mainly produced by changes in the refractive index of light, caused by factors such as temperature and humidity in the channel, resulting in phase distortion and timing jitter of the received signal.

Aiming noise is caused by the inaccurate orientation of an optical receiver, which can cause changes and fluctuations in the intensity of the received signal, affecting its

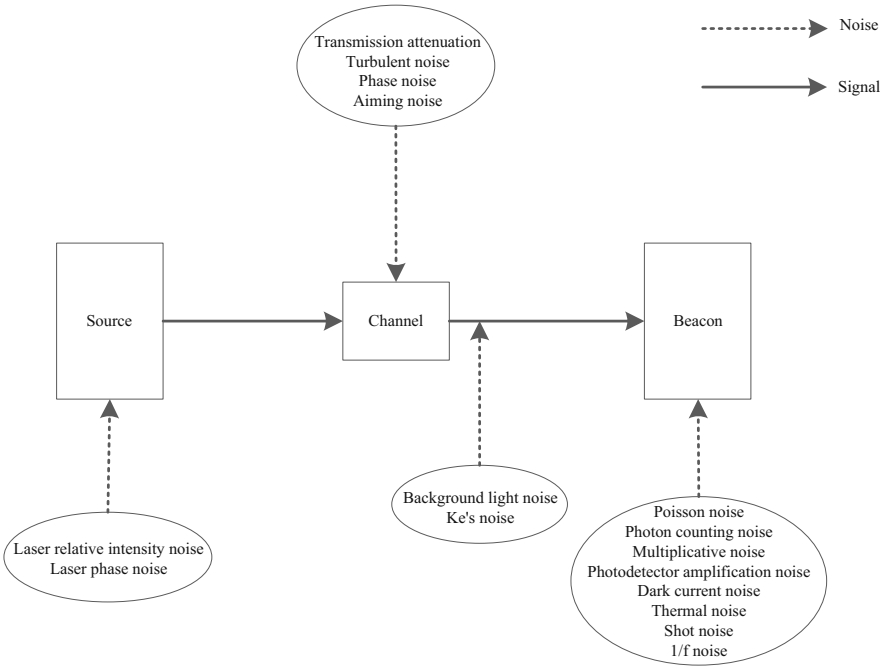

Fig. 7.1 Noise distribution in an optical wireless communication system

stability and reliability. Background-light noise mainly originates from the noise caused by other light sources in the environment surrounding the optical communication system. It can reduce the signal-to-noise ratio, leading to a decrease in the quality of the received signal.

A sink in an optical wireless communication system refers to a PIN or avalanche photodiode. Beacon noise includes Poisson, photon-counting, multiplication, thermal, dark-current, photodetector-amplification, shot, and 1/f noise. These noises primarily originate from the photodetector, which limits the sensitivity and reliability of the system.

Studying noise models is important precisely because noise has such a negative impact on optical wireless communication systems. By analyzing noise models, we can gain a deeper understanding of the impact of noise on communication performance. This helps evaluate the reliability and stability of a system and provides a foundation for optimizing the system performance.

Source Noise

Research Progress

It is an undeniable factor that source noise has a significant impact on the performance of the entire system. Source noise originates from the nonideal properties of optical emission devices, such as the spontaneous emission of lasers and other nonlinear effects, which can cause noise in the signal source and interfere with the transmission quality.

In recent years, researchers have made many achievements in the study of source-noise models. In 2003, Lu [3] analyzed and compared the characteristics of solid-state and semiconductor lasers in free-space optical communication systems. In 2004, Yang [4] found that a CO_2 laser, as a light source for optical wireless communication, could better adapt to harsh atmospheric environments and improve the system performance. In 2005, Gensty et al. [5] proposed a semiclassic noise model for the relative-intensity noise of quantum-cascade lasers.

In 2006, Yu et al. [6] designed a new type of low-noise fiber laser using a composite-cavity structure, which reduced the noise by approximately 25 dB at the 90-kHz relaxation oscillation peak. In 2008, Camatel et al. [7] evaluated two novel techniques for measuring laser phase noise in coherent transmission systems using a homodyne optical phase-locked loop and a signal-source analyzer. In 2010, Di Domenico et al. [8] proposed an approximate formula for evaluating laser linewidths that could be applied to any noise spectral density.

In 2011, Xie et al. [9] simulated and tested the intrinsic correlation between laser phase noise, laser coherence length, and reflected signal intensity. The results indicated that when the testing distance was close to the coherent length with a strong reflection signal in the link, the impact of the laser phase noise was more severe, and the impact range also increased. In 2012, Liu et al. [10] studied the impact of laser phase noise on the modulation-format selection, parameter

optimization, and carrier-phase estimation performance of coherent fiber-optic communication systems. The results indicated that when the carrier-phase estimation method was used in coherent fiber-optic communication systems, the optimal length of the average symbol sequence in the algorithm was inversely proportional to the laser phase noise.

In 2016, Chen et al. [11] derived an expression for the nonlinear intermodulation distortion of lasers using Bessel functions and investigated its effect on the system-carrier intermodulation noise ratio and bit-error rate (BER). In 2017, Warid et al. [12] theoretically investigated the static characteristics, relative-intensity noise, and intensity-modulation response of quantum-cascade lasers and analyzed the noise of such semiconductor-laser spectra and the modulation response of such semiconductor lasers. The results showed that static characteristics, such as the threshold injection current and steady-state photon density, deviated from the ideal values as the optical-phonon emissivity increased.

In the same year, Song et al. [13] used power and integral spectra to qualitatively analyze the phase noise of fiber lasers with different pump powers, seed-source powers, and wavelengths. The results showed that the higher the pump power, the greater the proportion of low-frequency phase noise; for different seed-source powers, the proportion of phase noise in the tested frequency bands was basically at the same level. For the wavelengths of the different seeds tested, the phase noise in the high proportion of the frequency band was different.

In 2019, Bai [14] derived the relationship between the laser linewidth, frequency-noise power-spectral density, and phase-noise power-spectral density and derived a method to calculate the laser linewidth by measuring the laser phase noise. In 2021, Didier et al. [15] investigated the relative-intensity noise in 4.1-μm multimode interband cascade lasers. The results indicated that the relaxation frequency increased with the bias current at much higher than the threshold current. The simulation results were in agreement with the experimental results.

In 2022, Du [16] et al. numerically investigated the conditions for the codriven chaotic synchronization of distributed Bragg-reflector (DBR) lasers, effect of parameter mismatches, and chaotic-synchronization switch keying. In 2022, Seminara et al. [17] investigated a free-space quantum-cascade laser-based method and carried out a detailed experimental analysis of the noise conditions that could occur in an optical communication system. The results showed that there were two noise regions in the system corresponding to different channel-attenuation conditions, and error-free communication could be achieved within an effective distance of 8 km with 1 km low-visibility conditions.

Noise Models

Laser Relative-Intensity Noise Model

In a communication system, the intrinsic noise of the laser is the main source of source noise, which can be expressed in terms of the relative-intensity noise (RIN). When the average power of the emitted beam is P, and it is received by a detector

with responsivity ρ and bandwidth Δf, the average value of the current in the detector is equal to the product of the responsivity and the average power, ρP [9]; then, the mean-square value of the current is

$$\overline{i_{NL}^2} = \mathrm{RIN}(\rho P)^2 \Delta f. \tag{7.1}$$

The average power which caused fluctuations in the light intensity of the laser is

$$\overline{P_{NL}^2} = \frac{\overline{i_{NL}^2}}{\rho^2}. \tag{7.2}$$

The relative-intensity noise of the laser can be obtained as

$$\mathrm{RIN} = \frac{\overline{P_{NL}^2}}{P^2 \Delta f}, \tag{7.3}$$

where $\overline{i_{NL}^2}$ is the mean-square value of the current and $\overline{P_{NL}^2}$ is the average power. Thus, it can be seen that the laser noise is mainly related to the average beam power and detector bandwidth.

Laser Phase-Noise Model

Spontaneous-radiation noise can cause phase fluctuations in the laser, resulting in a nonzero spectral linewidth Δv. In semiconductor lasers, the linewidth Δv is generally large, up to megahertz, because a small number of photons is confined in a small cavity, and the linewidth-enhancement factor is not negligible.

The relationship between the spectrum of the radiated light field $E(t) = \sqrt{P}\exp(j\phi)$ and the field autocorrelation function $\Gamma_{EE}(t)$ is

$$S(\omega) = \int_{-\infty}^{\infty} \Gamma_{EE}(t) e^{-j(\omega-\omega_0)\tau} \mathrm{d}\tau \tag{7.4}$$

$$\Gamma_{EE}(t) = \langle E^*(t)E(t+\tau)\rangle = \langle \exp(j\Delta\phi(t))\rangle = \exp\left(-\left\langle \Delta\phi^2(t)\right\rangle/2\right), \tag{7.5}$$

where $\Delta\phi(t) = \phi(t+\tau) - \phi(t)$, E represents the light field, t represents time, τ represents the time interval, j represents an imaginary number, ω represents the angular frequency, and ϕ represents the phase.

The Wiener process can be used to describe the phase noise process of lasers [10], namely,

$$S_{EE}(v) = \frac{P}{2\pi\Delta v}\left[\frac{1}{1+\left(\frac{2(v+v_0)}{\Delta v}\right)^2} + \frac{1}{1+\left(\frac{2(v-v_0)}{\Delta v}\right)^2}\right], \tag{7.6}$$

where P is the optical power, v is the frequency, v_0 is the center frequency, and v is the laser linewidth.

Channel Noise

Research Progress

When a light beam propagates in a channel, the transmitted beam may attenuate or drift, owing to the influence of particulate molecules and meteorological factors in the channel. To ensure the quality and reliability of the wireless communication system, the noise introduced in it must be analyzed.

In 2005, Razavi et al. [18] investigated the effects of atmospheric turbulence, background light, amplified spontaneous radiation, and receiver thermal noise. In the same year, Kiasaleh et al. [19] analyzed a weak turbulence (clear-air) scenario and a negative-exponential distribution of the received signal strength and provided numerical results for the pulse-position modulation case to elucidate the effect of turbulence on the overall performance.

In 2008, Zhu [20] conducted an in-depth investigation on the performance of multiple modulation modes for indoor optical wireless communication and investigated the high-speed transmission process in which a root-mean-square (RMS) delay was generated by multipath channels and the resulting intercode interference. In the same year, Mabaoke et al. [21] explored the characteristics of laser-propagation attenuation in fog and analyzed the effects of field-of-view angle variations on the signal-to-noise ratio.

Jaruwatanadilok et al. [22] used the vector radiative-transfer theory to model an underwater optical wireless communication channel and quantified the scattering effect as a function of the distance and bit-error rate using the Monte Carlo method. In 2009, Cochenour et al. [23] investigated the effects of underwater scattering on optical communication signals, received optical power, and the link range. In 2010, Meng [24] used the classic quadratic generalized Lagrange method to analyze the optical wireless communication model under equation constraints. They established an optical wireless communication model affected by the atmospheric-transmission window, as well as atmospheric turbulence.

In 2011, Wang [25] constructed a mathematical computational model to evaluate the error performance of optical wireless communication systems under weak turbulence. In 2012, Tu [26] proposed a method for calculating the bit-error rate under binary amplitude-keying modulation based on a hybrid noise model. The simulation results showed that the performance of free-space optical communication was significantly affected by atmospheric turbulence and noise. In the same year, Mohamed et al. [27] presented the impact of inclement weather conditions, such as rain, fog, and snow, on the transmission performance of optical wireless communication systems.

In 2013, Yao et al. [28] analyzed a channel model of underwater optical wireless communication (UOWC) and derived the BER expression of fixed-length digital

pulse-spacing modulation in an underwater optical wireless communication model. In the same year, Tang et al. [29] proposed a model of the channel impulse response with a closed expression for the double-gamma function. Ansari [30] conducted an in-depth study of the aiming-error problem in optical communication systems using the Meijer G-function and integrated the results into a unified expression.

In 2014, Nistazakis et al. [31] studied the wireless BER performance of optical communication systems over atmospheric-turbulence channels modeled with a gamma–gamma distribution or negative-exponential distribution. In the same year, Varotsos [32] analyzed the effects of group velocity dispersion and atmospheric turbulence on communication systems, owing to laser atmospheric propagation. Zhu et al. [33] proposed a phase-noise measurement scheme based on the delay-line method. It employed a multifunctional microwave photonic processor that simultaneously performed an electro-optical conversion, provided a time delay, and controlled the phase of the output microwave signal.

In 2015, Ke [34] established a space optical wireless communication receiving-diversity system model under strong turbulence. He verified its applicability and antijamming capability in an atmospheric environment by simulation. In the same year, Yang [35] derived an expression for the false-symbol rate of an optical wireless communication system under multipulse-position modulation using the exponential Weber fading model. Rashed [36] developed a model for evaluating the operational performance of an optical wireless communication system under different fog-density levels and in the presence of noise. Xu et al. [37] proposed a model for evaluating the effect of balanced augmented phase noise on the performance of coherent optical transmission systems.

In 2016, Wu et al. [38] analyzed atmospheric-turbulence channel-intensity fluctuation based on the K-distribution and numerically analyzed and compared the BER of circularly polarized keying with that of switched keying. The results showed that the system BER increased with an increase in the atmospheric scintillation index at the same signal-to-noise ratio, whereas circularly polarized keying modulation outperformed switched-keying modulation in strongly turbulent channels.

In 2016, Hamza et al. [39] investigated the effect of ambient noise induced by underwater solar radiation on UOWC from the perspective of the BER. This study was conducted on different types of photodetectors to highlight the practical limitations of establishing UOWC links in the presence of undersea solar noise and provided valuable insights into the design of UOWC links. In 2017, Anbarasi et al. [40] used relaying, diversity, and modulation techniques in different channels to mitigate turbulence in FSO systems and compared their performances.

In 2017, Fan et al. [41] modeled sky background-optical noise and performed theoretical-analysis and simulation studies. The simulation results showed that the sky background light decreased the signal-to-noise ratio of the detectors used in the coarse and fine tracking units, which led to a decrease in tracking accuracy and an increase in the communication BER. In 2017, Zhang [42] described the specific classification of noise in free-space optical communication systems and time-varying fading and stationary fading models owing to turbulence.

In 2018, Ke [43] considered an optical wireless subcarrier multivariate phase-shift keying modulation system and investigated the effect of the demodulation-module phase noise on the error performance of the optical wireless communication system. He also simulated and analyzed the effects of the light-intensity scintillation variance, phase noise, and modulation order on the error performance of the system.

In 2019, Wang [44] derived a Fourier-series expression for the probability-density function of the phase-noise model of a Tikhonov distribution. In 2020, Xing [45] analyzed the effects of absorption, scattering, and solar-radiation noise on the performance and power distribution of underwater optical communication systems.

In the same year, Hong et al. [46] used Monte Carlo simulation to construct an underwater optical wireless communication model for long-distance weak links and investigated the effects of the demodulation threshold, signal optical power, and noise optical power on the system performance. The experimental results showed that the simulation results of the established system model were basically consistent with the experimental data.

Fu et al. [47] conducted a simulation study of a UOWC system to investigate the effects of the beamwidth, receiving aperture, ocean-turbulence parameters, and aiming error on the performance of the average BER and interruption probability. Wang et al. [48] conducted a simulation study of the low signal-to-noise ratio of the receiving spot through digital signal filtering and denoising to improve the spot-position detection accuracy. The spot-position detection error of this method in a high background-noise environment was only 0.0277 mm, and the root-mean-square error was 0.0065 mm.

Liu [49] analyzed the effect of the absorption scattering of seawater channels on the attenuation of light and compared the time-domain expansion of a light pulse under different water-quality conditions by simulation. Wang [50] modeled the underwater optical propagation characteristics and analyzed the attenuation due to light absorption and scattering, background noise, and energy consumption in the ocean when transmitting data. Zhang et al. [51] proposed an asymptotic-growth metalearning adaptive-multirate scheme based on orthogonal frequency-division multiplexing and analyzed it over UOWC turbulent channels.

In 2021, Ke et al. [52] investigated the effect of atmospheric turbulence on optical wireless communications, exploring phenomena such as beam spreading, drifting, and scintillation. In the same year, Abigail et al. [53] designed a receiver system based on a deep-confidence network. The simulation results showed that the system performance improved by 13.2 dB at a 10^{-3} BER.

Xu [54] used lognormal and gamma–gamma channel models to describe weak to strong turbulence. In addition, the average BER and channel capacity of the FSO communication system under the influence of background, thermal, and quantum noises were analyzed. Han [55] analyzed the channel characteristics and noise model of an indoor visible-light communication system, focusing on the effects of scattered-particle and thermal noise on system performance.

Ke et al. [56] proposed a background optical-noise model for nighttime visible-light communication systems in vehicular networks, based on the superposition of double-Gaussian functions. Majlesein [57] introduced an analytical model of

scattering noise and investigated its effect on the BER performance of UOWC systems for three types of water and a range of transmission-link spans.

In 2022, Zhang et al. [58] analytically modeled the receiver-side noise of a UOWC system and built an experimental UOWC platform with an 852 nm wavelength under ambient-light noise interference. They demonstrated that the use of optical filters could effectively improve the communication performance and link length of underwater optical wireless communication under ambient-light noise interference.

In the same year, Li et al. [59] systematically studied and compared the theory and construction of various atmospheric-turbulence spectral models and detailed the atmospheric-turbulence models used in practical studies. Chen et al. [60] proposed an architecture for wavelength-division-multiplexed coherent data-center links and found that in each frequency comb, the phase noise in all the combs was completely dominated by the seed laser's optical phase noise and the phase noise of the microwave oscillator.

Yang et al. [61] developed a composite channel model under the synergistic effect of ocean turbulence and fading channels and analyzed the system performance by simulating the signal waveforms and counting the BERs. In 2023, Ke et al. [62] derived a multiplicative-noise model for atmospheric turbulence and conducted experimental measurements. The results showed that the effect of turbulent-multiplicative noise on the communication quality of optical communication intensified in the order of sunny, hazy, snowy, light, medium, and heavy rain, and cloudy days. The skewness and steepness of the noise signals increased gradually, and the fading probability of the light intensity of the signals increased.

In the same year, Jin et al. [63] investigated and discussed the performance of broadband long-haul nonlinear fiber-optic communication systems under balanced enhanced phase noise. The results showed that the growth of the symbol rate and transmission distance exacerbated the distortion of the C-band system. In 2023, Li et al. [64] discussed optical design, driving circuitry, and channel modeling in visible-light full-duplex communication.

Noise Model

Transmission-Attenuation Model

When a laser propagates in a channel, owing to the existence of a variety of gas molecules and particles in the channel, such as dust, smoke, wind, rain, snow, and other meteorological changes, a portion of the optical radiation energy is absorbed and transformed into other forms of energy (such as heat). The other part of the energy is scattered and deviates from the original propagation direction.

The total effect of the absorption and scattering is the attenuation of the transmitted optical-radiation intensity. The expression is

$$I_l = \exp[-c(\lambda)L], \tag{7.7}$$

where $c(\lambda)$ is the attenuation coefficient and L is the optical-transmission distance of the signal.

Turbulent-Noise Model

Turbulent noise in the channel originates from the scintillation effect. In addition, some particles, such as aerosols, sand, and dust, move randomly in the presence of the wind field, which leads to a random scintillation of the light intensity of the received signal. Based on field measurements, the received light intensity exhibits a specific probability-density distribution pattern in both cases. Therefore, this distribution can be used as a statistical feature to analyze the optical-signal transmission process.

In the field of optical wireless communication, the light-intensity distribution of the channel in weak-, medium-strong, and strong-turbulence scenarios can be described by probabilistic models, such as the lognormal, gamma–gamma, and K-distribution models [33].

Lognormal Model

The lognormal model is suitable for describing light-intensity flickering under weak turbulence. Under weak-turbulence conditions, fluctuations in the optical-signal intensity are mainly affected by random fluctuations in the refractive index of the atmosphere. The lognormal model assumes that the natural logarithm of the optical-signal intensity follows a normal distribution. The model is simpler but performs poorly when describing medium-strong and strong turbulence.

The probability-density function of the lognormal model can be expressed as

$$f_I(I) = \frac{1}{2I}\frac{1}{\sqrt{2\pi\sigma_\chi^2}}\exp\left\{-\frac{\left[\ln\left(\frac{I}{I_0}\right)+2\sigma_\chi^2\right]^2}{8\sigma_\chi^2}\right\}, \tag{7.8}$$

where I represents the received light intensity, I_0 represents the received light intensity before turbulence, and σ_χ^2 represents its logarithmic variance.

Γ-Γ Model

The Γ-Γ model, which is obtained by multiplying two independent gamma distributions, provides a better description of the fluctuations of the optical-signal intensity under moderate to strong turbulence. It is affected by multiple factors, such as random fluctuations of the atmospheric refractive index and scattering.

The probability-density function of the Γ-Γ model can be expressed as [39]

$$f_I(I) = \frac{2(\alpha\beta)^{\frac{\alpha+\beta}{2}}}{\Gamma(\alpha)\Gamma(\beta)} I^{\frac{\alpha+\beta}{2}-1}\mathrm{K}_{\alpha-\beta}\left(2\sqrt{\alpha\beta I}\right), \tag{7.9}$$

where $\Gamma(\cdot)$ denotes the gamma function and $K_n(\cdot)$ is the n-order Type-II modified Bessel function. α and β represent the large-scale and small-scale eddy-current characteristics, respectively, and are usually calculated by the following equations:

$$\begin{aligned}\alpha &= \left[\exp\left(\frac{0.49\sigma_l^2}{\left(1+0.65d^2+1.11\sigma_l^{12/5}\right)^{7/6}}\right)-1\right]^{-1}\\ \beta &= \left[\exp\left(\frac{0.51\sigma_l^2\left(1+0.69\sigma_l^{12/5}\right)^{-5/6}}{\left(1+0.9d^2+0.62d^2\sigma_l^{12/5}\right)^{5/6}}\right)-1\right]^{-1},\end{aligned} \tag{7.10}$$

where $\sigma_l^2 = 1.23C_n^2k^{7/6}L^{11/6}$ is the Rytov variance, $d = (kD^2/4L)^{1/2}$, $k = 2\pi/\lambda$ is the number of light waves, λ is the wavelength, D is the receiver-aperture diameter, and L is the beam-transmission distance. C_n^2 is the atmospheric refractive-index structure constant. The light-intensity scintillation index σ_I^2 for the Γ-Γ model is

$$\sigma_I^2 = \exp\left[\frac{0.49\sigma_l^2}{\left(1+0.65d^2+1.11\sigma_l^{12/5}\right)^{7/6}}+\frac{0.51\sigma_l^2\left(1+0.69\sigma_l^{12/5}\right)^{-5/6}}{\left(1+0.9d^2+0.62d^2\sigma_l^{12/5}\right)^{5/6}}\right]. \tag{7.11}$$

K-Distribution Model

Under strong turbulence, the fluctuation of optical-signal intensity has complex characteristics consisting of small- and large-scale fluctuations, and the K-distribution model can well describe the optical-intensity scintillation in this case.

The probability-density function of the K-distribution model is expressed as follows:

$$f_I(I;\alpha_K) = \frac{2\alpha_K}{\Gamma(\alpha_K)}(\alpha_K I)^{(\alpha_K-1)/2}K_{\alpha_K-1}\left(2\sqrt{\alpha_K I}\right), \tag{7.12}$$

where α_K is a parameter related to the variance of the received light intensity ${\sigma_I}^2$; its relationship with ${\sigma_I}^2$ is

$$\alpha_K = \frac{2}{{\sigma_I}^2-1}. \tag{7.13}$$

Negative-Exponential Distribution Model

In the case of strong turbulence, the radiation field of the light wave can be approximated as a Gaussian distribution with zero mean; therefore, the

light-intensity distribution is approximated as an exponential distribution, which can be expressed as

$$f(I) = \frac{1}{I_0} \exp\left(-\frac{I}{I_0}\right), \tag{7.14}$$

where $I_0 = E(I)$.

Malaga Distribution Model

The Malaga turbulence model describes several different types of turbulence-intensity distribution models, including the lognormal, gamma–gamma, K, and negative-exponential distributions. The probability-density function of the Malaga distribution for the turbulence-channel light intensity is defined as

$$f_I(I) = A \sum_{k=1}^{\beta} a_k I^{\frac{\alpha+k}{2}-1} K_{\alpha-k}\left(2\sqrt{\frac{\alpha\beta I}{\gamma\beta + \Omega'}}\right), \tag{7.15}$$

where

$$A = \frac{2\alpha^{\frac{\alpha}{2}}}{\gamma^{1+\frac{\alpha}{2}}\Gamma(\alpha)} \left(\frac{\gamma\beta}{\gamma\beta + \Omega'}\right)^{\beta+\frac{\alpha}{2}} \tag{7.16}$$

$$a_k = \binom{\beta - 1}{k - 1} \frac{(\gamma\beta + \Omega')^{1-\frac{k}{2}}}{(k-1)!} \left(\frac{\Omega'}{\gamma}\right)^{k-1} \left(\frac{\alpha}{\beta}\right)^{\frac{k}{2}} \tag{7.17}$$

$$\Omega' = \Omega + 2\rho b_0 + 2\sqrt{2b_0\Omega\rho}\cos(\varphi_A - \varphi_B), \tag{7.18}$$

where α is a positive real parameter related to the effective number of the large-scale turbulence, and β is a natural number indicating the number of fading parameters. Ω' is the coherent mean optical power, γ is the receiver signal-to-noise ratio, ρ is the ratio of the scattered optical power coupled to the line of sight to the total optical power, and φ_A and φ_B are the phases of the line-of-sight propagation component and the propagation-coupling component of the light wave in the atmospheric-turbulence channel, respectively.

Atmospheric-turbulence channel models, such as the lognormal, gamma–gamma, and K-distribution models, can be obtained by setting the corresponding α and β parameters to the Malaga-distributed light-intensity probability-density function.

Exponential-Generalized Gamma Distribution Model

The exponential-generalized gamma distribution model is a combination of the exponential and generalized gamma distributions, which is more flexible and can characterize turbulence phenomena from weak to strong. It also considers the turbulence characteristics when air bubbles and temperature and salinity gradients are present in the channel (Table 7.1):

Table 7.1 Turbulence-channel model classification diagram

Channel model	Probability-density function	Adapted to turbulence range
Lognormal model	$f_I(I) = \frac{1}{2I}\frac{1}{\sqrt{2\pi\sigma_\chi^2}}\exp\left\{-\frac{\left[\ln\left(\frac{I}{I_0}\right)+2\sigma_\chi^2\right]^2}{8\sigma_\chi^2}\right\}$	Weak turbulence
Γ-Γ model	$f_I(I) = \frac{2(\alpha\beta)^{\frac{\alpha+\beta}{2}}}{\Gamma(\alpha)\Gamma(\beta)} I^{\frac{\alpha+\beta}{2}-1}\mathrm{K}_{\alpha-\beta}(2\sqrt{\alpha\beta I})$	Medium to strong turbulence
K-distribution model	$f_I(I;\alpha_\mathrm{K}) = \frac{2\alpha_\mathrm{K}}{\Gamma(\alpha_\mathrm{K})}(\alpha_\mathrm{K} I)^{(\alpha_\mathrm{K}-1)/2}\mathrm{K}_{\alpha_\mathrm{K}-1}\left(2\sqrt{\alpha_\mathrm{K} I}\right)$	Strong turbulence
Negative-exponential distribution model	$f(I) = \frac{1}{I_0}\exp\left(-\frac{I}{I_0}\right)$	Strong turbulence
Malaga distribution model	$f_I(I) = A\sum_{k=1}^{\beta} a_k I^{\frac{\alpha+k}{2}-1} K_{\alpha-k}\left(2\sqrt{\frac{\alpha\beta I}{\gamma\beta+\Omega'}}\right)$	Weak, medium, and strong turbulence
Exponential-generalized gamma-distribution model	$f_I(I) = \frac{\omega}{\lambda}\exp\left(-\frac{I}{\lambda}\right) + (1-\omega)c\frac{I^{ac-1}\exp\left(-\left(\frac{I}{b}\right)^c\right)}{b^{ac}\Gamma(a)}$	Weak, medium, and strong turbulence

$$f_I(I) = \omega f(I;\lambda) + (1-\omega)g(I;[a,b,c]) \tag{7.19}$$

$$f(I;\lambda) = \frac{1}{\lambda}\exp\left(-\frac{I}{\lambda}\right) \tag{7.20}$$

$$g(I;[a,b,c]) = c\frac{I^{ac-1}\exp\left(-\left(\frac{I}{b}\right)^c\right)}{b^{ac}\Gamma(a)}. \tag{7.21}$$

Therefore,

$$f_I(I) = \frac{\omega}{\lambda}\exp\left(-\frac{I}{\lambda}\right) + (1-\omega)c\frac{I^{ac-1}\exp\left(-\left(\frac{I}{b}\right)^c\right)}{b^{ac}\Gamma(a)}. \tag{7.22}$$

The model is weighted using the exponential and generalized gamma distributions. $f(I;\lambda)$ is an exponential-distribution function; $g(I;[a,b,c])$ is a generalized gamma-distribution function; ω is the mixed weight coefficient of the distribution, which satisfies $0 < \omega < 1$; λ is a parameter of an exponential distribution; a, b, and c are parameters of the generalized gamma distribution; and $\Gamma(\cdot)$ is a gamma function.

Phase-Noise Model

Phase variations caused by fluctuations in the refractive index of atmospheric turbulence lead to phase noise. In the communication process, the photodetector converts the optical signal at the receiving end into an electrical signal, which is subsequently multiplied by the signal output from the local oscillator to obtain an intermediate-frequency signal, which is coherently demodulated. However, with the passage of time, the phase of the output signal of the local oscillator may fluctuate,

and the noise caused by such fluctuations may cause difficulties in demodulating the subcarrier signal, which may lead to the deterioration of the system performance.

The phase noise φ generated by the local oscillator follows the Tikhonov distribution [40], and its probability-density function is

$$P(\varphi) = \frac{\exp\left[\frac{\cos(\varphi)}{\sigma_\varphi{}^2}\right]}{2\pi \mathrm{I}_0\left(\frac{1}{\sigma_\varphi{}^2}\right)}, |\varphi| \le \pi, \tag{7.23}$$

where $\sigma_\varphi{}^2$ is the phase-noise variance, and $\mathrm{I_n}()$ is the first type of deformed Bessel function of order n.

The Jacobi–Anger formula can convert Eq. (7.23) into

$$\exp\left[\frac{\cos(\varphi)}{\sigma_\varphi{}^2}\right] = \mathrm{I}_0\left(\frac{1}{\sigma_\varphi{}^2}\right) + 2\sum_{n=1}^{\infty} \mathrm{I_n}\left(\frac{1}{\sigma_\varphi{}^2}\right)\cos n\varphi. \tag{7.24}$$

Substituting Eq. (7.24) into Eq. (7.23), the Fourier series can be used to represent the probability-density function of the phase noise as

$$p(\varphi) = \frac{1}{2\pi} + \sum_{n=1}^{\infty} c_n \cos(n\varphi), \tag{7.25}$$

where $c_n = \frac{\mathrm{I}_n\left(\frac{1}{\sigma_\varphi{}^2}\right)}{\pi \mathrm{I}_0\left(\frac{1}{\sigma_\varphi{}^2}\right)}$ is the Fourier coefficient of the Tikhonov phase-noise probability-density function.

Aiming-Noise Model

When a light beam is transmitted through a channel, it causes a misalignment between the receiver and transmitter, owing to phenomena such as beam expansion and spot drift, which, in turn, leads to aiming errors in the system.

Assuming that a beam with beamwidth w_z arrives at a receiver that is distance z from the transmitter, the radius of the receiver aperture is R, and the attenuation coefficient due to the aiming error can be expressed as [44]

$$h_p(r, \mathrm{z}) = A_0 \exp\left(-\frac{2r^2}{w^2{}_{z_{eq}}}\right) \tag{7.26}$$

$$A_0 = [\mathrm{erf}(v)]^2. \tag{7.27}$$

$$v = \frac{\sqrt{\pi}\mathrm{R}}{\sqrt{2}\mathrm{w}_z} \tag{7.28}$$

$$w_{Z_{eq}}^2 = \frac{\mathrm{w}_z^2 \sqrt{\pi}\mathrm{erf}(v)}{2v\exp(-v^2)}, \tag{7.29}$$

where h_p is the loss owing to the aiming error, r is the radial deviation, z is the distance between the transmitter and receiver, A_0 is the $r = 0$ received power component, erf(·) is the error function, v is the beam-transfer rate, w_z is the beam width, and $w_{Z_{eq}}^2$ is the equivalent beamwidth. According to the Rayleigh distribution, the probability-density function of h_p is

$$f_{h_p}(h_p) = \frac{\gamma^2}{A_0^{\gamma^2}} h_p^{\gamma^2 - 1}, 0 \le h_p \le A_0, \tag{7.30}$$

where $\gamma = w_{z_{eq}}/2\sigma_s$ represents the ratio of the equivalent beam radius at the receiving end to the standard deviation of the aiming-error displacement and σ_s^2 represents the equivalent variance at the receiving end (Fig. 7.2).

In summary, it can be seen that in an optical wireless communication system, the impact of the aiming error on the system is mainly reflected as follows: By choosing the appropriate a/w_z ratio, the f_{h_p} curve is an incremental function of the relationship, which can improve the performance of the communication system; otherwise, it will increase the signal-fading probability.

Background-Light Noise Model

Interfering light emitted or reflected from light sources other than the signal light, such as sunlight, moonlight, and artificial light sources, and received by the optical wireless receiver is called background optical noise.

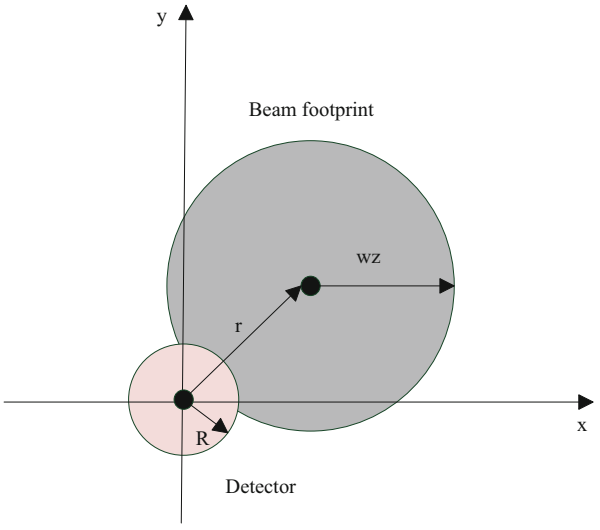

Fig. 7.2 Offset of the detector and beam on the receiving plane [47]

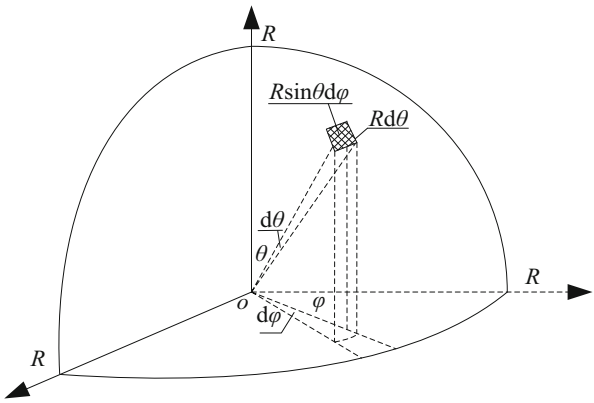

Fig. 7.3 Solid angle and bin projection in a spherical coordinate system

M_λ represents the total power radiated into the hemispherical space over a unit area and wavelength range. $L_\lambda(\theta, \varphi)$ represents the power radiated into a unit steradian angle over a unit projected area and wavelength range in a spherical coordinate system pointing in the direction of (θ, φ). The integral conversion relation between M_λ and $L_\lambda(\theta, \varphi)$ is shown in Fig. 7.3 [53] and can be expressed as

$$M_\lambda = \int_o L_\lambda(\theta, \varphi) \cos\theta \mathrm{d}\Omega, \tag{7.31}$$

where o represents the hemisphere, λ is the wavelength, θ is the angle between the beam and longitudinal axis, φ is the angle between the beam and transverse axis, and Ω is the integration region.

If the brightness of the light source is the same in each direction,

$$M_\lambda = \pi L_\lambda. \tag{7.32}$$

If the light source can be regarded as a point source,

$$M_\lambda = \frac{2\pi c^2 h}{\lambda}\left[\exp\left(\frac{hc}{k_\mathrm{B}\lambda T}\right) - 1\right]^{-1}, \tag{7.33}$$

where c is the speed of light; h is Planck's constant, value: $h = 6.6260693 \times 10^{-34}\mathrm{J} \cdot \mathrm{s}$; λ is the wavelength; k_B is Boltzmann's constant, value: $k_\mathrm{B} = 1.380649 \times 10^{-23}\mathrm{J/K}$; and T is the blackbody temperature of the radiation source.

Ke's Model

Visible-light communication (VLC) both illuminates and communicates and has attracted much attention in intelligent-transport systems. Ke et al. proposed a nighttime background-light noise model (Ke's model) using a double-Gaussian function for fitting. The expression of the noise model is [56]

$$f(I) = A_1 \times \frac{1}{\sqrt{2\pi} \times \sigma_1} \times e^{\left[-\frac{(I-\mu_1)^2}{2\times\sigma_1{}^2}\right]} + A_2 \times \frac{1}{\sqrt{2\pi} \times \sigma_2} \times e^{\left[-\frac{(I-\mu_2)^2}{2\times\sigma_2{}^2}\right]}, \tag{7.34}$$

where A_1 and A_2 are normalized correction coefficients that take values in the range of 0–1, such that $\int_0^{+\infty} f(I) = 1$; μ_1 and σ_1 are, respectively, the mean and variance of the flicker of the streetlight intensity where the vehicle is located. μ_2 and σ_2 are, respectively, the mean and variance of the flicker of the intensity of the light from other sources.

The cumulative distribution function (CDF) of the background-light noise model is fitted by a double-Gaussian function, and the expression is [58]

$$\begin{aligned} F(I) &= \int_0^I f(X)d\mathrm{X} \\ &= \int_0^I A_1 \times \frac{1}{\sqrt{2\pi} \times \sigma_1} \times e^{\left[-\frac{(X-\mu_1)^2}{2\times\sigma_1^2}\right]} + A_2 \times \frac{1}{\sqrt{2\pi} \times \sigma_2} \\ &\quad \times e^{\left[-\frac{(X-\mu_2)^2}{2\times\sigma_2^2}\right]} \mathrm{d}X, \end{aligned} \tag{7.35}$$

where X is the variable.

Gaussian curves 1 and 2 in Fig. 7.4 characterize the noise model with weak and strong light-intensity fluctuations, respectively, and the double-Gaussian model superimposed on the two Gaussian curves is the Koch model. The model well matches the actual situation and can be used to characterize the noise model of visible-light communication for vehicular networking in different regions and under different weather conditions.

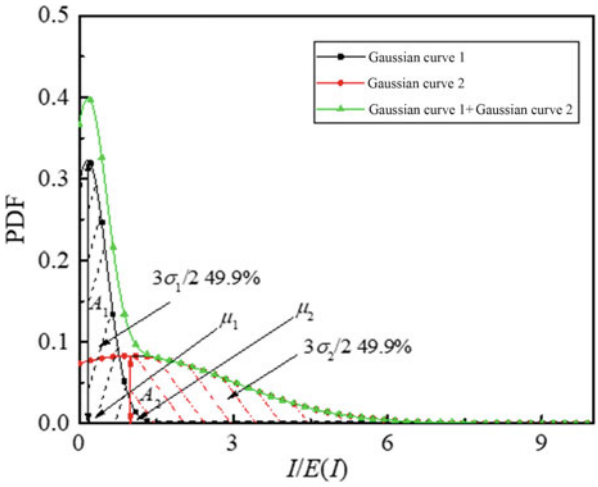

Fig. 7.4 Ke's noise model [56]

Beacon Noise

Research Progress

Beacon noise in optical wireless communication systems is mainly caused by the nonideal nature of optical receiving devices and signal processors, which can lead to signal distortion and signal-to-noise-ratio degradation. Beacon noise mainly includes thermal noise, dark-current noise, scattering noise, and 1/f low-frequency noise. In 2005, Bao et al. [65] conducted experimental and theoretical studies on the flicker noise (1/f noise) of optoelectronically coupled devices before and after electric stress and established a quantitative analysis model of 1/f noise. In 2007, Gao et al. [66] derived a mathematical model for the characteristics of avalanche photodiodes (APDs), based on Poisson's equation and the continuity equation of carriers.

In 2008, Wang [67] analytically modeled the scattering noise, thermal noise, and background noise in an optical wireless communication system and qualitatively analyzed the transmission performance of each part of the system, confidentiality performance, and other important indexes. In 2010, Hu et al. [68] elaborated on photodetector photoconversion circuits, amplifier-circuit noise, amplifier-circuit stability, etc., and designed an amplifier circuit that could effectively reduce the noise and temperature drift with a large dynamic input range.

In 2012, Wang et al. [69] theoretically analyzed the effect of background-light-induced scattering grain noise on a communication system, proposed a theoretical model that allowed for receiver sensitivity and the corresponding power loss, and experimentally verified the model. The experimental results showed that, in this system, when the operating bit rate was low, the background light led to a power loss of several decibels. The noise induced by the preamplifier increased as the bit rate increased, eventually dominating the noise process. In the same year, Wu et al. [70] explained in detail the physical model of the 1/f noise of tunnel-junction magnetoresistive sensors, built a test platform for it, and verified that the magnetic-shielding system had a good shielding effect on the ambient magnetic field.

In 2013, Kharraz et al. [71] analyzed the performance of PIN and APDs, which are commonly used photodetectors in optical communication systems, in terms of the bandwidth, gain, extinction ratio, and scattering noise. In the same year, Xu et al. [72] analyzed the time- and frequency-domain characteristics of circuit-board thermal noise and photomultiplier-tube dark-current noise in ultraviolet (UV) optical communication. In 2016, Li [73] proposed that the noise in photodetection circuits could be effectively addressed through a reasonable selection of amplifiers and amplification circuits.

In 2017, Zhai [74] illustrated the working principle and performance analysis of UV photodetectors with different structures, including photoconductive, PIN-type, Schottky-type, metal–semiconductor–metal (MSM)-type, and avalanche UV detectors. In 2019, Yan et al. [75] proposed a method to recover the clock and data directly from a discrete random-pulse sequence output from a single-photon avalanche diode. They experimentally verified the effects of the system-setup parameters,

such as the number of selective signals, length of synchronization characters, and baud rate, on the average bit-error rate.

In 2021, Xu [76] analyzed the average BER and average channel capacity of a free-space optical communication system under the influence of background noise, thermal noise, and quantum noise. In 2022, Mostafapour et al. [77] discussed the case of multiplicative noise in visible-light communication, modeled the implementation of a mobile adaptive network, and analyzed its performance. The results showed that the network had a completely different performance compared to the additive-noise case.

In the same year, Song et al. [78] investigated the effects of the receiver-temperature, average received light intensity, and magnitude of the avalanche-photodiode gain value on the reliability of an underwater optical wireless communication system subjected to the limitation of scattered grain noise. The results showed that the BER performance of the system could be improved to a certain extent by selecting a suitable avalanche-photodiode gain value. In 2023, Ke et al. [79] described a detector's scatter-grain noise, generating-complex noise, 1/f noise, and thermal noise, according to the photodetector noise-generation mechanism, and provided the corresponding mathematical model.

Noise Models

Poisson Noise Model

Poisson noise, also known as photon-counting noise or photon-jitter noise, arises primarily from the discrete nature of photons. When an optical signal passes through a detector, such as an avalanche photodiode, the randomness of the photon count causes the photocurrent to generate Poisson noise. Poisson noise is statistical noise that describes the randomness of the photon-counting process.

Poisson noise is related to the light intensity. As the fluctuation of the photon count increases with the light intensity, the Poisson noise becomes more severe. Therefore, the Poisson distribution can be used for modeling:

$$P(X = k) = \frac{e^{-\lambda}\lambda^k}{k!}, \tag{7.36}$$

where X represents the random variable, k is the number of occurrences per unit time, ! represents the factorial, and λ is the average occurrence rate per unit time.

When designing an optical wireless communication system, Poisson noise should be considered for its impact on the signal-to-noise ratio and bit-error rate, and corresponding measures should be taken to reduce its damage to system performance. These measures include selecting high-performance photodetectors, adopting digital signal-processing techniques, and optimizing the optical system design. The Poisson noise model has important applications in many fields, such as medical imaging, and can be used to describe the absorption of X-rays as they pass through human tissue.

Photon-Counting Noise Model

Photodiodes and avalanche diodes are often used as detection devices in optical wireless communication receiving systems. When a photon strikes the diode surface, the avalanche effect triggered by the diode generates a high current, thus counting the photons once. In the receiver, the relationship between the input optical signal S_i and the output electrical signal S_0 can be expressed as follows:

$$S_0 = S_i \cdot \mathrm{C}_P \cdot M + S_n, \tag{7.37}$$

where C_P is the photon-detection efficiency, M is the device gain, and S_n is the noise signal.

To detect the amplitude of the output impulse response, a judgment threshold can be set to ensure that the probability distribution meets the following requirements:

$$P(n, \lambda) = \frac{\lambda^n \exp(-\lambda)}{n!}, \tag{7.38}$$

where n represents the number of photoelectrons, λ represents the average pulse amplitude, and ! represents the factorial.

Multiplicative-Noise Model

In optical wireless communication systems, when using APDs and other devices with multiplication characteristics, the PN junction generates electron–hole pairs under the action of an external field. These electrons and holes move to the N and P regions, respectively, under the action of an electric field. In the high electric-field region (avalanche region), electrons and holes obtain sufficient energy to collide and dissociate to form more electron–hole pairs. This process is called avalanche multiplication.

The avalanche-multiplication process is random because it depends on the paths of the electrons and holes within the avalanche region, their velocities, and their interactions with the lattice. This randomness leads to fluctuations in the multiplication factor, resulting in avalanche multiplication noise. Avalanche multiplication noise is superimposed on the detected photocurrent signal, reducing the signal-to-noise ratio and thus affecting the performance of the communication system.

To assess the effect of avalanche multiplication noise on the system performance, the noise can be quantified by calculating the avalanche multiplication-noise factor (F_n). F_n is a function of the gain (M) of the APD and can be calculated using the following equation:

$$F_n = k \cdot M + \frac{1 - k}{M}, \tag{7.39}$$

where M is the gain of the APD. k is the ratio of the ionization coefficients of the APD and represents the relative strength of the avalanche multiplication effect produced by electrons and holes. The value of k is usually between 0 and 1 and is related to the material and structure of the APD.

When designing an optical wireless communication system, the relationship between the gain of the APD and avalanche multiplication noise must be determined. The impact of avalanche multiplication noise on the system performance can be reduced by optimizing the operating voltage of the APD, selecting a suitable gain, and using digital signal-processing techniques.

Photodetector-Amplification Noise Model

In photodetectors, the amplifier noise is an important source of noise, caused by the thermal movement of electrons across resistors and capacitors. The magnitude of this noise is related to the capacitance, resistance, and amplification of the photocurrent, and the gain of the device.

In optical receivers, in addition to the detector, other devices generate a large amount of thermal noise, particularly high-frequency preamplifiers. Because the total gain of the amplifier group is very high and the high-frequency amplification occurs first, the noise of the high-frequency amplifier will be progressively amplified in the subsequent levels. Therefore, a noise figure is required to describe the deterioration of the signal-to-noise ratio after the signal has passed through the amplifier circuit [61]. The noise factor is

$$N_F = 101g\frac{P_i}{P_o}(\text{dB}), \tag{7.40}$$

where N_F is the amplification of thermal noise by a high-frequency amplifier, P_i is the signal-to-noise power ratio at the input, P_o is the signal-to-noise power ratio at the output, and dB is the unit of the noise coefficient. It can be seen that the smaller N_F is, the lower the additional noise caused by the amplifier. Because both transistors and resistive elements in the circuit cause thermal noise, their noise factor is usually greater than 1.

Photodetector amplification noise is frequency-independent white noise. In this case, the noise can be reduced by improving the internal structure of the amplifier. Therefore, establishing and analyzing the amplified noise model of the photodetector will help optimize the structure and performance of the photodetector and improve its antinoise performance and accuracy in practical applications.

Dark-Current Noise Model

In the absence of external light of any type, there is no photocurrent output from the photodetector under ideal conditions. However, carriers excited by hot electron emission, field emission, or thermal vibration of the semiconductor lattice produce an output current called a dark current. It mainly consists of the complex current generated by carriers in the depletion layer, the diffusion current generated by minority carriers at the boundary of the depletion layer, and the leakage current at the surface.

The size of the dark current is proportional to the bias voltage and the junction area of the photodiode. When the bias voltage increases, the dark current increases with the junction area. The dark current also increases with the increase in the

operating temperature of the device. The process is essentially random fluctuation, and the resulting noise is called dark-current noise. It can be expressed as

$$\left\langle i_D^2 \right\rangle = 2q(I_D + I_L) \cdot \Delta f, \tag{7.41}$$

where I_D is the dark current and I_L is the leakage current.

Thermal Noise Model

Thermal noise, which is primarily caused by currents generated by free electrons and ions inside the material as they randomly move, can be characterized by calculating the noise-equivalent bandwidths, noise coefficients, and other relevant information.

For a single carrier, the direction of thermal motion is highly random, and the average value of its current tends to zero over time. For a large number of carriers, the number of carriers moving in one direction at one instant in time is relatively large, and the number of carriers moving in the other direction at another instant in time is also relatively large. However, they have equal chances in each direction; thus, the total current effect is zero over time.

At a given instant, the current is not always zero; however, localized charges may build transiently, giving rise to undulating currents and voltages. This thermal noise in the load resistor is further amplified using a front-end amplifier. The thermal-noise power in the load resistor R_{L} can be defined as

$$S_t(f) = \frac{2k_{\mathrm{B}}T}{R_{\mathrm{L}}}, \tag{7.42}$$

where t denotes time, f denotes frequency, T denotes absolute temperature, R_{L} denotes load resistance, and k_{B} denotes Boltzmann's constant with the value of $k_{\mathrm{B}} = 1.380649 \times 10^{-23}\mathrm{J/K}$.

It can be seen that the power spectral density of the thermal noise is temperature- and amplifier-gain-dependent and is white noise. The noise figure can be used to describe the noise level of the device.

Shot Noise Model

When light collides with the surface of the detector, a large number of electrons are generated, and the movement of the electrons at the output of the detector triggers a current pulse effect that affects the external monitor or sensor [64]. This process can be described as follows:

$$x(t) = \sum_{j=1}^{\mathrm{K(v)}} h\big(1 - Z_j\big), \tag{7.43}$$

where t represents time, v represents the volume of the detection site, j represents the j^{th} electron, $h(t)$ represents the impulse response of a single electron, Z_j represents the release time of the j^{th} electron, and K(v) is a parameter used for counting. This count

represents the number of electrons generated in a volume v with a detector area of ϖ over the entire time interval, a process known as shot noise.

1/f Noise Model

1/f noise is a class of random noise with long-range correlation, self-similarity, and nonsmoothness; it is a common rise-and-fall phenomenon in the collective motion of particles and reflects the internal characteristics of the system. 1/f noise is mainly caused by the interaction of impurities and defects with carriers in the device and can sensitively reflect the existence of various potential defects in the device.

The main characteristic of 1/f noise is that the noise power-spectral density is inversely proportional to the frequency. Specifically, the power-spectral density of 1/f current noise decreases with increasing frequency, showing a decaying trend. That is, low-frequency components contribute more to the noise, while high-frequency components contribute less to the noise.

The 1/f current-noise power-spectrum expression is [65]

$$S(f) = \frac{AI^{\beta}}{f^{\gamma}}, \tag{7.44}$$

where I is the current in the device, f is the frequency, A is determined by the structural characteristics of the device, and γ and β are specific coefficients.

The effect of 1/f noise on optical communication systems may lead to data-transmission errors and degrade the system performance. Therefore, designers of optical communication systems must take measures to minimize the effects of 1/f noise.

Performance Analysis of Optical Wireless Communication Systems Under the Influence of Turbulence

In a turbulent channel with a Malaga probability distribution, the probability-density function of I can be expressed as

$$f_I(I) = \frac{g^2 A^{(G)}}{2I} \sum_{k=1}^{\infty} {a_k}^{(G)} \left(\frac{\alpha}{\xi_g}\right)^{-\frac{\alpha+k}{2}} G_{1,3}^{3,0}\left[\frac{\alpha I}{\xi_g A_0 I_1}\sqrt{\frac{\gamma_{th}}{\gamma_0}}\middle| \begin{matrix} 1+g^2 \\ g^2, a, k \end{matrix}\right] \tag{7.45}$$

$$A^{(G)} \triangleq \frac{2\alpha^{\frac{\alpha}{2}}}{{\xi_g}^{1+\frac{\alpha}{2}}\Gamma(\alpha)} \left(\frac{\xi_g \beta}{\xi_g \beta + \Omega'}\right)^{\beta} \tag{7.46}$$

$${a_k}^{(G)} \triangleq \frac{(\beta)_{k-1}\left(\alpha\xi_g\right)^{\frac{k}{2}}}{[(k-1)!]^2} \left(\frac{\Omega'}{\xi_g + {\xi_g}^2 \beta}\right)^{k-1}, \tag{7.47}$$

where k is the wave number; $K_n(\cdot)$ is the n-order type-II modified Bessel function; α and β are parameters related to the outer scale L_0 and inner scale l_0 of turbulence, respectively; g is the ratio of the equivalent beam radius at the receiver to the standard deviation of the displacement of the alignment direction error; ξ_g is the average power of the scattered light received off-axis; Ω' is the ratio of the distribution of the average optical power related to the average optical power of the line-of-sight component, etc.

γ_{th} is the communication interruption threshold of an optical receiver, i.e., when the signal-to-noise ratio $\gamma < \gamma_{th}$, a communication system, can be considered to be interrupted. γ_0 is the average signal-to-noise ratio of the received signal at the optical receiver, and $G_{p,q}^{m,n}(\cdot|\cdot)$ represents the Meijer G-function.

Turbulence significantly affects the error rate, interruption probability, and channel capacity of optical wireless communication systems. The average error rate under the influence of turbulence can be expressed as [80]

$$\overline{R}_{\mathrm{BER}} = \int_0^{\infty} P_{\mathrm{BER}}(I) f_I(I) dI, \tag{7.48}$$

where $P_{\mathrm{BER}}(I)$ is the probability-density function of the error rate. For M-order modulation optical communication systems, the probability-density function of the bit-error rate can be expressed as

$$P_{\mathrm{BER}}(I) = 2\left(1 - \sqrt{M}^{-1}\right) erfc\left(\gamma_0 I^2\right), \tag{7.49}$$

where $erfc(\cdot)$ is the compensation error function, which can be expressed as a Meijer G-function:

$$erfc\left(\sqrt{x}\right) = \frac{1}{\sqrt{\pi}} G_{1,2}^{2,0}\left[x \middle| \begin{matrix} 1 \\ 0, \frac{1}{2} \end{matrix}\right]. \tag{7.50}$$

Substituting Eqs. (7.45) and (7.49) into Eq. (7.48), the expression for the average bit-error rate can be obtained as

$$\overline{R}_{\mathrm{BER}} = \frac{\left(1 - \sqrt{M}^{-1}\right) g^2 A^{(G)}}{\pi\sqrt{\pi} \times 2^{3-(a+k)}} \sum_{k=1}^{\infty} a_k{}^{(G)} \left(\frac{a}{\xi_g}\right)^{-\frac{a+k}{2}} \times$$
$$G_{7,4}^{2,6}\left[16\gamma_0 \left(\frac{\xi_g A_0 I_1}{\alpha}\right)^2 \middle| \begin{matrix} \frac{1-g^2}{2}, \frac{2-g^2}{2}, \frac{1-\alpha}{2}, \frac{2-\alpha}{2}, \frac{1-k}{2}, \frac{2-k}{2}, 1 \\ 0, \frac{1}{2}, -\frac{g^2}{2}, \frac{1-g^2}{2} \end{matrix}\right]. \tag{7.51}$$

Owing to the influence of turbulence, the average channel capacity of an optical wireless communication system is

$$\overline{C} = \int_0^{\infty} 1b\left(1+\gamma_0 I^2\right) f_I(I) dI \tag{7.52}$$

$$1b\left(1+\gamma_0 I^2\right) = \frac{1}{\ln 2} G_{1,2}^{1,2}\left[\gamma_0 I^2 \middle| \begin{matrix} 1,1 \\ 1,0 \end{matrix}\right]. \tag{7.53}$$

Equations (7.45) and (7.53) are substituted into Eq. (7.52) to derive the average channel capacity of the system, as follows:

$$\overline{C} = \frac{g^2 A^{(G)}}{\pi \ln 2} \sum_{k=1}^{\infty} 2^{a+k-4} {a_k}^{(G)} \left(\frac{a}{\xi_g}\right)^{-\frac{a+k}{2}} \times G_{8,4}^{1,8}\left[16\gamma_0 \left(\frac{\xi_g A_0 I_1}{\alpha}\right)^2 \middle| \begin{matrix} 1, 1, \frac{1-g^2}{2}, \frac{2-g^2}{2}, \frac{1-\alpha}{2}, \frac{2-\alpha}{2}, \frac{1-k}{2}, \frac{2-k}{2} \\ 1, -\frac{g^2}{2}, \frac{1-g^2}{2}, 0 \end{matrix}\right]. \tag{7.54}$$

The interruption probability of an optical wireless communication system can be expressed as

$$P_{\text{oug}} = P_{\text{BER}}(\gamma < \gamma_{th}) = \int_0^{\gamma_{th}} f_{\gamma}(\gamma) d\gamma. \tag{7.55}$$

The relationship between the probability-density function of the signal-to-noise ratio γ and I is

$$f_{\gamma}(\gamma) = \frac{1}{2\sqrt{\gamma\gamma_0}} f_I\left(\sqrt{\frac{\gamma}{\gamma_0}}\right). \tag{7.56}$$

Thus, it can be concluded that the average channel capacity of the system is

$$P_{\text{oug}} = \frac{g^2 A^{(G)}}{2} \sum_{k=1}^{\infty} {a_k}^{(G)} \left(\frac{a}{\xi_g}\right)^{-\frac{a+k}{2}} \times G_{2,4}^{3,1}\left[\frac{\alpha}{\xi_g A_0 I_1} \sqrt{\frac{\gamma_{th}}{\gamma_0}} \middle| \begin{matrix} 1, 1+g^2 \\ g^2, a, k, 0 \end{matrix}\right]. \tag{7.57}$$

Conclusion

Noise modeling in optical wireless communication systems is a key tool for evaluating the system performance, optimizing parameters, and designing signal-processing algorithms. Studying noise models can help investigators understand

the effect of noise on the system, predict the performance limit of the system, and provide methods to guide system design and optimization.

This chapter summarized the main research work on noise models in optical wireless communications at home and abroad and highlighted Ke's model, the turbulent noise model, thermal noise model, background-light noise model, etc. Each model has different adaptive scenarios and their characteristics, as shown in Table 7.2.

Table 7.2 Summary of noise models

Noise model	Characteristics
Laser relative-intensity noise model	Laser noise is mainly related to the average power of the beam and the bandwidth of the detector
Laser phase noise model	The laser phase-noise process can be described by the Wiener process
Turbulent noise model	When the turbulence intensity in atmospheric channels is small, the lognormal model and Γ-Γ model can be used; the K-distribution model can be used to describe the situation when the turbulence intensity in the atmospheric channel is high
Phase noise model	Phase noise can seriously affect the demodulation of subcarrier signals, leading to system-performance degradation
Aiming noise model	By designing an appropriate a/w_z ratio to make the f_{h_p} curve an increasing function, the communication system performance can be improved; otherwise, it will increase the probability of signal fading
Background-light noise model	As the receiving field-of-view angle increases, the power of the background light increases
Ke's model	This model characterizes the visible-light communication noise of vehicle-to-everything in different regions and under different weather conditions
Poisson noise model	Poisson noise is related to the light intensity; the greater the light intensity, the greater the fluctuation in the number of photons received, resulting in more severe Poisson noise
Photon-counting noise model	The photon distribution is a Poisson distribution
Multiplicative noise model	Avalanche doubling noise is random
Photodetector-amplification noise model	The magnitude of amplification noise in photodetectors is related to various factors, such as the capacitance, resistance, and the amplification factor of the photocurrent
Thermal noise model	The power-spectral density of thermal noise is related to the temperature, amplifier gain, and other factors and is a white noise. The noise figure can be used to describe the noise level of a device
Dark-current noise model	The magnitude of the dark current is proportional to the bias voltage and the junction area of the photodiode
Shot noise model	Shot noise is a strongly random noise; its size and distribution can be analyzed based on Poisson's distribution theory
1/f noise model	1/f noise has long-range correlations, and its composition is relatively complex

Current noise-modeling research still faces some challenges and shortcomings. For example, more in-depth studies are required to model background-light noise in complex environments, and more accurate modeling methods are required to determine the effects of nonlinear effects and multipath propagation on noise. In addition, more in-depth and detailed explorations are required for noise modeling in different application scenarios and system requirements.

Based on the above analyses, future research can focus on the following aspects. First, noise models can be further improved to increase their accuracy and applicability. Second, additional experimental and simulation studies should be conducted to verify the validity of the noise models and provide guidance for practical system design and optimization. In addition, new noise-modeling methods and noise-suppression strategies should be explored in combination with techniques, such as machine learning and deep learning, to improve the performance and stability of the system.

Abstract

The transmission of optical signals in atmospheric turbulent channels causes signal fading and light intensity flicker, and the baseband signal cannot be recovered correctly by fixed threshold detection at the receiving end, so adaptive adjustment of the received signal decision threshold is required. Adaptive threshold detection technology can effectively suppress the atmospheric turbulence effect, which is an important means to improve the bit error rate performance of optical wireless communication systems and enhance system reliability. Its detection performance is mainly optimized and

improved for the threshold detection algorithm and feedback mechanism. Reviewing the development process of adaptive threshold detection technology, starting from the structure of optical wireless communication system, deriving the optimal decision threshold model for the received signal based on Bayesian maximum likelihood estimation and maximum posterior probability criteria, and the realization of baseband signal demodulation by comparing the received signal with the optimal decision threshold. The typical adaptive threshold detection models based on the minimum mean square error filter, Kalman filter, and fading Kalman filter are analyzed, which are suitable for stationary input signals and nonstationary input signals, respectively. At the same time, the related research work of Xi′an University of Technology using high-order cumulants instead of traditional second-order statistics in the field of adaptive threshold detection is introduced. Finally, the future development trend of this field is summarized and foreseen, which can provide some reference for the future research and development of adaptive threshold detection technology for optical wireless communication.

Introduction

When an optical signal is transmitted in a turbulent atmospheric channel, the signal fades and the light intensity flickers, and the receiver cannot correctly recover the baseband signal using fixed-threshold detection [1]. Therefore, it is necessary to adaptively adjust the decision threshold of the received signal. This chapter reviews the development of adaptive-threshold detection technology.

Starting from the structure of optical wireless communication systems, based on Bayesian maximum-likelihood estimation and the maximum a posteriori probability criterion, the optimal decision threshold model of the received signal is derived, and the baseband signal is demodulated by comparing the received signal with the optimal decision threshold.

This chapter analyzes typical adaptive-threshold detection models based on three algorithms: least mean-squared error filtering, Kalman filtering, and fading Kalman filtering, which are applicable to stationary and nonstationary input signals. In addition, it introduces the research work of Xi'an University of Technology in the field of adaptive-threshold detection and finally summarizes and projects the development trends of this field in the future. It can provide a reference for the research and development of adaptive-threshold detection technology in future optical wireless communications [2, 3].

Domestic and Foreign Research Progress

Adaptive-Threshold Detection

In a optical wireless communication system, the received signal must be compared with the threshold value after receiving an optical signal. When the signal is greater than the threshold, the output is "1," and when the signal is lower than the threshold, the output is "0." Affected by atmospheric scintillation, the amplitude of the received signal fluctuates randomly, as shown in Fig. 8.1.

Errors can easily occur when using a fixed threshold. Therefore, it is necessary to study adaptive thresholds. Adaptive-threshold detection automatically adjusts the decision threshold according to changes in the received signal strength. Compared with fixed-threshold detection, adaptive-threshold detection has a wide dynamic range, and fast establishment and tracking speeds.

Using binary-threshold detection [4] as an example, adaptive-threshold detection is shown in Fig. 8.2. After receiving a signal, the receiver compares the sample value $r\ (k-1)$ of the current bit signal with the optimal decision threshold $U_T(k-1)$ and obtains the decision result, according to the decision criteria. If $r\ (k-1)$ is greater than $U_T\ (k-1)$, the decision result outputs a "1"; otherwise it outputs a "0." Then, the mean and variance of the current bit signal are estimated according to a certain amount of sampling data, and input into the adaptive predictor, which predicts the mean and variance of the signal the next time through the prediction algorithm. Then, the optimal decision-threshold value $U_T\ (k)$ at the next time is obtained and the

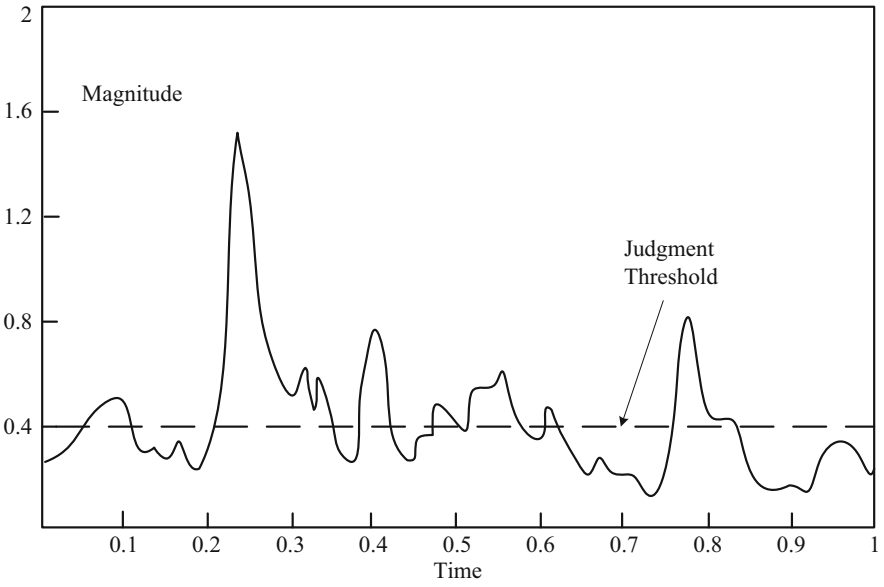

Fig. 8.1 Signal threshold detection waveform

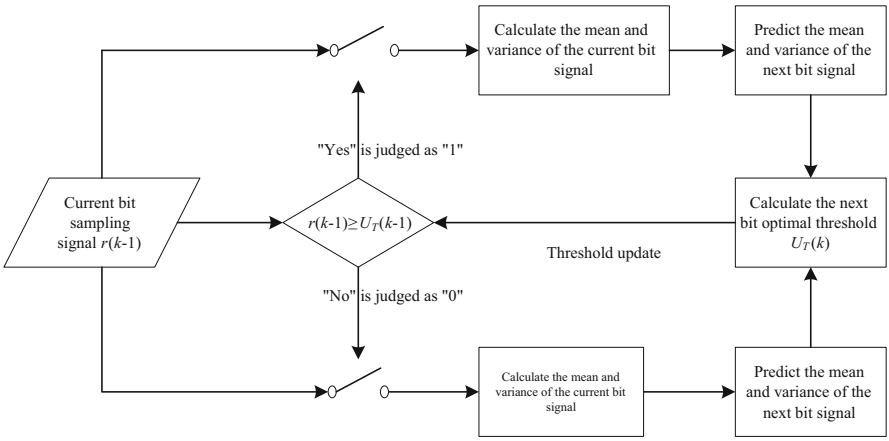

Fig. 8.2 Schematic diagram of adaptive-threshold detection [4]

threshold is updated, so that $U_T(k)$ can make a comparative decision about the next bit signal.

Foreign Research Progress

Threshold detection technology [5] appeared in the 1960s and was first proposed by Urkowitz, based on signal energy, as an unknown signal-detection method. Because this method is greatly affected by noise and has certain limitations, it has been continuously studied and improved since then. A fixed threshold has been used since early signal detection. With the increasing communication-quality requirement, an adaptive threshold, which automatically adjusted the decision threshold with the change in received signal strength, was urgently needed [6]. Therefore, adaptive-threshold detection was proposed in the late 1990s.

In 2001, Mukai et al. [7] used adaptive threshold detection technique in deep space optical communication, which uses the average signal strength to estimate the degree of signal fading and total attenuation in response to changing channel conditions. However, the adaptive threshold detection technique used is not yet mature and requires further research.

In 2002, Burris et al. [8] introduced Kalman estimation for adaptive-threshold detection in optical wireless communication. In an optical communication receiver with multiplicative noise, the likelihood-ratio test (LRT) scheme was used. The Kalman filter algorithm was used to track the mean and variance of the bits and update the detection threshold.

In 2003, Kahn et al. [9] investigated the effect of three time-domain detection techniques, Maximum-Likelihood (ML) symbol-by-symbol detection, Maximum-Likelihood Sequence Detection (MLSD), and Pilot-Symbol (MLSD) and Pilot-Symbol Assisted Detection (PSAD) techniques to mitigate the light intensity

fluctuations caused by atmospheric turbulence. Experimental results show that MLSD and PSAD obtain signal-to-noise gains of 2.4 dB and 1.9 dB, respectively, compared to ML-by-symbol. Since MLSD exploits the temporal correlation of intensity fluctuations, its detection performance is better than the other two time-domain detection techniques and thus has been widely studied since then, but its cost and complexity are high.

In 2004, Cole et al. [10] proposed using the minimum mean-square error (MMSE) to estimate the fading degree of a signal. In weak turbulence, the detection performance of this algorithm was significantly higher than that of the maximum-likelihood algorithm.

In 2005, Namazi et al. [11] proposed a new method for the binary-data synchronization and detection of free-space optical signals, based on wavelet transform and adaptive Wiener filtering. The fixed-scale Haar wavelet transform was analyzed, the bit-error probability was obtained using the Bayesian ternary hypothesis test, and the optimal threshold detection model was deduced.

In 2007, Schober et al. [12] investigated Decision-Feedback Detection (DFD) link for symbol-by-symbol decision using the observation window of the previous decision and reception statistics. Simulation results show that the performance of the judgment-feedback link approaches the lower limit of coherent detection as the window length increases.

In 2009, Rieger et al. [13] proposed an optimal multisymbol detection (MSD) fast-search algorithm for incoherent detection in space optical communication, as well as suboptimal multisymbol detection with a low-complexity decision metric. This significantly improved the detection performance of optical wireless communication with long sequences; however, the algorithm required extensive calculation time.

In 2010, Moradi et al. [14] further studied pilot-symbol-assisted detection technology based on Kahn et al. When the channel coefficients were time-dependent, pilot-symbol-assisted detection was used to modify the maximum-likelihood function and could be extended to multiple-input multiple-output optical communication systems. However, this detection technology required a time-joint and edge probability-distribution density function, which increased the complexity of the receiver.

In 2010, Chatzidiamantis et al. [15] proposed a low-complexity suboptimal detection scheme based on generalized MLSD, considering the high computational complexity of optimal MLSD in practical applications. The scheme did not require any channel information and only used the observations of the received sequence, avoiding a complex decision process; however, it had poor performance in small observation windows.

In 2013, Kam et al. [16] designed a generalized maximum-likelihood ratio test receiver, based on maximum-likelihood sequence detection and the generalized likelihood ratio test. It did not require channel-state or channel-model information. It used the data symbols detected in the past to estimate the instantaneous channel gain and transmit power and adaptively adjusted the decision threshold. Compared

with a receiver that needs channel-model information, it has better robustness but needs a pilot at the beginning of the data transmission.

In 2013, Beaulieu et al. [17] deduced the optimal signal-detection formula for Laplace white noise and compared it with a digital matched filter for Gaussian noise. The simulation results showed that the signal-to-noise ratio (SNR) of this method was twice that of a Gaussian-noise matched filter.

In 2017, Dabiri et al. [18] considered the complexity and cost of MLSD and differential signal technology and adopted a blind estimation algorithm for on–off keying (OOK) signals. It achieved a lower bit-error performance without increasing the complexity of the receiver; however, the data length in the observation window needed to be adjusted frequently.

In 2019, Choi et al. [19] inserted single-tone guide frequency in the transmit signal to estimate the turbulent channel information for satellite optical communication, and the extracted channel state information is close to the full channel state information, which can mitigate the scintillation effect caused by turbulent atmosphere, but complex filtering process is required to suppress the crosstalk.

In 2019, Shin et al. [20] proposed an OOK differential-detection technology to solve the problem in which the implementation complexity of adaptive-threshold detection increased with an increase in the data transmission rate. It used the best decision threshold with a sequence-symbol differential method to reduce the implementation complexity.

In 2021, Choi et al. [21] proposed an adaptive-threshold decision mechanism using a random-approximation algorithm to predict the next-frame decision threshold for multilevel pulse amplitude modulation in optical wireless communication. This technology adaptively tracked the dynamics of intensity fluctuations, smoothed the intensity fluctuations, including noise signals, and improved the performance of the receiver.

Domestic Research Progress

In 2006, Wang et al. [22] used the adaptive-Kalman and homomorphic filters of a linear state model to predict the signal and turbulence statistical characteristics contained in the detection threshold. It used adaptive-threshold detection under different signal-to-noise ratio conditions and had a good inhibitory effect on atmospheric turbulence noise. The simulation and experimental results showed that under weak turbulence, the bit-error rate (BER) of the communication system with an SNR of 10–20 dB was better than that of the system with adaptive-threshold detection technology.

In 2008, Wu et al. [23] studied an adaptive-threshold detection method for signal and noise power and proposed an adaptive-threshold detection method for comparison and decisions in a sliding window. This method effectively eliminated false alarms when the signal was small and captured the signal more accurately.

In 2008, Wang [24] proposed a decision-directed (DD) algorithm based on the third-order cumulant. It used the higher-order cumulant as the cost function to update the tap coefficients of the adaptive filter, which effectively suppressed additive noise. They also verified the insensitivity of the higher-order cumulant to Gaussian noise.

In 2009, Zhao [25] proposed an adaptive sliding correlation detection method that performed cumulative correlation on the received signal, according to the sliding correlation-detection principle, to obtain the adaptive decision threshold. This method reduced the false-alarm probability and improved the probability of detecting the received signal, without increasing the system complexity.

In 2012, Wang et al. [26] studied the effect of a dynamic decision threshold (DDT) scheme adopted by the receiver to improve the bit-error performance of a coherent-optical communication system. The scheme detected the received optical signal frame by frame and provided a decision threshold for signal detection by monitoring the preamble in each detection frame, which is only applicable to low-data-rate communication. The experimental results showed that when the flicker index was 1.0, the dynamic decision threshold scheme achieved a 10^{-3} bit-error rate.

In 2013, Li et al. [27] fitted an optimal synchronization-threshold curve by analyzing the change rule of the synchronization threshold under different signal-to-noise ratios and proposed an optimal threshold-selection method. The system performance of this method was close to that of optimal threshold detection under an additive Gaussian white-noise channel, which was approximately 3 dB better than the fixed-threshold system performance.

In 2014, Shang et al. [28] proposed an improved algorithm to adjust the threshold, based on the signal-to-noise ratio according to the parameter setting. It was intended to address the low detection probability of the adaptive-threshold decision pseudo-random (PN) code-acquisition method for low signal-to-noise ratios. Monte Carlo simulation results showed that the algorithm had a higher detection probability, lower false-alarm probability, better anti-interference ability, and strong practicability.

In 2015, Zhang et al. [29] proposed an adaptive-threshold detection algorithm for the variable threshold factor estimation of noise energy using the k^{th} small element to replace the ranking noise-energy estimation. This algorithm only used a few iterations in the sorting algorithm, which greatly reduced its computational load and enabled fast adaptive-threshold decision detection without reducing the detection performance.

In 2015, Tian [30, 31] studied the problem of signal detection in strong atmospheric-turbulence channels. The experimental results showed that adaptive-threshold detection could significantly reduce the bit-error rate of optical communication systems in K-distributed turbulent channels. The more symbol samples, the better the system performance, but the higher the algorithm complexity.

In 2017, Dang et al. [32] studied an adaptive-threshold decision scheme for optical wireless communication systems without channel-state information. Based on the low-pass characteristics of atmospheric turbulence, a low-pass filter extracted instantaneous intensity fluctuations from the optical carrier component; the filtered output could be directly used as the decision threshold. Monte Carlo simulation results showed that the performance of this scheme was very close to the lower decision limit of ideal channel-state information for high-speed data transmissions.

In 2018, Zhang et al. [33] introduced a fading-Kalman filter algorithm into the adaptive-threshold detection process of optical wireless communication, effectively suppressing the impact of atmospheric turbulence. The simulation results showed that, when SNR = 10, the error rate of the adaptive-threshold detection using the

fading Kalman filter algorithm was approximately four orders of magnitude higher than that of the fixed threshold.

In 2018, Zhang et al. [34] studied the bit-error rate performance of duplex reverse-modulation optical wireless communication systems with adaptive decision thresholds under weak and strong turbulence conditions, considering the influence of detector noise. While solving for the optimal adaptive decision threshold and analyzing the bit-error rate performance, an expression for calculating the optimal adaptive decision threshold of the duplex reverse-modulation optical-communication system was also derived. Simulation results showed that an adaptive decision threshold could improve the bit-error performance of an optical communication system.

In 2018, Zhu et al. [35] proposed an adaptive-threshold detection method, based on the quantized voltage of the determined signal, to obtain the current symbol decision threshold. The DC component of the signal was extracted as a continuous-wave reference light to estimate the fluctuation characteristics of the atmospheric-turbulence channel. This reduced the high cost caused by the reference light carrying no information, and the power loss was lower.

In 2018, Geng et al. [36] designed two adaptive thresholds at the receiving end to detect the same and orthogonal branches of the signal; they did not require instantaneous channel-state information or a probability-density function. To improve the accuracy of the threshold, a decision-aid method for setting the second detection threshold was also provided. The simulation results showed that the performance of the double adaptive-threshold detection system was close to that of an ideal adaptive detection system.

In 2019, Li et al. [37] studied the error-rate performance under atmospheric-turbulence fading with a large-range correlation and proposed a new blind-detection method based on an adaptive threshold. The closed expressions of the instantaneous and average bit-error rates using the optimal adaptive threshold were derived and provided some references for the design of optical wireless communication systems.

In 2019, Jiang et al. [38] designed a new signal-detection algorithm that used stochastic-resonance technology to transform part of the noise energy into useful signal energy to improve the system's signal-to-noise ratio. It then used a two-threshold two-step algorithm for signal detection. The algorithm improved the accuracy of detection signals and reduced the interference between signals.

In 2020, Zhang et al. [39] proposed a local adaptive-threshold frequency-hopping (FH) signal-extraction and detection method. Based on a short-time Fourier transform, the appropriate local adaptive threshold was solved to eliminate the fixed-frequency interference, extract the frequency-hopping signal in the communication, and detect the extraction result. Simulation results showed that this method could effectively detect FH signals and had low complexity and high reliability.

In 2020, Liu [40] proposed a 16-way quality amplitude modulation (16-QAM) carrier-lock detection algorithm based on an adaptive threshold. Through a statistical analysis of input signals, the threshold was adjusted in real time, according to the input-signal distribution. The proposed adaptive threshold better adapted to carrier-

locking detection under different data conditions and improved the detection reliability. This was verified in satellite-docking experiments.

In 2022, Liu et al. [41] proposed a local adaptive-threshold method that was calculated in a small local window. It effectively reduced the probability of false and missed alarms and had good background-suppression ability and high detection accuracy.

System Structure and Model

Optical Wireless Communication System Structure

The structure of a optical wireless communication system [42, 43] is shown in Fig. 3.1. It mainly includes an optical transmitter, atmospheric channel, and optical receiver. The optical transmitter is composed of a signal source, modulator, laser, driving circuit, and transmitting telescope. The transmitter's function is to convert the generated electrical signal into an optical signal by modulating it onto the optical carrier, and then transmit it using the optical transmitting antenna.

The beam emitted by the transmitting antenna reaches the receiving end after transmission through a turbulent atmospheric channel. The optical receiver is composed of an optical receiving antenna, optical filter, photoelectric detector, and decision apparatus. Its function is to filter the received optical signal, send it to a photoelectric detector for a photoelectric conversion and comparison, demodulate it into an electrical signal, and recover the transmitted data.

Photoelectric Detection Noise

In long-distance optical wireless communication systems, photoelectric detectors are required to have high reception sensitivity, and avalanche photodiode (APD) detectors are generally used. The APD is a P-N structure optical-detection diode that uses the avalanche effect of carriers to amplify the photoelectric signal. However, the detector output current contains thermal, shot, amplifier, undercurrent, and other noise sources, which affect the optimal decision threshold of the system.

Thermal and shot noise are the main noise sources of photoelectric detectors. They are independent of each other and can be approximated as zero-mean Gaussian noise. Thermal noise [44] can be expressed as the mean-square thermal-noise current:

$$\sigma_T^2 = 4kTfG^2/R_L, \tag{8.1}$$

where k is the Boltzmann constant, T is the thermodynamic temperature, F is the working bandwidth of the detector, G is the amplifier gain, and R_L is the load resistance.

Shot noise describes the random fluctuation in the photoelectron-generation process, and its variance is related to the signal strength. It is expressed as the mean-square shot-noise current [45]:

$$\sigma_S^2 = 2efMNG\langle U_S\rangle = 2efM^2NG^2\langle P_R\rangle R, \tag{8.2}$$

where the signal voltage $U_S = MGP_RR$, P_R is the optical receiving power, $\langle\rangle$ represents the ensemble average, and e is the electronic charge. M is the APD multiplication factor, N is the APD noise coefficient, and R is the detector response when $M = 1$.

Error Rate

In an optical wireless communication system, the bit-error rate refers to the probability that the received symbol is misjudged. This is an important performance index for evaluating communication systems. It is composed of the false-alarm probability (P_F) and missing-alarm probability (P_M).

A false-alarm probability refers to the probability of misjudging a transmitted "0" as "1" when the amplitude of the source noise voltage exceeds the detection threshold. The probability of a missing alarm refers to the probability that the sum of the noise and signal voltages is less than the detection threshold, and a "1" is misjudged as a "0" when transmitting.

The false-alarm probability [46] can be expressed as

$$P_F = \frac{1}{2}erfc\left(\frac{U_T - U_0}{\sqrt{2\sigma_0^2}}\right). \tag{8.3}$$

The probability of a missing alarm [46] can be expressed as

$$P_M = \frac{1}{2}erfc\left(\frac{U_1 - U_T}{\sqrt{2\sigma_1^2}}\right), \tag{8.4}$$

where $erfc()$ represents the complementary error function, U_T represents the decision threshold, $\langle U_0\rangle$ and σ_0^2 represent the mean and variance of the signal voltage at "0," respectively, and $\langle U_1\rangle$ and σ_1^2 represent the mean and variance of the signal voltage at "1," respectively.

If "0" and "1" are sent, the error rate [46] of the system is expressed as

$$BER = \frac{1}{4}erfc\left(\frac{U_T - \langle U_0\rangle}{\sqrt{2\sigma_o^2}}\right) + \frac{1}{4}erfc\left(\frac{\langle U_1\rangle - U_T}{\sqrt{2\sigma_1^2}}\right). \tag{8.5}$$

Optimal Threshold Detection

To recover the information of a transmitted signal, the receiver must set a critical value for comparison with the received signal and demodulate the signal. The critical value is the threshold value. A value higher or lower than the threshold causes different changes in the signal-decision state.

Taking the binary return-to-zero code as an example, the decision threshold is typically set to 0.5. If the received-signal sampling value is greater than 0.5, it will be judged as a "1"; otherwise, it will be judged as a "0." Generally, an optimal decision threshold that can minimize the bit-error rate of the system can be found to enable the optimal reception of the received signal by the receiver.

In an adaptive receiver, optimal threshold detection [47] is based on the Bayesian likelihood-ratio test (LRT), according to the maximum a posteriori (MAP) criterion. It involves estimating and predicting the mean and variance of the signal level and relevant parameters of the atmospheric channel to obtain an optimal decision threshold and achieve adaptive reception. Therefore, the optimal decision threshold corresponding to the minimum bit-error rate is not a constant value; rather, it is a variable value that changes with atmospheric turbulence.

(1) Receiving-Signal Analysis

The receiver's adaptive-threshold decision system is shown in Fig. 8.3. It is composed of an optical receiver, front-end symbol estimator, decision circuit, and adaptive-threshold estimator and predictor [48]. The receiver first uses maximum-likelihood sequence estimation to estimate the front-end symbols, predicts and tracks the received signal, and then predicts the changes in the mean and variance of the symbols. It then obtains the optimal detection-threshold value to ensure that the bit-error rate is close to the theoretical minimum value. It compares the received signal with the obtained optimal detection threshold, makes a decision in the decision circuit, and demodulates the baseband signal.

Assuming that the received signal follows a lognormal distribution and adopts OOK modulation, the received signal model [49] can be expressed as

$$r(t) = \frac{\gamma e\lambda}{hc} I_0(t) \exp[2\chi - 2E(\chi)] + n_1(t) + n_2(t), \tag{8.6}$$

where γ is the quantum efficiency of the detector, λ is the laser wavelength, h is the Planck constant, c is the propagation speed of light in a vacuum, and $\frac{\gamma e\lambda}{hc}$ is defined as

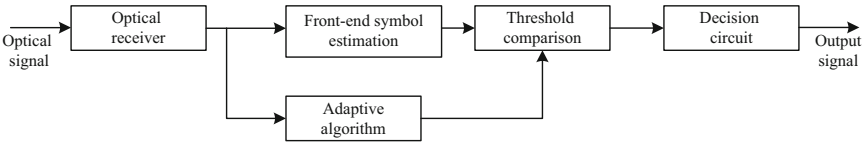

Fig. 8.3 Adaptive-threshold decision system [49]

the photoelectric-conversion efficiency η. $I_0(t)$ is the light intensity of the received signal without considering atmospheric turbulence, χ is the logarithmic amplitude fluctuation, $E[\chi]$ is the mean value of χ, $n_l(t)$ is the sum of Gaussian noise, such as thermal noise and amplifier noise unrelated to the received signal, $n_2(t)$ is the multiplicative noise related to the received signal, and $n_1(t)$ and $n_2(t)$ are statistically independent.

(2) **Maximum-Likelihood Estimation**

To achieve the best reception effect, the receiver generally uses maximum-likelihood estimation (MLE) to estimate the actual input value through several observations without any prior knowledge [50].

Assuming that the received data is optimally sampled and the symbols have been synchronized, the conditional-probability distribution function [51] when the transmitter sends a "0" (H0) is expressed as

$$p(r|H_0) = \frac{1}{\sqrt{2\pi\sigma_n^2}} \exp\left(-\frac{r^2}{2\sigma_n^2}\right), \tag{8.7}$$

where σ_n^2 is the detector noise variance; $\sigma_n^2 = \sigma_{n_1}^2 + \sigma_{n_2}^2$; $\sigma_{n_1}^2$ and $\sigma_{n_2}^2$ are the variances of noises $n_1(t)$ and $n_2(t)$, respectively; and r is the received signal.

The conditional-probability distribution function [51] when sending a "1" (H1) is

$$p(r|H_1) = \frac{1}{\sqrt{2\pi\sigma_n^2}} f_\chi(\chi) \exp\left(-\frac{\left(r - \frac{\gamma e\lambda}{hc} I_0(t) \exp[2\chi - 2E(\chi)]\right)^2}{2\sigma_n^2}\right), \tag{8.8}$$

where $f_\chi(\chi)$ is the probability density function of the logarithmic amplitude fluctuation χ.

Assuming that the probability of sending a "0" is equal to the probability of sending a "1," that is, $p(H_0) = p(H_1) = 1/2$, according to the maximum posterior probability criterion and the Bayesian formula, the maximum-likelihood detection output bit $\hat{s}$ [52] per symbol can be deduced as follows:

$$\hat{s}_{MLE}(r) = \underset{s}{^{argmax}} p(r|s). \tag{8.9}$$

The likelihood ratio (LR) is obtained from the above derivation [53]:

$$\wedge(r) = \int_{-\infty}^{\infty} f_\chi(\chi) \exp\left[-\frac{\left(r - \frac{\gamma e\lambda}{hc} I_0(t) \exp[2\chi - 2E(\chi)]\right)^2 - r^2}{2\sigma_n^2}\right] \begin{matrix} > H_1 \\ < H_0 \end{matrix} 1, \tag{8.10}$$

where $\wedge(r)$ is the likelihood ratio of the received signal, $f_\chi(\chi)$ is the probability-density function of the logarithmic amplitude fluctuation, σ_n^2 is the detector noise

variance, and I_0 (t) is the light intensity of the received signal without considering atmospheric turbulence.

(3) **Optimal Decision Threshold**

To improve the system-detection performance, the false-alarm probability P_F and missed-alarm probability P_M must be as small as possible. The detection threshold satisfying this condition is called the optimal decision threshold. The optimal decision threshold U_{OT} can be expressed as [54]

$$U_{OT} = \text{argmin}(P_F + P_M), \tag{8.11}$$

where argmin() represents the minimum value of the objective function, P_F represents the false-alarm probability, and P_M represents the missed-alarm probability. Equation (8.11) can be solved by finding the zero point using a partial differential [54], that is,

$$\frac{\partial P_F}{\partial U_T} - \frac{\partial P_M}{\partial U_T} = 0. \tag{8.12}$$

Combining Eqs. (8.3) and (8.4), Eq. (8.12) can be converted into

$$-\frac{1}{2} erfc\left(\frac{U_T - U_0}{\sqrt{2\sigma_0^2}}\right) = -\frac{1}{2} erfc\left(\frac{U_1 - U_T}{\sqrt{2\sigma_1^2}}\right), \tag{8.13}$$

where U_0, U_1 and σ_0^2, σ_1^2, respectively, represent the mean and variance of the signal voltage at "0" and "1." Taking the natural logarithm of both sides of Eq. (8.13) and sorting it out:

$$\left(\sigma_1^2 - \sigma_0^2\right)U_T^2 + \left(2U_1\sigma_0^2 - 2U_0\sigma_1^2\right)U_T + \left(U_0^2\sigma_1^2 - U_1^2\sigma_0^2 + 2\sigma_0^2\sigma_1^2 \ln\frac{\sigma_0}{\sigma_1}\right) = 0. \tag{8.14}$$

Solving for U_T in Eq. (8.14), the optimal decision threshold [54] corresponding to the lowest bit-error rate is

$$U_{OT} = \frac{\sigma_1\sigma_0}{\sigma_1^2 - \sigma_0^2}\sqrt{(U_1 - U_0)^2 + 2\left(\sigma_1^2 - \sigma_0^2\right)\ln\left(\frac{\sigma_1}{\sigma_0}\right)} + \frac{U_0\sigma_1^2 - U_1\sigma_0^2}{\sigma_1^2 - \sigma_0^2}. \tag{8.15}$$

Under the influence of atmospheric turbulence, the optimal threshold changes with time. According to Eq. (8.15), the threshold can be changed from the perspective of signal and variance tracking, and the minimum bit-error rate can be obtained theoretically.

Typical Adaptive-Threshold Detection Models

LMS Filter Adaptive-Threshold Detection Model

The least-mean-square (LMS) algorithm [55] is based on the most jittery gradient-descent method, which includes two basic processes: filtering and adaptive. The filtering process calculates the response of the linear-filter output to the input signal. By comparing the output result y_k with the expected response d_k, the estimated error ε_k ($\varepsilon_k = d_k - y_k$) is generated, and the error signal ε_k is fed back to the filter. The adaptive process automatically adjusts the filter parameters according to the feedback error to make the mean-square-error signal close to zero to obtain the best prediction value of the signal mean and variance.

The LMS filtering adaptive-threshold detection model is applicable to stable input signals. It is illustrated in Fig. 8.4. The difference between the output signal and the expected signal is used as the error signal. The error signal is controlled by the adaptive weight control algorithm, and the transverse-filter weight vector is adjusted to make the mean-square value of the error signal infinitely close to zero. This obtains the best predicted value of the signal mean and variance. Then, the value is substituted into the maximum-likelihood ratio expression of the receiver, and the optimal decision threshold is obtained.

According to the LMS adaptive-threshold detection model, the output signal y_k and transfer function H_k of the system are expressed as [56]

$$y_k = W_k^T X_k \tag{8.16}$$

$$H_k = \sum_{i=1}^{l} w_{ik}\delta(t - iT), \tag{8.17}$$

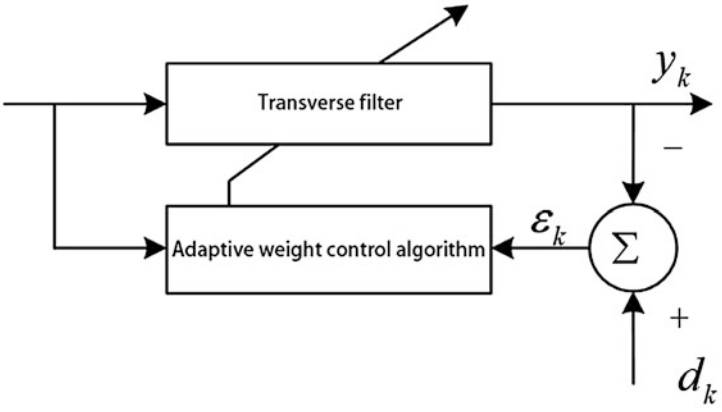

Fig. 8.4 LMS filter algorithm model [56]

where X_k is the input vector of the filter, W_k is the weight vector, l is the horizontal filter length, w_{ik} is the weight coefficient, and T is the symbol duration.

The output signal y_k is substituted into the error-signal ε_k expression, $\varepsilon_k = d_k - W_k^T X_k$, and its mean-square value is calculated to obtain the mean-square-error performance surface [56]:

$$\xi = E\left(d_k^2\right) + W_k^T R W_k - 2PW_k, \tag{8.18}$$

where R is the input signal X_k correlation matrix and P is the cross-correlation matrix between the expected signal d_k and the input signal y_k. The gradient of the mean-square error performance surface is calculated by $\nabla_k = \partial\xi_k/\partial W_k = 2RW_k - 2P$ because ε_k^2 is used as an estimate of ε_k in the LMS filtering algorithm:$\widehat{\nabla}_k = -2\varepsilon_k X_k$.

The LMS algorithm weight-vector update equation [56] is expressed as

$$W_{k+1} = W_k + 2\mu_c \varepsilon_k X_k \tag{8.19}$$

where W_k is the initial weight vector, μ_c is the step size of the LMS, which is used to control the algorithm stability and convergence rate, and ε_k is the error between the output signal and the expected signal.

Adaptive-threshold detection based on an LMS filter does not need to clarify the statistical relationship between the noise and signal, and the algorithm is easy to implement. However, the weight adjustment process of the LMS filter is prone to nonconvergence and a large amount of computation, which leads to an increase in the bit-error rate of the communication system.

Kalman-Filter Adaptive-Threshold Detection Model

The Kalman filter [55] is an optimal estimation algorithm that uses the linear-system state equation to combine the past measurement-estimation error with the new measurement error to estimate the future error. It is generally used to process nonstationary input signals. The working principle is illustrated in Fig. 8.5. The system state x_k at time k is obtained by multiplying the system-disturbance noise vector w_k with the system state x_{k-1} at time $k-1$ and the state-transition matrix A_{k-1}.

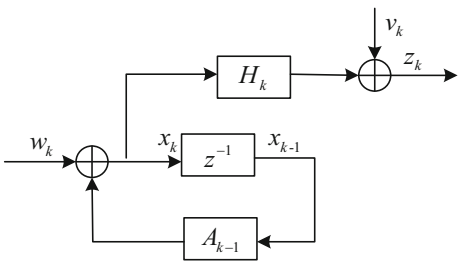

Fig. 8.5 Kalman-filtered signal model [57]

The observation value z_k at time k can be obtained by multiplying x_k with the observation matrix H_k and adding the observation noise vector v_k.

An adaptive threshold based on the Kalman filter is often used to solve prediction problems. It estimates the current value of the state variable using the estimated value of the previous state and the current observation value. It then compares the current value with the decision threshold calculated by the previous symbol, gives the decision result, and updates the detection threshold. Essentially, it is a group of optimal predictor–corrector estimators. The best approach is to minimize the covariance of the estimated error when certain limited conditions are met.

The system-state and measurement equations are established according to the Kalman adaptive-threshold detection signal model [55]:

$$x_k = A_{k-1}x_{k-1} + w_k \tag{8.20}$$

$$z_k = H_k x_k + v_k. \tag{8.21}$$

The gain K_k of the Kalman filter is defined as [58]

$$K_k = P_{k|k-1}{H_k}^T \left(H_k P_{k|k-1}{H_k}^T + R_k\right)^{-1}, \tag{8.22}$$

where R_k is the covariance matrix of the measurement noise vector v_k, $P_{k|k-1} = A_{k|k-1}P_{k-1}A_{k|k-1}^T + Q_k$ is the covariance matrix of the one-step prediction error, and Q_k is the covariance matrix of the process noise vector w_k. From this, the predicted value of the signal [58] is

$$\widehat{x}_k = \widehat{x}_{k|k-1} + K_k\left(z_k - H_k\widehat{x}_{k|k-1}\right). \tag{8.23}$$

The prediction of the fluctuation variance of the logarithmic amplitude of the turbulence [58] can be expressed as

$$\widehat{\sigma}^2{}_\chi = \frac{1}{4}\left(\widehat{\sigma}^2{}_k + 1\right), \tag{8.24}$$

where $\widehat{\sigma}^2{}_k$ is the estimated value of the signal variance at time k. According to the maximum-likelihood ratio expression, the decision threshold of the receiver is related to the amplitude fluctuation variance of the number. By knowing the estimated value of the amplitude-fluctuation variance, the maximum-likelihood ratio can be obtained for adaptive-threshold detection.

Adaptive-threshold detection based on the Kalman filter avoids the online calculation of the system transfer function; the transfer function can be calculated offline. This simplifies the calculation of the filter and reduces the computational burden, making it easier to implement in hardware, and the real-time performance of the filter is better. However, the relationship between noise and the

signal needs to be clarified, which is applicable to nonstationary random processes.

Adaptive-Threshold Detection Model with a Fading Kalman Filter

As shown in Fig. 8.5, the traditional Kalman filter estimates the current state based on an estimated value of the previous state and the current observation value. When the observation model is inaccurate, the old observation value has a significant impact on the current-state estimation and the role of the current observation data is ignored, which causes a filtering error. Adaptive-threshold detection with a fading-memory Kalman filter can solve the above problems.

This method adds a fading factor λ_k to the traditional Kalman filter so that the prediction-variance matrix [57] is

$$P_{k|k\text{-}1} = \lambda_k \left(A_{k|k\text{-}1} P_{k\text{-}1} A_{k|k\text{-}1}^T + Q_k \right). \tag{8.25}$$

In the formula, λ_k is the fading factor; it will reduce the state-filtering performance if it is too large. $A_{k|k-1}$ is the one-step state-transition matrix, P_{k-1} is the k_1-moment error covariance matrix, and Q_k is the correlation matrix of the process noise vector.

The estimated values of the prediction-error and innovation covariances [33] are as follows:

$$\widehat{P}_{k|k\text{-}1} = \lambda_k P_{k|k\text{-}1} \tag{8.26}$$

$$\widehat{C}_k = \alpha_k C_k, \tag{8.27}$$

where α_k is a scalar factor, $\widehat{C}_k$ is determined by the windowing estimation method, and the fading factor λ_k is solved. Then, the signal state filtering is [33]

$$\widehat{x}_k = A_{k|k-1} \widehat{x}_{k|k-1} + K_k \left(z_k - H_k A_{k|k-1} \widehat{x}_{k|k-1} \right). \tag{8.28}$$

The estimated logarithmic fluctuation variance is the same as that of adaptive-threshold detection with a traditional Kalman filter. The predicted value of the logarithmic amplitude-fluctuation variance is calculated using the predicted signal-variance value at time k, and the likelihood ratio of the receiver is obtained for threshold judgment. The adaptive threshold based on a fading Kalman filter reduces the filter memory length and causes the current data to play a greater role in the filtering process.

These three adaptive-threshold detection models are applicable to adaptive signal processing under weak-turbulence conditions. For strong-turbulence conditions, adaptive-threshold detection technology based on high-order cumulants is typically used.

High-Order Cumulant Adaptive-Threshold Detection

In recent years, Professor Ke Xizheng of Xi'an University of Technology has extensively researched adaptive optical systems in optical wireless communications, including adaptive algorithms, blind equalization, and threshold detection technology with high-order cumulants [24, 25, 31, 61, 62].

The noise model in optical wireless communication systems typically follows a Gaussian distribution and generally uses second-order statistics (correlation function and power spectrum) to analyze and process the noise. For non-Gaussian signal processing, higher-order (third and higher) cumulants can be used. Adaptive-threshold detection based on higher-order cumulants can estimate channel parameters and noise, better suppress the impact of strong turbulence on the received signal, improve the system communication quality, and is suitable for correlated, partially correlated, and uncorrelated signal models.

Decision-Guided Adaptive-Filtering Algorithm

The decision-guided algorithm has a weak convergence, but its steady-state tracking performance is good. Therefore, the decision-guided algorithm was combined with the LMS adaptive-filtering algorithm based on higher-order cumulants [24]. The decision-guided adaptive-filtering algorithm based on higher-order cumulants uses higher-order cumulants as the cost function to update the tap coefficients of the filter. This not only obtains a small mean-squared error but also effectively suppresses additive noise and symmetrically distributed non-Gaussian colored noise.

Figure 8.6 shows the mean-squared error curve when the higher-order cumulant decision-guided algorithm and the decision-guided algorithm select the optimal step size. As shown in Fig. 8.6, compared with the decision-guided algorithm, the higher-order cumulant decision-guided algorithm converges slowly, but its steady-state error is improved.

In addition, the error performance of the high-order cumulant decision-guided adaptive-filtering algorithm was studied for different noise types in the atmospheric channel, and the mean-squared error curves of different step sizes and those of the three noise models under the same step size were obtained, as shown in Figs. 8.7 and 8.8, respectively. As shown in Fig. 8.7, the larger the step size, the faster the curve convergence speed, but the larger the steady-state error.

As shown in Fig. 8.8, under the additive-noise condition, the convergence speed of the algorithm is fast and the steady-state error is small. With multiplicative noise, the convergence speed is obviously slowed down, and the steady-state error is also relatively increased. Multiplicative noise converges faster than combined multiplicative and additive noise, but the steady-state error difference between them is small.

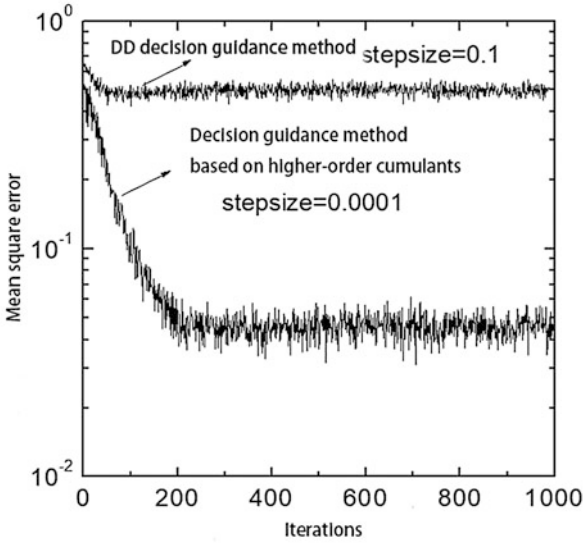

Fig. 8.6 Performance comparison of two decision-guided algorithms [24]

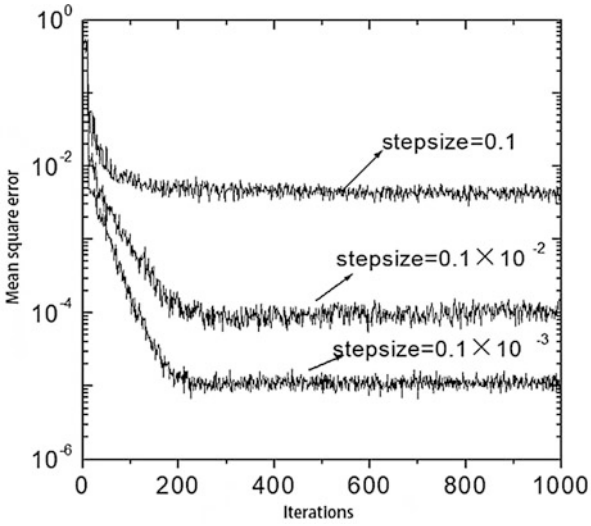

Fig. 8.7 Mean-square error (MSE) curve of asynchronous lengths [24]

Sliding-Correlation Adaptive-Threshold Algorithm

Sliding-correlation detection [59] refers to the detection or denoising of signals through autocorrelation and cross-correlation operations. Generally, the sliding-window method is used to judge the presence or absence of each window signal.

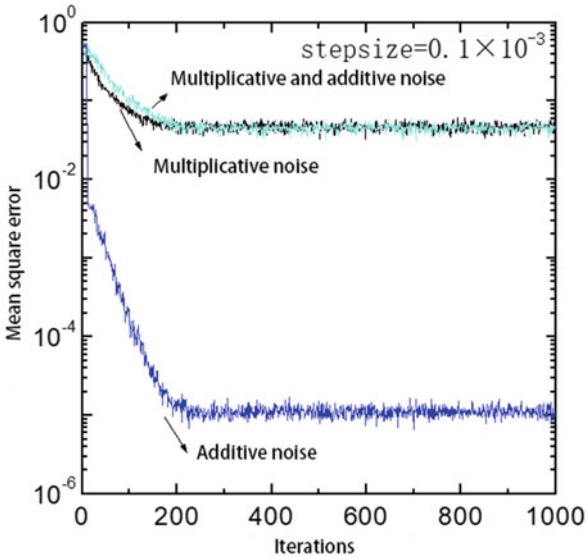

Fig. 8.8 Mean-square error (MSE) curve of three noise models [24]

Because the correlation function only considers the observed additive-white-noise data, it is proposed to combine the higher-order cumulant with correlation detection.

The detection principle is illustrated in Fig. 8.9. When a local pulse signal is input, the phase of the signal carrier is random; therefore, it needs to be nonlinearly transformed ($[\cdot]^4$ represents a fourth-power nonlinear transformation). The fourth harmonic component is extracted, and then the signal is detected using a digital filter and a sliding-correlation algorithm. This method can achieve multiple correlations and improve the detection probability of the system (Fig. 8.9).

Sliding-correlation adaptive-threshold detection based on higher-order cumulants [25] performs a cumulative correlation operation on the received signal according to the sliding-correlation principle. There are L correlation peaks in each frame of length L of the output signal, of which only one is the maximum autocorrelated peak carrying the transmitted signal information. The adaptive-threshold control algorithm then judges, accumulates, and compares the cumulative-output correlation peaks within a given observation frame length and obtains the adaptive decision threshold. The adaptive-threshold control model is shown in Figs. 8.10 and 8.11.

The correlation-peak sample value U_j of the threshold decision box is input, and the sample value of its adjacent signal frames U_{j-M+1}, U_{j-M}, …, U_j is used as the observation object (M is an integer). The threshold decision maker determines the maximum autocorrelation peak obtained by the correlation operation in each frame period. If $U_{j-M} \geq \lambda_j$, the decision maker outputs $Z(j) = 1$; if $U_{j-M} < \lambda_j$, the decider outputs $Z(j) = 0$. The accumulator accumulates the sample values of the signal output $N \times L$ $Z(j)$ by the decision, and the output signal is $X_j = \sum_{M=0}^{M-1} Z(j-M)$.

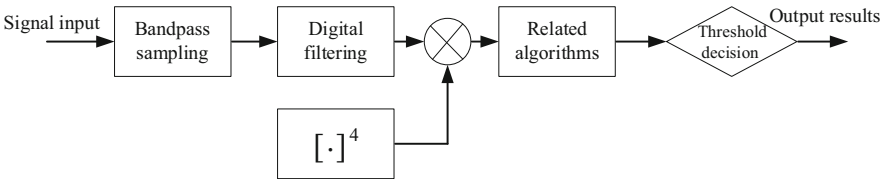

Fig. 8.9 High-order cumulant sliding-correlation detection [25]

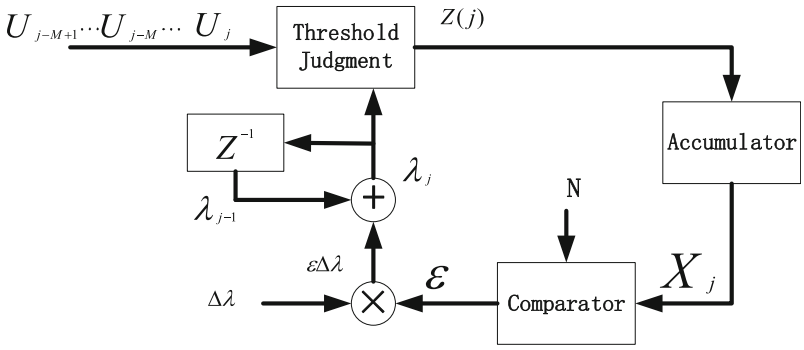

Fig. 8.10 Adaptive-threshold control algorithm for sliding correlation detection [25]

In the comparator, the sum of accumulation N and X_j is compared with the predetermined number of reference symbols to obtain a value for variable ε to control the threshold-adjustment direction. The comparison process is equivalent to a symbol function, that is, $\varepsilon = SGN(X_j - N)$. The threshold change amount $\Delta\lambda$ is obtained by multiplying it by the threshold control increment $\varepsilon\Delta\lambda$. Finally, adaptive control with the decision threshold $\lambda_j = \lambda_{j_1} + \varepsilon\Delta\lambda$ is realized.

Adaptive-Threshold Detection in a Strong-Turbulence Channel

Optical wireless communication divides atmospheric channels into weak-, medium-, and strong-turbulence channels, according to the degree of atmospheric turbulence and state of motion [60]. A strong-turbulence channel refers to an atmospheric channel where the atmospheric refractive-index structure constant $C_n^2 > 2.5 \times 10^{-13} m^{-2/3}$.

For the adaptive-threshold detection of strong-turbulence channels, the Xi'an University of Technology has established a K-distribution strong-turbulence channel model [30] using a modified spherically invariant random-process method to avoid the ergodic problem of random variables. Based on this channel model, the high-order cumulant of the innovation process obtained from the light-intensity signal is analyzed using the protection characteristics between the high-order and low-order

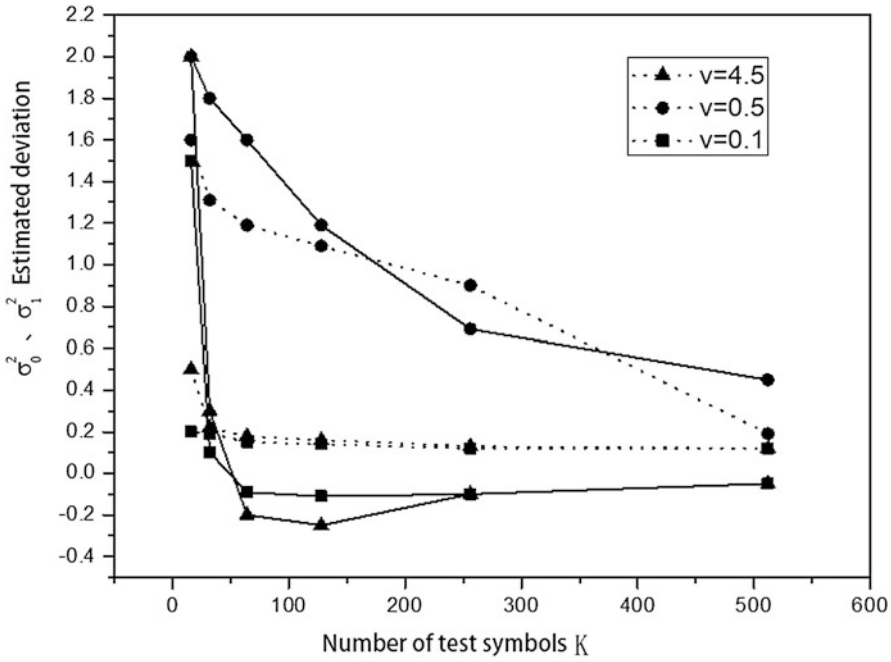

Fig. 8.11 Relationship between the estimated deviation and number of test symbols [31]

cumulants [31, 61]. Thus, the signal fading and Gaussian noise are estimated and then separately processed to obtain the real-time parameters of the turbulence signal to control the signal decision threshold.

Under OOK modulation, the signal-to-noise ratio $SNR = \mu/2\sigma_n^2$ of the system is defined under this K distribution and the signal-fading noise ratio $\mathrm{CNR_K}$ and two types of noise ratio $\mathrm{CNR_G}$ are set to 10 dB. The channel and noise correlation coefficients are set to 0.9, and the sample number $m = 32$. The deviation and variance between the noise parameters and theoretical values are studied [31].

Figures 8.11 and 8.12 show the estimated deviation and variance-change curves with theoretical values when using higher-order cumulants to estimate Gaussian noise parameters under different order-parameter v conditions, $\sigma_{n_1}^2$ and $\sigma_{n_2}^2$. $\sigma_{n_1}^2$ is represented by a dotted line, and $\sigma_{n_2}^2$ is represented by a solid line. As shown in Figs. 8.11 and 8.12, when $v = 0.1$, the deviation and variance of the estimated value are the largest. With an increase in the order parameter v, the deviation and variance of the estimated value become increasingly smaller, indicating that the system tends to stabilize when the order parameter increases. However, the deviation and variance of the estimated value will not always decrease with an increase in v but will reach a critical point and tend to saturate.

When sampling at 50% of the pulse of the received digital signal, the mean value $\mu = 1$, order parameter $v = 2$, and the fixed threshold are set to 0.5. The system BER performance is studied when different detection methods are used, as shown in

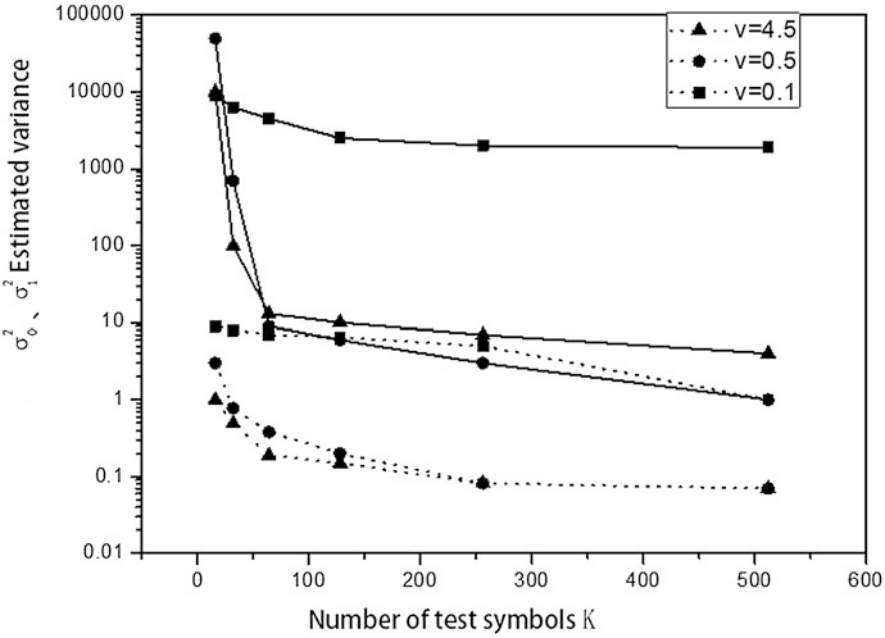

Fig. 8.12 Relationship between the estimated variance and number of test symbols [31]

Fig. 8.14. The dotted line represents the fixed-threshold detection method, and the solid line represents the adaptive-threshold detection method, when the sampling numbers *m* are 8, 16, 32, and 64.

As shown in Fig. 8.13, the bit-error rate of adaptive-threshold detection is significantly lower than that of the fixed-threshold detection method at the same signal-to-noise ratio. Moreover, the larger the number of samples in the adaptive-threshold detection, the more obviously the system performance improves.

Figures 8.14, 8.15, and 8.16 show the BER change curves with the SNR under heavy, moderate, and light rain, respectively. It can be seen that under the same SNR, the larger the number of samples, the lower the system BER and the more obvious the performance improvement of the adaptive-threshold detection method. When the number of samples exceeds 32, the performance improvement tends to flatten.

Figure 8.17 shows the change curves of the received bit-error rate with the signal-to-noise ratio in heavy, moderate, and light rain when the number of samples is 64. Under the same signal-to-noise ratio, the bit-error rate of the received signal in heavy rain is lower than that in moderate and light rain. They significantly improve the quality of the received signal and decrease the bit-error rate.

Based on the above adaptive-threshold detection experiments on rainy days, the error-rate performance of adaptive-threshold detection on sunny and foggy days was further studied [62]. The BER change curves with SNR on sunny, foggy, and rainy days are shown in Figs. 8.18, 8.19, and 8.20, respectively. The same conclusions were obtained from Figs. 8.18, 8.19, and 8.20 as those in

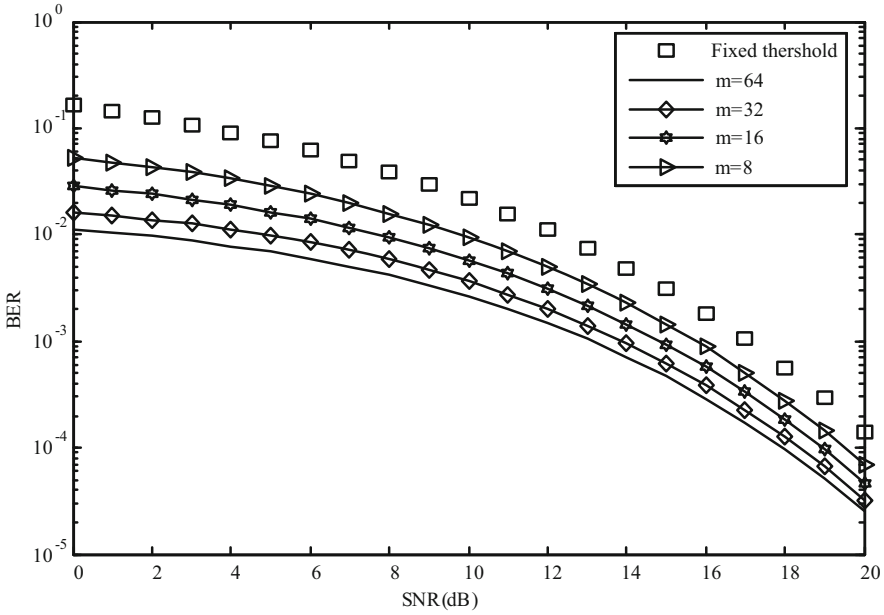

Fig. 8.13 BER change curve with SNR [61]

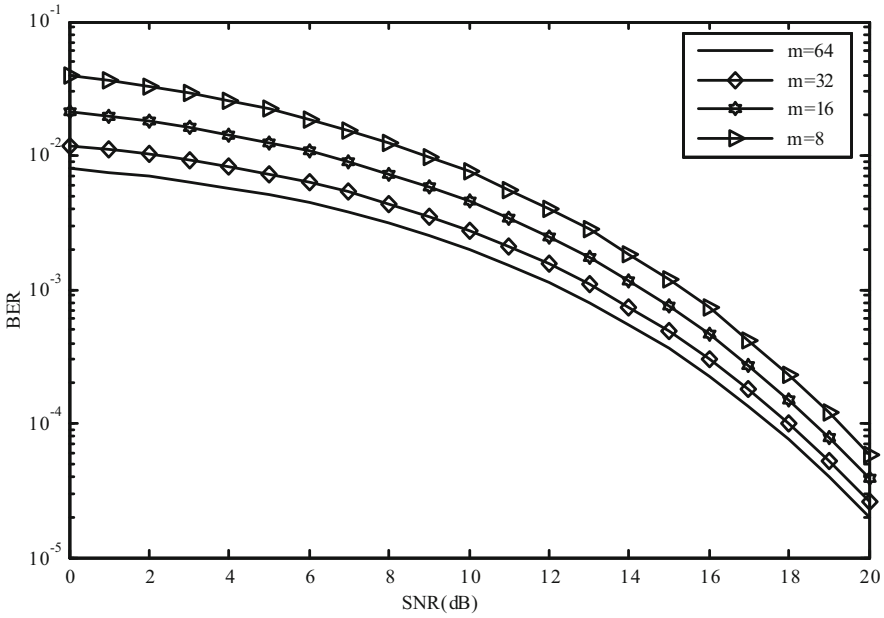

Fig. 8.14 Change curve of the bit-error rate with SNR in heavy rain [31]

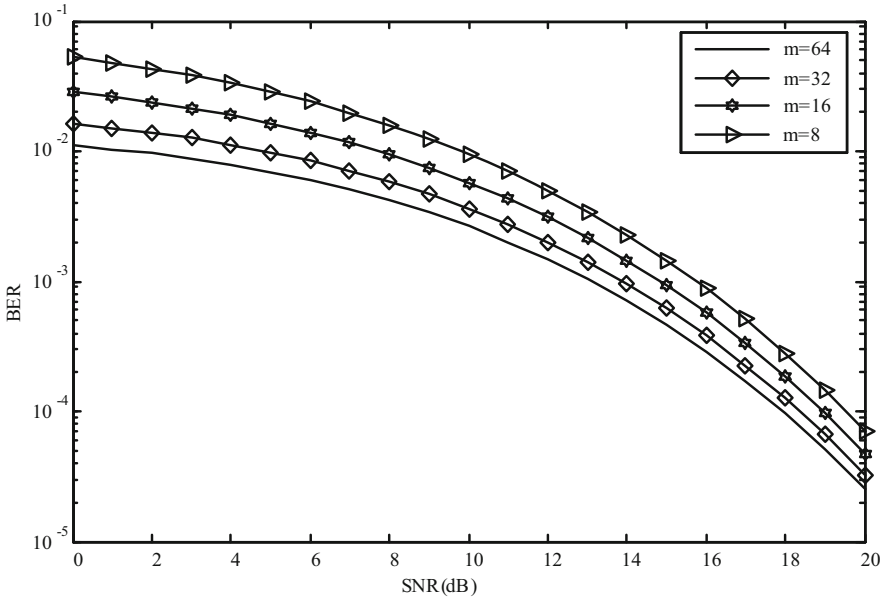

Fig. 8.15 Change curve of the bit-error rate with SNR in moderate rain [31]

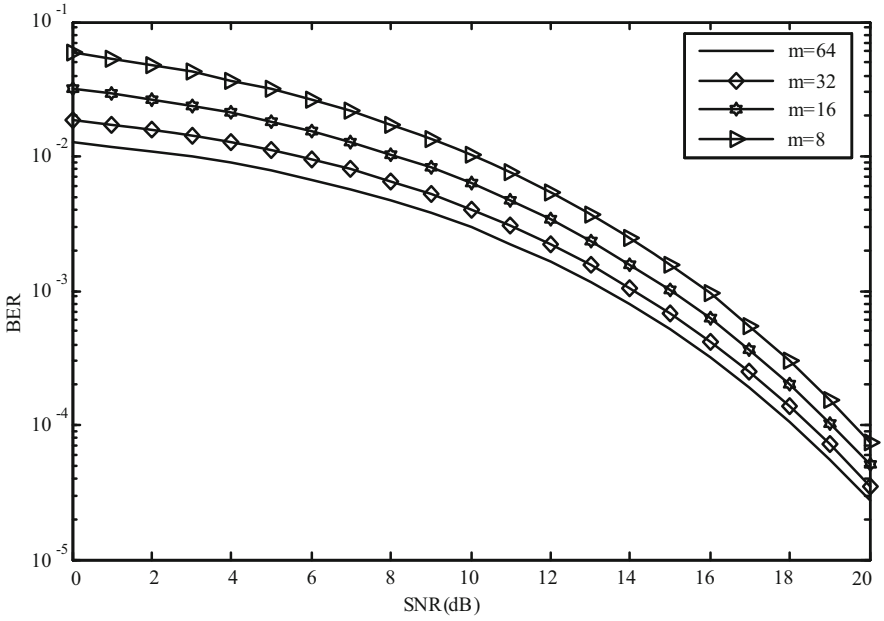

Fig. 8.16 Change curve of the bit-error rate with SNR in light rain [31]

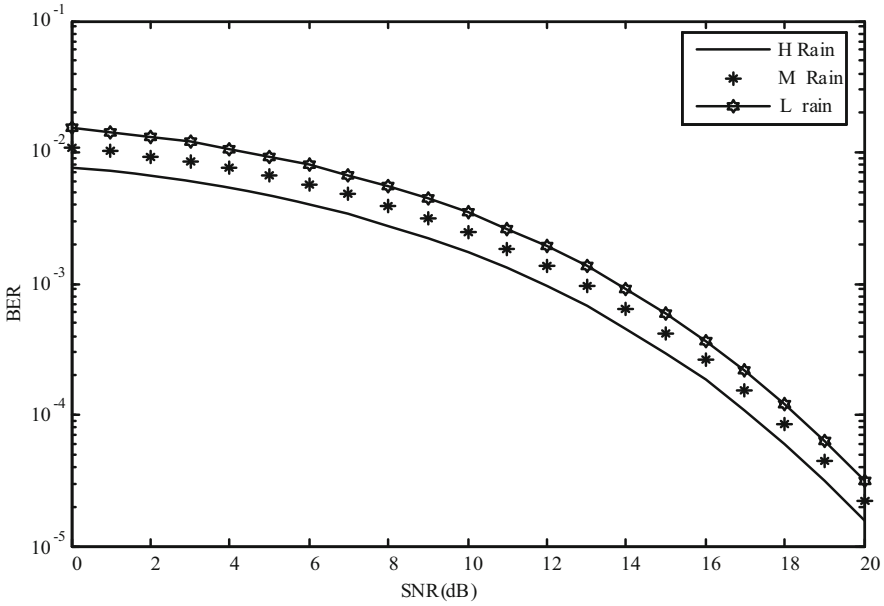

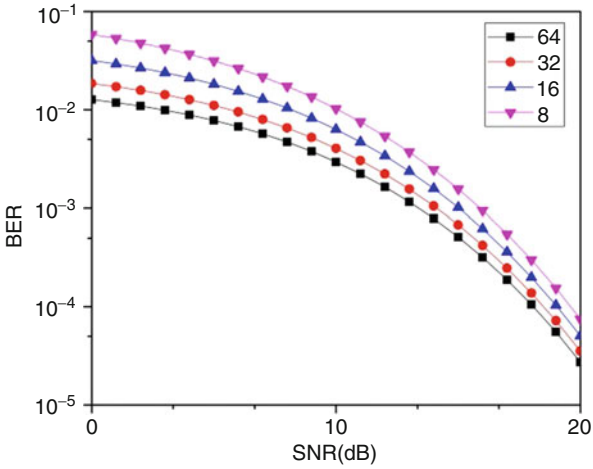

Fig. 8.17 BER change curve with SNR in different weather conditions [31]

Fig. 8.18 Relationship between the SNR and BER on sunny days [62]

Figs. 8.14, 8.15, and 8.16, which again verifies the correctness of the relationship between the sample number and BER.

Figure 8.21 shows the change curves of the received-signal error rate with the signal-to-noise ratio under different weather conditions. Under the same sampling value, the signal-to-noise ratio is inversely proportional to the error rate, indicating that increasing the signal-to-noise ratio can improve the communication quality.

Summary

The performance of an atmospheric optical wireless communication system is significantly affected by its decision threshold. Compared with traditional fixed-threshold detection, adaptive-threshold detection can update the optimal decision threshold in real time, improve the detection probability, shorten the acquisition time, and effectively reduce the bit-error rate at a lower cost.

This chapter reviewed the research progress of adaptive-threshold detection and introduced the optimal threshold strategy and several commonly used adaptive-threshold detection algorithms. Moreover, it discussed the development trends of

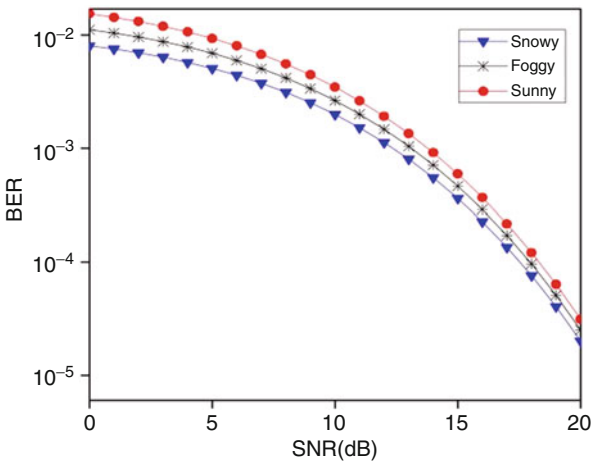

Fig. 8.21 Relationship between SNR and BER under different weather conditions [62]

adaptive-threshold detection technology in optical wireless communication, including the following aspects:

(1) As the data-transmission rate of optical wireless communication progressively increases, it is difficult to obtain channel-state information in high-speed optical communication. Therefore, it is necessary to study threshold detection techniques without channel-state information, such as blind estimation.
(2) Adaptive-threshold control algorithms (such as maximum likelihood, generalized maximum likelihood, and minimum mean square error) should be optimized, the number of iterations and algorithm complexity should be reduced, and real-time threshold decisions of the received signal should be made.
(3) The optimal decision threshold was studied under different modulation formats and turbulence intensities to observe signal detection under complex atmospheric-channel conditions.
(4) Based on the relatively slow-varying characteristics of statistics such as average signal intensity and turbulence intensity, the optimal constant threshold detection technique is studied to reduce the difficulty of implementing adaptive threshold detection.

Abstract

Spot detection technology plays an important role in modern scientific research and application. Due to its advantages of high detection sensitivity, simple signal processing, and strong anti-interference ability, four-quadrant detectors have been widely used in spot detection technology and are the key components in acquisition, tracking, and pointing systems. First, the spot models commonly used in spot detection and the principle of four-quadrant detector spot detection are introduced. Then, the research results of four-quadrant detector spot detection at home and abroad, as well as the factors affecting the accuracy of four-quadrant detector spot detection and the commonly used spot detection algorithms, are analyzed. The four-quadrant detector spot detection system is introduced, including the beam alignment detection system, four-quadrant detector tracking communication composite system, and micronano laser communication system. Finally, the development prospects of spot detection technology are prospected.

Keywords

Spot detection · Four-quadrant detector · Spot model · Spot detection algorithm

Introduction

Acquisition, pointing, and tracking (APT) technology is a research focus in wireless laser communication systems, and spot-detection technology is key to APT technology. Commonly used spot detectors are position-sensitive detectors, charge-coupled devices (CCDs), and four-quadrant detectors (QDs). Compared with position-sensitive detectors and charge-coupled devices, QDs have a high detection resolution and short response time and are therefore widely used.

This chapter introduces several common spot models used in spot detection and then analyzes and summarizes the detection principle, domestic and foreign research progress, influencing factors, detection algorithms, and applications around the four-quadrant detector. Finally, it discusses potential applications of spot-detection technology and its development prospects, according to the development status.

Light-Spot Model and Detection Principle

Light-Spot Model

Each input spot model is different, as is the output signal value of the QD. The spot model is divided into uniform and Gaussian distributions by energy and into circular, elliptical, and toroidal spots by shape. The ideal spot is a uniformly distributed circular spot with an energy-density distribution function of [1]

$$I(x,y) = \begin{cases} I_0 & (x-x_0)^2+(y-y_0)^2 \le R^2 \\ 0 & \text{otherwise} \end{cases}. \tag{9.1}$$

I_0 is the peak light intensity, R is the spot radius, and the coordinates of the spot center are (x_0, y_0). The spot output from the laser can be regarded as a circular spot with a Gaussian distribution; its energy-density distribution function is [2, 3]

$$I(x,y) = I_0 \exp\left(\frac{-2\left((x-x_0)^2+(y-y_0)^2\right)}{R^2}\right). \tag{9.2}$$

To reduce the experimental error in experimental analyses, the received light spot is approximated as a uniformly distributed elliptical light spot with an energy-density distribution function of

$$I(x,y) = \begin{cases} I_0 & \dfrac{x^2}{w_a^2}+\dfrac{y^2}{w_b^2} \le 1 \\ 0 & \text{Otherwise} \end{cases}. \tag{9.3}$$

I_0 is the peak light intensity, and w_a and w_b are the elliptical light spot's long and short axes, respectively. When the spot drifts, the blocked spot is viewed as a Gaussian-distributed elliptical spot with an energy-density distribution function of [4, 5]

$$I = I_0 \frac{2}{\pi w_a w_b} \exp\left(-2\left[\frac{x^2}{w_a^2}+\frac{y^2}{w_b^2}\right]\right). \tag{9.4}$$

In practice, when using a Cassegrain telescope to receive the spot, the secondary mirror obscures the center of the spot, and a ring-shaped spot is presented. The energy-density distribution function of a uniformly distributed annular spot is [6]

$$I = k \iint\limits_{S_2-S_1} I_0 \frac{2}{\pi R^2} \exp\left(-2\left(\left((x-x_0)^2+(y-y_0)^2\right)/R^2\right)\right) ds, \tag{9.5}$$

where k is the conversion factor, R is the radius of the outer ring spot, S_1 is the area of the inner-ring circle, and S_2 is the area of the outer-ring circle.

QD-Based Spot-Position Detection Principle

QDs are photovoltaic-type semiconductor detector devices. A schematic diagram is shown in Fig. 9.1. It consists of four quadrants, each of which has a photodiode or avalanche photodiode mounted on the photosensitive surface. The spot is positioned at the center of the device by the output current of the four quadrants, when the spot is irradiated on the QD [7].

When the laser spot is incident on the QD, the four quadrants output different photocurrents I_A, I_B, I_C, and I_D, and the offset is calculated to determine the spot-

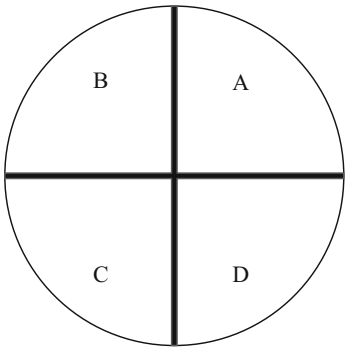

Fig. 9.1 Diagram of a QD

center position. The offsets on the σ_{x0} and σ_{y0} axes are represented by x_0 and y_0, and their equations using the conventional addition and subtraction algorithm are as follows:

$$\sigma_{x0} = (I_A + I_D) - (I_B + I_C) \tag{9.6}$$

$$\sigma_{y0} = (I_A + I_B) - (I_C + I_D). \tag{9.7}$$

Let the ratio coefficient between the QD output photocurrent and the corresponding quadrant spot energy be k. Then,

$$\sigma_{x0} = (I_A + I_D) - (I_B + I_C) = k[(E_A + E_D) - (E_B + E_C)] \tag{9.8}$$

$$\sigma_{y0} = (I_A + I_B) - (I_C + I_D) = k[(E_A + E_B) - (E_C + E_D)]. \tag{9.9}$$

E_A, E_B, E_C, and E_D denote the total energy of the spot incident on the four quadrants.

After normalizing σ_{x0} and σ_{y0}, we have

$$\sigma_x = \frac{(I_A + I_D) - (I_B + I_C)}{I_A + I_B + I_C + I_D} = \frac{(E_A + E_D) - (E_B + E_C)}{E_A + E_B + E_C + E_D} \tag{9.10}$$

$$\sigma_y = \frac{(I_A + I_B) - (I_C + I_D)}{I_A + I_B + I_C + I_D} = \frac{(E_A + E_B) - (E_C + E_D)}{E_A + E_B + E_C + E_D}. \tag{9.11}$$

Assuming a uniform spot-energy distribution, the spot area is proportional to the energy; then, we have

$$\sigma_x = \frac{(E_A + E_D) - (E_B + E_C)}{E_A + E_B + E_C + E_D} = \frac{(S_A + S_D) - (S_B + S_C)}{S_A + S_B + S_C + S_D} \tag{9.12}$$

$$\sigma_y = \frac{(E_A + E_B) - (E_C + E_D)}{E_A + E_B + E_C + E_D} = \frac{(S_A + S_B) - (S_C + S_D)}{S_A + S_B + S_C + S_D}. \tag{9.13}$$

S_A, S_B, S_C, and S_D denote the spot areas incident on the four quadrants.

Four-Quadrant Detector-Based Spot-Position Detection

Foreign Research Progress

Detecting the laser-spot position of a four-quadrant detector is a key technology in APT systems, and the spot-position detection accuracy directly affects the system performance. Many foreign scholars have conducted in-depth research on QD spot detection.

In 1985, the Japanese Space Agency developed the laser-utilizing communication equipment (LUCE) system [10]. The fine-tracking and overtargeting detectors of the APT subsystem of the LUCE system both used QDs, and the fine-tracking accuracy was better than 0.7 μrad.

Figure 9.2 shows the internal structure of the LUCE terminal [11], including the transmitting and receiving light paths. The receiving light path detects the spot position using the coarse-pointing mechanism sensor to drive the coarse-pointing mechanism for coarse alignment. The transmitting light path detects the change of the spot using the presighting sensor, which drives the presighting mechanism for alignment. After alignment, the transmitted beam is directed to the corner reflector, which reflects it to the fine-pointing sensor, which detects the change in the spot position.

In 1995, the Communication Research Laboratory (CRL) [12] of the Ministry of Posts and Telecommunications of Japan used Engineering Test Satellite VI to conduct a laser-communication test between the satellite-terminal laser communication equipment (LCE) and a ground station.

A block diagram of the LCE is shown in Fig. 9.3. The tracking module uses a QD with a 400-rad field of view, and the accuracy can be $\leq$2 μrad. The uplink is aligned by CCD and QD. The gimbal controller controls a two-axis gimbal mirror for coarse alignment, according to the spot information collected by the CCD. The fine-alignment controller controls the fine-aiming device for fine alignment according to the spot offset determined by the QD, and the aligned beam is irradiated to the communication Si avalanche photodiode (APD) through the polarizer.

The downlink is emitted by two lasers. After the beam expander, the beam is synthesized through the combined beam mirror into a single beam, and the beam direction is precisely controlled by a presighting device.

In 2001, Guelman [13] developed a broadband laser inter-satellite link (BLISL) system that uses QD to align and track the spot. The structure of the designed BLISL system is shown in Fig. 9.4. The communication beam is transmitted through the primary reflector, secondary reflector, fine-steering mirror, front-pointing mirror, and beam splitter to the receiver and quadrant detector. The fine-steering mirror is aligned according to the spot information detected by the quadrant detector.

The transmitting beam is transmitted through the transmitter, front-pointing mirror, and fine-steering mirror. The front-pointing mirror is used to compensate the beam deviation of the transmitter. The star tracker estimates the attitude of the gimbal with respect to the inertial reference system to minimize the aperture aiming error.

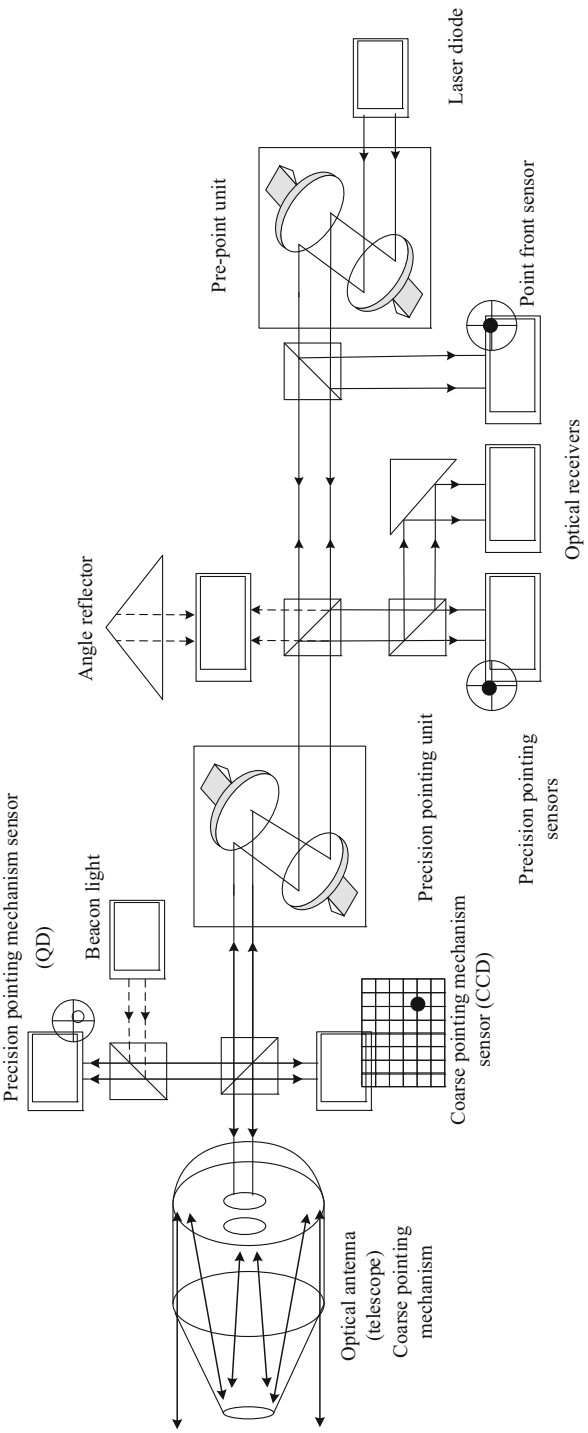

Fig. 9.2 Schematic diagram of the LUCE terminal [11]

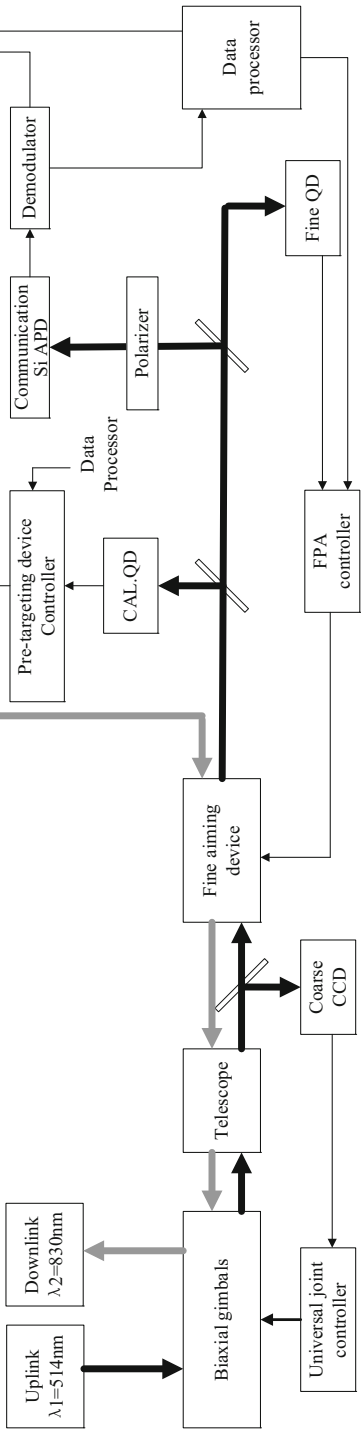

Fig. 9.3 LCE block diagram [12]

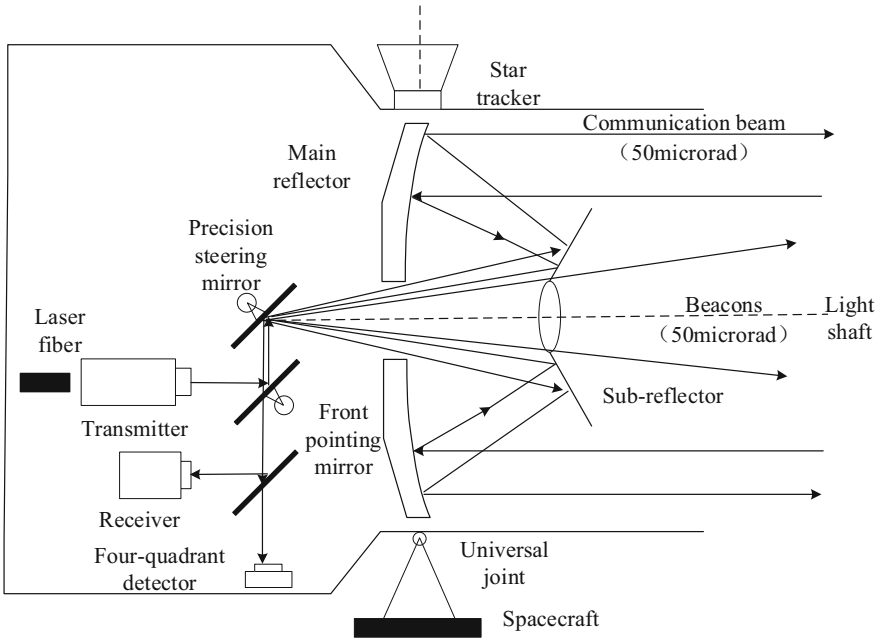

Fig. 9.4 BLISL system-architecture diagram [13]

In 2002, Toyoda et al. [8] performed a comparative study of the spot-detection sensor shown in Fig. 9.5 for a laser-tracking system. The received laser beam is focused on a quadrant APD, and a controller calculates the tracking signal and compensates the closed-loop system to drive the tilt mirror to keep the spot in the center of the four cells. An equivalent noise angle of less than 1 μrad is achieved at a received optical power greater than 4 pW.

In 2006, the Optical Inter-orbit Communication Engineering Test Satellite (OICETS) successfully conducted a two-way communication experiment with the optical ground-station terminal KODEN [14]. Figure 9.6 shows the KODEN receiver. The laser beam from OICETS is received and detected by a CCD camera, a QD sensor, and an avalanche photodetector (APD). QDs were used to detect and locate the spot position with a tracking accuracy of up to 2 μrad.

In 2009, Lee et al. [15] investigated the effect of the incident spot size on a four-quadrant photodetector. Experimental and analytical studies showed that the sensitivity of the optical displacement detection increased as the Gaussian spot size decreased.

The experimental setup is shown in Fig. 9.7. It consists of a beam expander, objective lens, mirror, and quadrant photodetector mounted on a linear-translation stage. After the beam expander, a 3-mW He–Ne laser with a 632-nm wavelength is focused by the objective mirror onto the reflector and reflected to reach the quadrant photodetector. The spot size is varied by changing the distance between the two lenses, L_1 and L_2, of the beam expander.

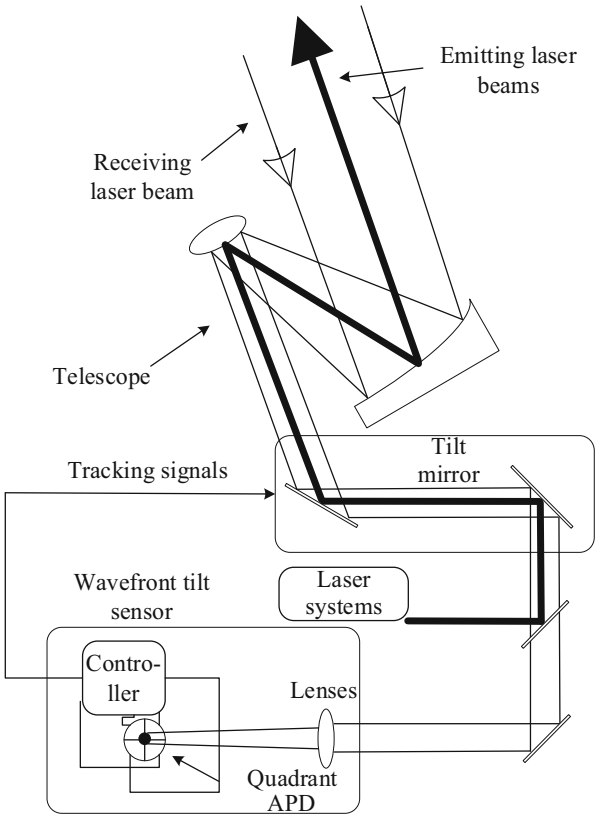

Fig. 9.5 Quadrant APD-based laser-tracking system [8]

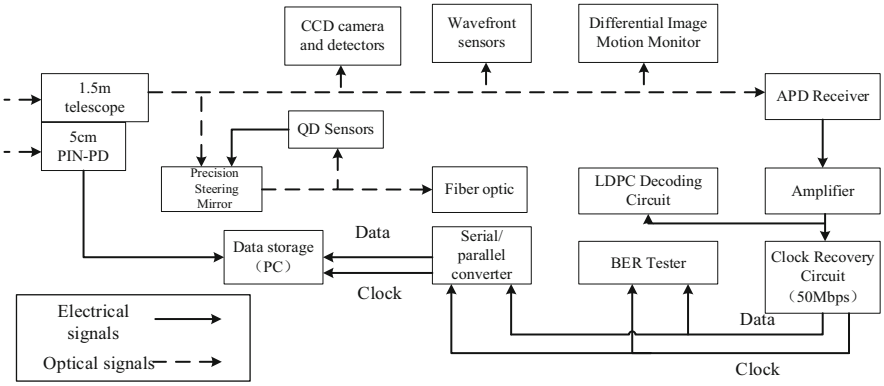

Fig. 9.6 KODEN receiver [14]

In 2012, Horwath et al. [16] designed a small laser terminal (SLT) using a QD as a spot-detector device, with a maximum communication distance of 3 km and bit-error rate (BER) of 10^{-6}. The basic block diagram of the SLT is shown in Fig. 9.8.

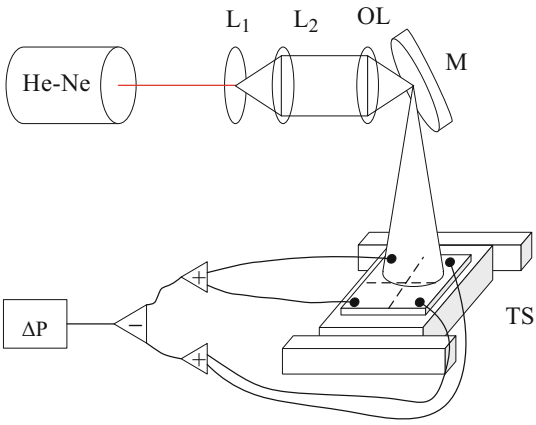

Fig. 9.7 Experimental-setup diagram [15]

The optical system and objective lens split the incident and outgoing beams of the received laser signal between the data receiver and the four-quadrant detector. The digital signal processor controls the actuator, according to the four-quadrant detector. The beam-coupling device is responsible for separating the input and output laser beams. The output laser beam is generated by the laser module and amplified by the optical amplifier.

In 2013, Barbarić et al. [17] derived a new relationship between the QD area and position to analyze a laser-tracker system model. The results showed that the new relation signal processing could improve the tracking accuracy by 30%.

In 2013, the Lunar Atmosphere and Dust Environment Explorer (LADEE) carried the optical communication Lunar Lasercom Space Terminal (LLST) for two-way laser-communication experiments with the ground [18–20]. The APT subsystem is shown in Fig. 9.9. The telescope is mounted on a gimbal to ensure the coarse alignment of the optical link over a wide range. The rate sensor is used to detect angular perturbations, which are then suppressed by a voice coil actuator. The QD receives the beam, determines the spot position, and drives a fiber-optic chapter actuator to achieve fine tracking.

In 2021, Safi et al. [21] investigated a ground-to-air free-space optical link for a multirotor hovering unmanned aerial vehicle (UAV), using a four-quadrant array of photodetectors on an optical receiver to detect light spots.

Domestic Research Progress

Chinese researchers and scholars have also conducted in-depth research on QD-based laser-spot position-detection technology, studied the factors affecting the spot-position detection accuracy, proposed different detection algorithms, and designed different QD spot-detection systems. The research progress is as follows.

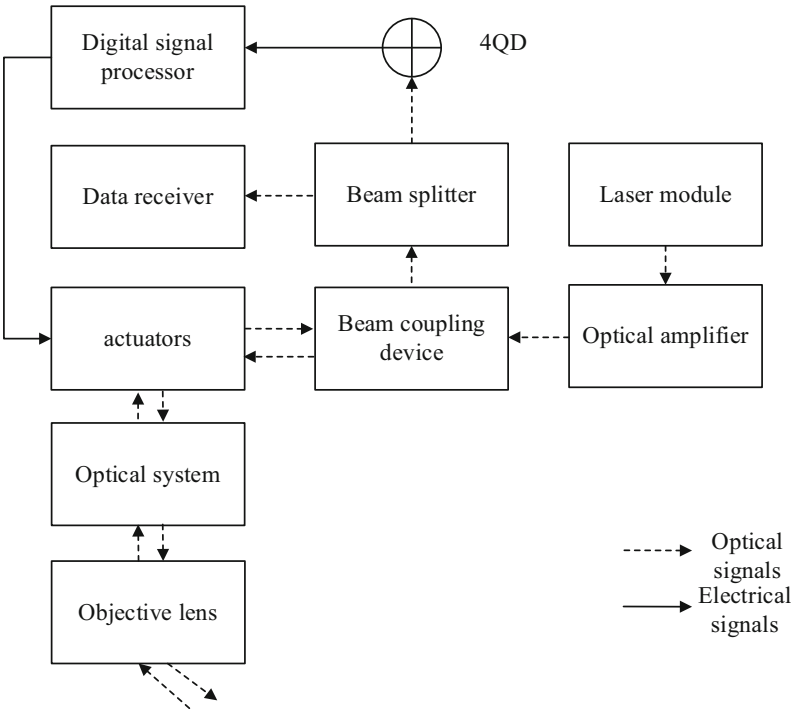

Fig. 9.8 Basic block diagram of SLT [16]

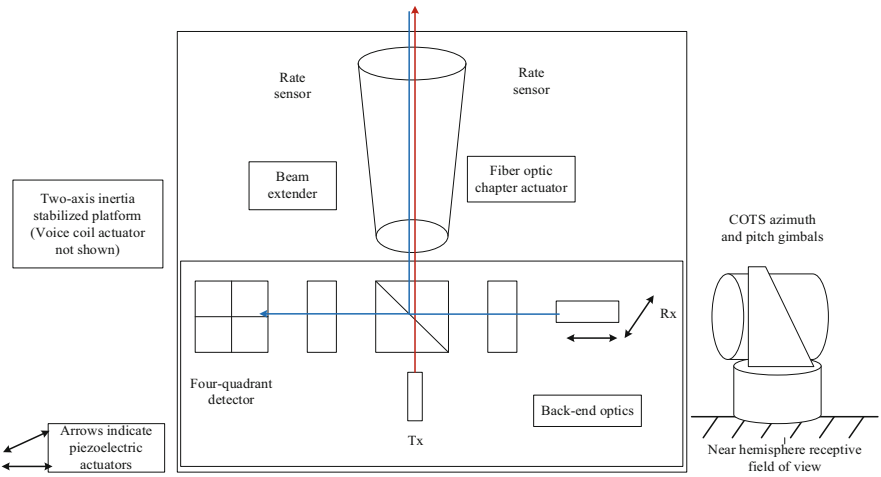

Fig. 9.9 LLST optical-path diagram [46]

In 1996, Feng Longling et al. [45] conducted a more detailed computational analysis of the error-data extraction algorithm, spot size, and other influencing factors in QD tracking technology.

In 1996, Tian et al. [42] described the principle of the sum-difference detection algorithm for angle measurement, carried out error and noise analyses, and found that spot and atmospheric-turbulence noise were the main error sources.

In 1997, Zhou [44] designed an electromechanical four-quadrant detector to measure the spot position. Its measurement resolution was better than 0.1 μm.

In 1999, Wan et al. [43] designed a beam fine-tracking system using a QD and fast reflector and tested the system performance. The results showed that the system had a good fine-tracking capability.

In 2003, Wang et al. [22] designed a two-axis tracking-control experimental demonstration system using QD to measure the spot position and digital signal processing (DSP) to control fast and wide-range scanning systems that could quickly capture and smoothly track the target.

In 2007, Xu [23] studied the relationship between the QD error signal and the spot position, size, and detector and analyzed and quantitatively estimated the causative factors. They proposed an optimized spot-size design and concluded that a spot size slightly larger than one-half of the effective radius of the detector could help improve the system performance.

In 2009, Chen et al. [9] proposed an improved algorithm combining the interpolation method and a diagonal algorithm. It first calculated the spot center using the actual offset and then processed the results of the traditional algorithm, using the interpolation method to bring it closer to the actual value. The angular error could be controlled to within 0.1°.

In 2010, Zhao et al. [5, 24] studied various QD properties and the influence of the external environment on their performance. They conducted experimental tests to examine the ultimate sensitivity, subdivision ability, signal-to-noise ratio, background light, spot size, and other characteristics.

In 2012, Chen et al. [25] discussed and compared four algorithms—sum-difference, diagonal, Δ/Σ, and logarithmic—for various light-spot models.

In 2012, Li et al. [26] proposed the gain-adjustable fast tracking and positioning (GAFT) algorithm. The GAFT algorithm improved the tracking accuracy to 0.0497 mm by changing parameters such as the spot radius and signal strength.

In 2013, Zhang et al. [27] developed a small-laser tracking system using a QD as a spot detector. The subsequent detector circuit had a simple structure and low complexity.

In 2017, Guo et al. [28] proposed and simplified a bipartite polynomial-fitting algorithm to improve the accuracy of QDs in detecting the spot-center position. The spot-detection accuracy of the QD was improved to the order of 10^{-4} mm.

In 2017, Li [6] proposed a spot-detection method to recognize the spot-absence state and adjust it to improve the detection accuracy and reduce the detection error.

In 2017, Zhang et al. [29] proposed a scheme for tracking and communication multiplexing using an avalanche diode–type QD. When the spot diameter was about half of the QD photosensitive-surface diameter, the minimum resolution for spot-position detection was 2 μm, the detection range could reach 0.8 mm, and the angular resolution was 0.8 μrad.

In 2018, Lin et al. [30] designed and tested a QD-based laser-beam 2D scanning–-tracking system. The test results showed that this tracking and scanning system could track moving targets more accurately and in real time.

In 2019, Liu et al. [31] proposed a QD-based laser-tracking system with a tracking error of approximately 0.1% and a tracking speed of 22.6°/s with a ± 20° moving change in the target position.

In 2019, Tong et al. [32] used a QD as a probe for a communication receiver to design a composite digital-tracking communication receiver. A 6.29-μm theoretical position resolution was obtained at a spot radius of 400 μm. A detection sensitivity of −30 dBm was obtained by experimental testing at a BER of 10^{-6} and a communication rate of 10 Mbit/s.

In 2020, Zou et al. [33] proposed a center opening-type four-quadrant detector fiber-positioning mechanism and designed a positioning algorithm. It calibrated the unit-spot bundle waist once and achieved multiple high-precision real-time spot-position determinations and fiber-position adjustments.

In 2021, Liang [34] discussed the relationship between the spot and QD output for different energy-distribution models and studied the center-positioning algorithm and spot-detection working mode for through-hole four-quadrant detectors.

In 2021, Liu et al. [35] proposed an improved algorithm (GII) based on the infinite integral-fitting method. The linear detection range of the GII algorithm was better than that of the traditional infinite integral-fitting algorithm and the eighth-order polynomial-fitting method, with high sensitivity.

In 2021, Wei et al. [36] improved the localization algorithm under a Gaussian spot model to improve the localization accuracy and linear range. It was experimentally verified that the root-mean-square error of the improved Gaussian algorithm was reduced by 60.4%, compared with the conventional Gaussian algorithm.

In 2021, Li et al. [37] investigated the effect of each noise factor when using QD for speckle-position localization. They found that increasing the transmit power could improve the signal-to-noise ratio of the signal at the receiver end, and improve the angular accuracy within a certain range.

In 2022, Xu and Long et al. [38] established the characterization equations of the QD output versus the spot position, considering the spot radius, energy distribution, and detector dead zone. In the 300-μm range, the QD spot-center localization accuracy was 0.35 μm and the root-mean-square error was 0.18 μm.

In 2022, Chen et al. [39] designed a set of micronano laser-communication terminals based on a QD and used a micro-electromechanical system (MEMS)

oscillator as the servo architecture to detect and track an optical spot. The experimental results showed a tracking error of 84 μrad.

QD Spot-Detection Influence Factors

The factors affecting the spot-position detection accuracy are the spot shape and distribution, QD defects, environmental factors, optical and electrical noise, and the detection algorithm.

Effect of Different Light-Spot Modes on the QD Output

Different spot patterns affect the output of the QD, and the generally studied energy-distribution models are uniform and Gaussian. From Eq. (9.12), it can be observed that for a Gaussian spot, the output of the QD in the x-direction with respect to the spot-moving distance can be expressed as [38]

$$\sigma_x = \frac{(S_A + S_D) - (S_B + S_C)}{S_A + S_B + S_C + S_D} = 1 - \left(\frac{2\theta}{\pi} - \frac{2x_0 \sin\theta}{\pi r}\right), \sigma_x = erf\left(\frac{\sqrt{2}x_0}{r}\right), \quad (9.14)$$

where $\theta = acr\cos\left(\frac{x_0}{r}\right)$, σ_x is the actual spot offset, r is the spot radius, x_0 is the moving distance, and S_A, S_B, S_C, and S_D denote the spot areas incident to the four quadrants, respectively.

Figure 9.8 in Reference [37] shows the relationship between the spot center and the QD output value for different spot modes. The spot-position detection sensitivity of a uniform spot is poor, and the linear dynamic range is large. The spot-position detection sensitivity of a Gaussian spot is high, and the linear dynamic range is small.

Effect of Different Spot Radii on the QD Output

Assuming a uniform spot model, the relationship between the spot center and QD output value is investigated for different spot radii. See Fig. 9.4 in Reference [37], with spot radii of $r = 1$, 2, and 3 mm. As the spot radius increases, the detection sensitivity of the QD decreases.

Effect of Different Dead-Zone Widths on the QD Output

A dead zone exists between every two adjacent QD quadrants. The dead-zone size affects the detector's reception of the total spot energy and the accuracy of the spot

localization. When the dead-zone width is d, the detector output in the x direction with respect to the spot-moving distance can be expressed as [38]

$$\sigma_x = 1 - \left(2\theta r^2 - 2x_0 r\sin\theta - \left(2d(r - x_0) + 2d\sqrt{r^2 - x_0^2}\right)\right) / \left(\pi r^2 - \left(2dr + 2d\sqrt{r^2 - x_0^2}\right) - d^2\right). \tag{9.15}$$

Assuming a 2-mm spot radius and dead-zone widths of 0, 0.04, 0.2, and 0.3 mm, Fig. 9.6 in Reference [37] shows that the linear dynamic range of the QD decreases as the dead-zone width increases.

Effect of Different Background Lights on the QD Output

The presence of background light increases the total energy received by the QD, thus increasing the output current. Usually, the ambient-light intensity can be considered uniform, and thus, the background-light distribution in each quadrant on the QD can also be considered uniform. Thus, the output signal of the QD in the x direction with respect to the spot-moving distance can be expressed as [48]

$$\sigma_x = \frac{(I_A + I_D) - (I_B + I_C)}{I_A + I_D + I_B + I_C + I_{BF} + I_{DK}}, \tag{9.16}$$

where I_A, I_B, I_C, and I_D represent the photocurrents generated in each quadrant, I_{BF} represents the photocurrent generated by the entire QD illuminated by background light, and I_{DK} represents the dark current of the entire QD.

Figure 9.3 in Reference [48] shows the relationship between the spot center and detector output for different ratios of background light. As the background light increased, the spot-position detection accuracy and sensitivity decreased to some extent.

Effect of Different Signal-to-Noise Ratios on the QD Output

Improving the system signal-to-noise ratio can improve the position-detection accuracy of a QD. The relationship between the standard deviation of the spot position, influenced by the spot radius, position, and system S/N ratio, is [46]

$$\sigma_r = \frac{\sqrt{\pi}r}{2\sqrt{2}} \frac{1}{\sqrt{SNR_{\sum}}} \left[1 + \frac{x^2 erf^2\left(\frac{\sqrt{2}x}{r}\right) + y^2 erf^2\left(\frac{\sqrt{2}y}{r}\right)}{x^2 + y^2}\right], \tag{9.17}$$

where SNR_{Σ} is the total signal-to-noise ratio of the system, r is the spot radius, and x and y are the spot positions.

Figure 9.4.4 in Reference [46] shows that as the signal-to-noise ratio increases, the standard deviation of the spot position decreases.

Effect of Different Positioning Algorithms on the QD Output

The spot center-of-mass detection algorithm is an important factor that affects the accuracy of the QD detection. The commonly used algorithms are the addition-subtraction, diagonal, difference-ratio-sum, and logarithmic algorithms. Assuming that the spot is a uniform circular spot, the four algorithms are compared; see Fig. 9.6 in Reference [35].

It can be seen that for a circular spot with a uniform energy distribution, the linearity and sensitivity of the four algorithms differ. The difference-ratio-sum algorithm is the best in terms of sensitivity and the worst in linear range. The diagonal algorithm has good linearity but is lower than the difference-ratio-sum algorithm and has reduced sensitivity. The addition-subtraction algorithm is more balanced in sensitivity and linear range, and the logarithmic algorithm has a wider linear range.

The missing spot was modeled as an ideal elliptical spot, and its impact on the spot detection was simulated and analyzed. The offsets Δx, Δy, Δx_T, and Δy_T in the x- and y-axis directions for circular and elliptical spots are

$$\Delta x = P_0 erf\left(\frac{\sqrt{2}x_0}{R}\right) \tag{9.18}$$

$$\Delta y = P_0 erf\left(\frac{\sqrt{2}y_0}{R}\right) \tag{9.19}$$

$$\Delta x_T = P_0 erf\left(\frac{\sqrt{2}x_0}{w_a}\right) \tag{9.20}$$

$$\Delta y_T = P_0 erf\left(\frac{\sqrt{2}y_0}{w_b}\right), \tag{9.21}$$

where P_0 is the received optical power, x_0 is the travel distance in the x direction, y_0 is the travel distance in the y direction, r is the radius of the circular spot, w_a is the long axis of the elliptical spot, and w_b is the short axis of the elliptical spot.

Figure 9.6 in Reference [6] shows the variation curves of the x- and y-axis offsets with offset detection values under different spot models. It can be observed that the larger the spot variation, the smaller the linear interval. The missing spot reduces the detectable range of the QD.

Spot-Detection Algorithms

When a QD is used to detect the spot position, the spot center-of-mass position is determined according to the four signals output from the detector. Commonly used algorithms include addition-subtraction, diagonal, difference-ratio-sum, and logarithmic. Function-fitting methods include normalized-center, polynomial-fitting, infinite-integration, Boltzmann function-fitting, composite, and infinite integration-improvement.

Addition-Subtraction Algorithm

When a spot is irradiated onto the QD, the offset of the spot relative to the center of the detection surface is denoted by σ_x and σ_y, and the offset is calculated using the addition and subtraction algorithm to obtain [8]

$$\sigma_x = \frac{(U_A + U_D) - (U_B + U_C)}{U_A + U_B + U_C + U_D} \tag{9.22}$$

$$\sigma_y = \frac{(U_A + U_B) - (U_C + U_D)}{U_A + U_B + U_C + U_D}, \tag{9.23}$$

where U_A, U_B, U_C, and U_D denote the voltages in the four quadrants of the QD.

For the QD, the x- and y-axis offsets are proportional to the spot area, so the actual offsets σ_x and σ_y can be expressed as

$$\sigma_x = \frac{(S_A + S_D) - (S_B + S_C)}{S_A + S_B + S_C + S_D} \tag{9.24}$$

$$\sigma_y = \frac{(S_A + S_B) - (S_C + S_D)}{S_A + S_B + S_C + S_D}, \tag{9.25}$$

where S_A, S_B, S_C, and S_D are the spot areas in the four QD quadrants.

Diagonal Algorithm

The diagonal algorithm was generated to extend the linear region of the measurement. Using the diagonal algorithm to calculate offsets σ_x and σ_y yields

$$\sigma_x = \frac{U_A - U_C}{U_A + U_B + U_C + U_D} \tag{9.26}$$

$$\sigma_y = \frac{U_B - U_D}{U_A + U_B + U_C + U_D}. \tag{9.27}$$

The relationship between the spot-center offset and spot area in each quadrant of the detector in the linear region is

$$\sigma_x = \frac{S_A - S_C}{S_A + S_B + S_C + S_D} \tag{9.28}$$

$$\sigma_y = \frac{S_B - S_D}{S_A + S_B + S_C + S_D}. \tag{9.29}$$

Difference-Ratio-Sum Algorithm

The measurement sensitivity of the diagonal algorithm is reduced compared to that of the addition-subtraction algorithm, and the difference-ratio-sum algorithm was proposed to improve the measurement sensitivity. Using the difference-ratio-sum algorithm to calculate the offsets σ_x and σ_y yields

$$\sigma_x = \frac{U_A - U_C}{U_A + U_C} \tag{9.30}$$

$$\sigma_y = \frac{U_B - U_D}{U_B + U_D}. \tag{9.31}$$

In the linear region, the relationship between the spot-center offset and spot area in each quadrant of the detector is

$$\sigma_x = \frac{S_A - S_C}{S_A + S_C} \tag{9.32}$$

$$\sigma_y = \frac{S_B - S_D}{S_B + S_D}. \tag{9.33}$$

Logarithmic Algorithm

The logarithmic algorithm has a high bandwidth, wide dynamic range, and good linearity. Using the logarithmic algorithm to calculate the offsets σ_x and σ_y [9],

$$\sigma_x = \log\left(\frac{U_A}{U_C}\right) \tag{9.34}$$

$$\sigma_y = \log\left(\frac{U_B}{U_D}\right). \tag{9.35}$$

In the linear region, the relationship between the spot-center offset and spot area in each quadrant of the detector is

$$\sigma_x = \log\left(\frac{S_A}{S_C}\right) \tag{9.36}$$

$$\sigma_y = \log\left(\frac{S_B}{S_D}\right). \tag{9.37}$$

Function-Fitting Methods

The function-fitting method [45] uses various types of functions to fit the relationship between the solved QD value and the actual position of the spot center to determine the position of the spot center. Their relationship curve is an "S" type.

(1) **Normalized Center**

The normalized-center method approximates the response within a certain region near the center of the QD as a linear response and fits it with a first-order function to obtain the actual location of the spot center [47]:

$$x_0 \approx k \times \sigma_x, \tag{9.38}$$

where k is the scale factor, which is related to the QD shape, size, spot-intensity distribution, and dead-zone width. The normalized-center method error increases as the spot center gradually moves away from the detector center.

(2) **Polynomial Fitting**

The polynomial-fitting method uses a higher-order polynomial to fit a function between the solution value and the actual location of the spot center [45]:

$$x_0 \approx \sum_{i=0}^{n} a_n \sigma_X^n, \tag{9.39}$$

where a_n is the fitting coefficient. The accuracy of the polynomial-fitting method depends on the order; the higher the order, the higher the accuracy, but the higher the hardware requirements.

(3) **Infinite Integration**

The infinite-integration method assumes that the QD has no dead zone and is infinite. Its solution value can be expressed as [48]

$$\begin{aligned}\sigma_x &\approx \frac{\int_{-\infty}^{\infty}\int_{-\infty}^{0} I(x,y)dxdy - \int_{-\infty}^{\infty}\int_{0}^{\infty} I(x,y)dxdy}{\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} I(x,y)dxdy} \\ &= \frac{\frac{I^2\pi}{4}\left(1+erf\left(\frac{\sqrt{2}}{r}x_o\right)\right) - \frac{I^2\pi}{4}\left(1-erf\left(\frac{\sqrt{2}}{r}x_o\right)\right)}{\frac{I^2\pi}{2}}, \\ &= erf\left(\frac{\sqrt{2}x_0}{r}\right)\end{aligned} \tag{9.40}$$

where $erf(x) = \frac{2}{\sqrt{\pi}}\int_0^x e^{-t^2}dt$ is the error function. The actual position of the spot center is obtained by inverting both sides of Eq. (9.40):

$$x_0 \approx \frac{erf^{-1}(\sigma_x)r}{\sqrt{2}}. \tag{9.41}$$

(4) **Boltzmann-Function Fitting**

Boltzmann-function fitting involves finding the functional relationship between the solved value and the actual position of the spot center. The functional expression is [46]

$$y = \frac{A_1 - A_2}{1 + e^{(x_0 - x_a)/k}} + A_2, \tag{9.42}$$

where A_1, A_2, x_a, and k are parameters to be determined. By performing the following mappings, $y = \sigma_x$, $A_1 = -1$, $A_2 = 1$, and $x_a = 0$, we obtain [46]

$$\sigma_x \approx 1 - \frac{2}{1 + e^{x_0/k}}, \tag{9.43}$$

where k is the scale factor, which is related to the QD shape, size, spot-intensity distribution, and dead-zone width. The expression of the Boltzmann-function fitting method is [46]

$$x_0 \approx k \times \ln\left(\frac{1+\sigma_x}{1-\sigma_x}\right). \tag{9.44}$$

(5) **Composite Fitting**

Composite fitting is a new fitting algorithm that linearly fuses two algorithms: Boltzmann-function fitting and infinite fitting. Its spot center-of-mass position is expressed as [47]

$$x_0 \approx m \times k_1 \frac{erf^{-1}(\sigma_x) \cdot \omega}{\sqrt{2}} + (1-m) \times k_2 \ln\left(\frac{1+\sigma_x}{1-\sigma_x}\right), \tag{9.45}$$

where k_1 and k_2 are correction coefficients and m represents the weights. k_1, k_2, and m can be obtained by least squares using N sets of experimental or simulation data [46]:

$$k_1 = \frac{\sum_{n=1}^{N} f_1(\sigma_{X_n}) \times x_n}{\sum_{n=1}^{N} f_1^2(\sigma_{X_n})}, \quad f_1(E_X) = \frac{erf^{-1}(\sigma_X)}{\sqrt{2}} \tag{9.46}$$

$$k_2 = \frac{\sum_{n=1}^{N} f_2(\sigma_{X_n}) \times x_n}{\sum_{n=1}^{N} f_2^2(\sigma_{X_n})}, \quad f_2(E_X) = \ln\left(\frac{1+\sigma_X}{1-\sigma_X}\right) \tag{9.47}$$

$$m = \frac{\sum_{i=1}^{N} (x_n - k_1 f_1(\sigma_{X_n}))(k_1 f_1(\sigma_{X_n}) - k_2 f_2(\sigma_{X_n}))}{\sum_{i=1}^{N} (k_1 f_1(\sigma_{X_n}) - k_2 f_2(\sigma_{X_n}))^2}. \tag{9.48}$$

(6) **Infinite Integral-Fitting Improvement**

The infinite integral-fitting improvement algorithm is proposed to improve the positioning accuracy by considering the effects of the QD photosensitive-surface radius and dead-zone width. The compensation function is fitted by introducing a compensation factor and using a segmented polynomial-fitting method. The expression for the spot center-of-mass position is [46]

$$x_0 = \frac{erf^{-1}(\sigma_x)}{\sqrt{2}} \times r \times \lambda(r, R, d), \tag{9.49}$$

where r is the Gaussian spot radius, R is the QD radius, and d is the dead-zone width.

By combining the last two terms of Eq. (9.49) into a single parameter, it becomes [46]

$$x_0 = g(\sigma_x) \times \lambda_e(\sigma_x, r, R, d). \tag{9.50}$$

The least-squares method was used to model the position-detection error [46]:

$$I(\lambda_e) = \|\delta_x\|^2 = \sum_{i=1}^{N} [x_0(\lambda_e, \sigma_{x_i}) - x_i]^2. \tag{9.51}$$

Deriving the equation gives [46]

$$\frac{\partial I}{\partial \lambda_e} = 2\sum_{i=1}^{N} g(\sigma_x) \times \lambda_e - 2\sum_{i=1}^{N} g(\sigma_x) \times X_i. \tag{9.52}$$

Let $\frac{\partial I}{\partial \lambda_e} = 0$, to obtain the optimal λ_e [46]:

$$\lambda_e = \frac{\sum_{i=1}^{N} g(\sigma_x) \times X_i}{\sum_{i=1}^{N} g^2(\sigma_x)}. \tag{9.53}$$

QD Light-Spot Detection System

Beam-Alignment Detection System

The structure of the beam-alignment detection system is shown in Fig. 9.10. The optical receiving antenna uses a Cassegrain telescope. A detection module is placed behind the receiving telescope, and a cylindrical holder, dimming lens, and QD are placed vertically above the beam-splitting prism. The system detects the beam alignment using two motors.

Missing-Spot Detection Test

In Reference [40], Table 9.2 shows the actual position-measurement data obtained with the incident beam in the missing state. The long axis w_a of the tested spot was 0.6 mm, the short axis w_b was 1.2 mm, and the right side of the spot was missing. It can be observed that the actual value of the detector offset deviates from the calculated value under the missing spot. The detected missing spot is shown in Fig. 9.11.

System Alignment Test

Figure 9.12 shows the complete spot detected when the spot is adjusted to the no-detect state using the threshold-detection algorithm.

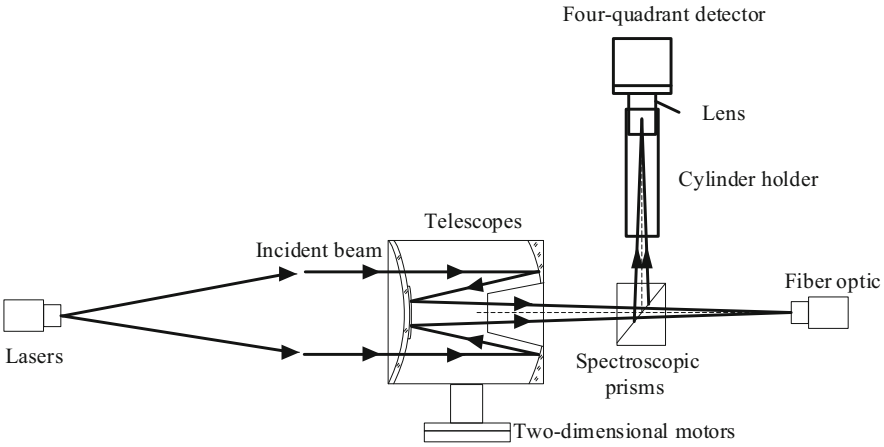

Fig. 9.10 System architecture [41]

Fig. 9.11 Missing-spot detection map [41]

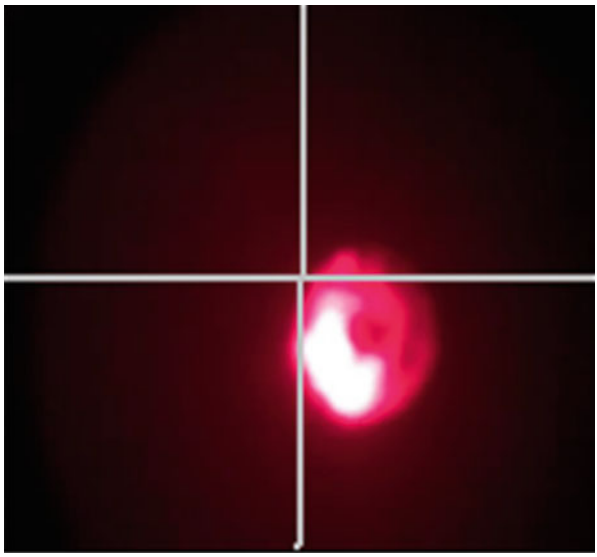

Figure 9.13 shows the output of the detector when the spot is adjusted from the missing state to the full-spot state.

QD Composite Tracking and Communication System

The QD composite tracking and communication detection system [29] is shown in Fig. 9.14 and consists of four parts: a laser-modulated emission unit, signal detection and processing unit, tracking control unit, and communication unit.

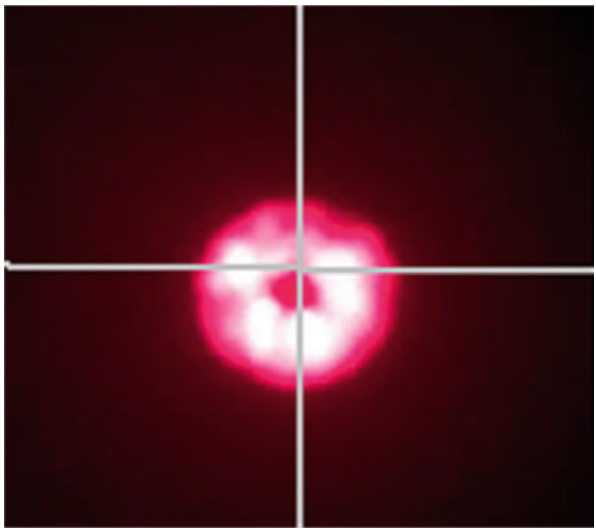

Fig. 9.12 Complete-spot detection map [41]

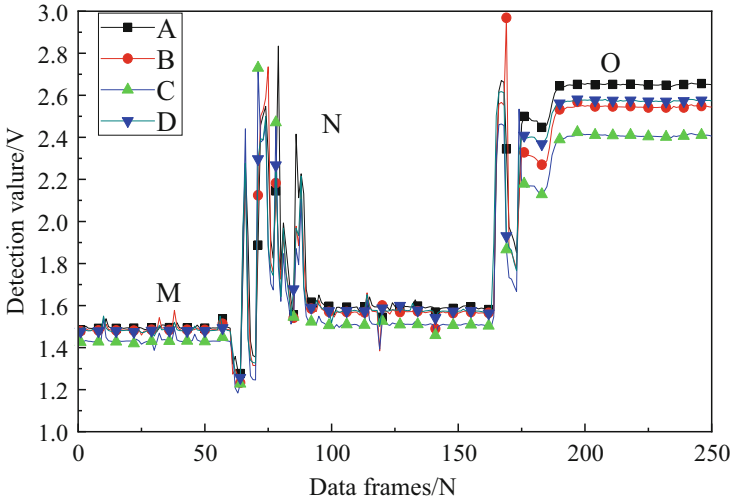

Fig. 9.13 QD output diagram of the regulation process [41]

Micro- and Nano-laser-communication Terminal

The optical architecture and servo-system structure of the micro- and nano-laser-communication terminal [39] is shown in Fig. 9.15. It consists of a four-quadrant detector, MEMS oscillator, oscillator driver, analog-to-digital converter, and digital-to-analog converter. The light spot is tracked using the four-quadrant detector and MEMS oscillator.

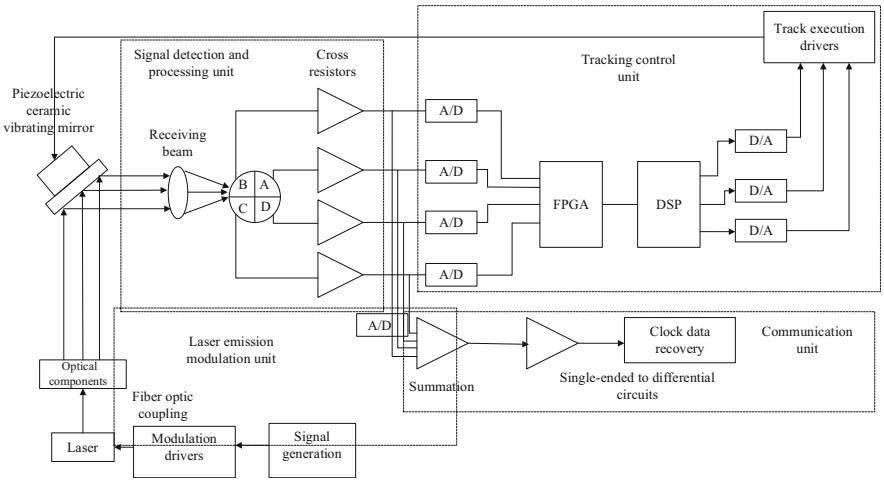

Fig. 9.14 Composite tracking and communication detection system [29]

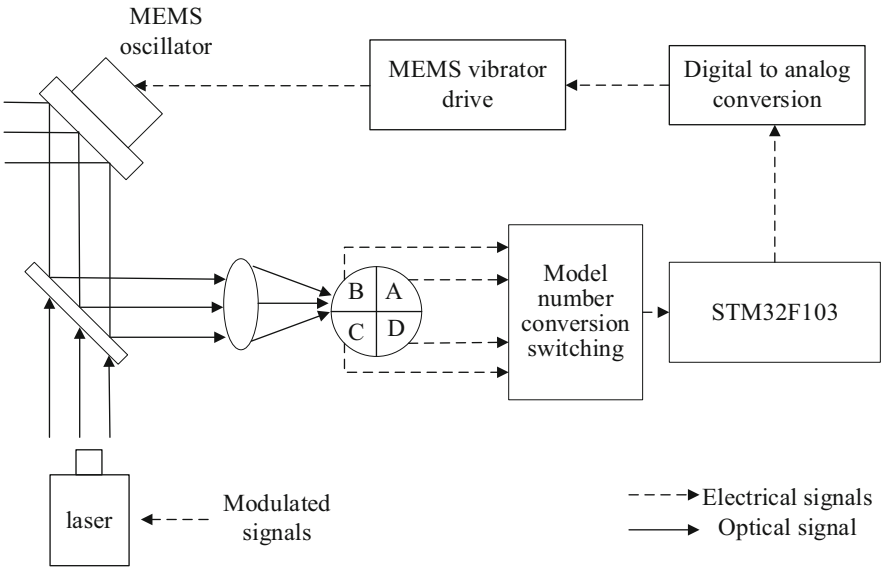

Fig. 9.15 Schematic diagram of the micro- and nano-laser-communication terminal system [39]

Summary

This chapter used spot detection as the entry point, introduced the basic spot model and QD detection principle, and reviewed the QD spot-detection development status. In addition, it described the QD spot-detection influencing factors and spot-detection

algorithms and introduced the QD spot-detection system. Spot-detection technology based on the four-quadrant detector is likely to develop in the following directions.

1. Use APD-type QDs to achieve composite tracking and communication detection, integrate tracking and communication, miniaturize servo-structure design, and reduce the size and power consumption of the laser-communication system.
2. Study the spot-position detection algorithm, improve the spot-position detection accuracy, and reduce the requirements for hardware processing capability.
3. Establish a complete mathematical model for describing and analyzing the effect of noise on the spot-position detection accuracy and study in depth how to suppress the noise.
4. Study the effects of different combinations of influencing factors on the detector accuracy.

Abstract

Optical antenna is used to transmit or collect optical signals in free space optical communication system, and the structure of optical antenna determines the detection performance of the system. This chapter introduces the basic structures of optical antenna, the research progress of Cassegrain optical antenna, pointing, acquisition, and tracking (PAT) system without independent beacon and the point-to-multipoint optical antenna in detail, the future research direction of optical antenna is prospected.

Introduction

An optical antenna is the optical-signal receiving and transmitting system and is a key component of optical wireless communication systems. It transmits optical signals at the transmitting end and receives and couples optical signals at the receiving end. The performance of the optical system directly affects the performance and communication quality of the entire optical wireless communication system. Therefore, research on optical systems is highly significant for improving the performance of optical wireless communication systems and meeting the increasing demand for speed and capacity in future communications.

In this chapter, the basic structure of the optical antenna is introduced, and the widely used Cassegrain optical system is analyzed and compared. This chapter introduces a beacon-free optical system and a point-to-multipoint communication optical system, which will be necessary for the development of optical-communication networks in the future.

Basic Structure of an Optical Antenna

Since the United States launched the "Star Wars" program in 1953, space laser communication technology has rapidly developed. Germany, France, the United Kingdom, Japan, and other countries have also successively conducted relevant research [1], such as studying the working wavelength of an optical antenna as the transceiver of a communication system, beacon optical capture and tracking, and antenna-structure form.

The common structural forms of optical transceiver antennas are refractive, reflective, and reentrant. A refractive optical system is usually suitable for optical wireless communication in the visible and near-infrared bands. The reflection system is applicable to all wavebands. The reentrant optical system is suitable for long-distance optical wireless communication under complex atmospheric conditions, owing to its aberration correction.

Reflective optical systems can have multiple focal points, so they can produce multiple relative apertures, field angles, and focal lengths. Newtonian, Gregory, and Cassegrain optical systems are commonly used, as shown in Fig. 10.1a–c, respectively.

Newtonian optical systems have a relatively large aperture and are often used in optical systems with large apertures. However, the manufacturing cost is high, and they produce a coma for off-axis lights. The Gregory system simultaneously eliminates spherical and chromatic aberrations; however, the manufacturing process has high requirements, and there are few practical applications.

The Cassegrain optical system [2] is a dual-reflection telescopic optical system that has the advantages of a short system length, small volume, light weight, compact structure, and other practical characteristics. Moreover, the system has no chromatic or spherical aberrations, and it can adjust the system aperture according to its actual needs. Because of these advantages and characteristics, the Cassegrain optical system is widely used in free-space optical communications [3].

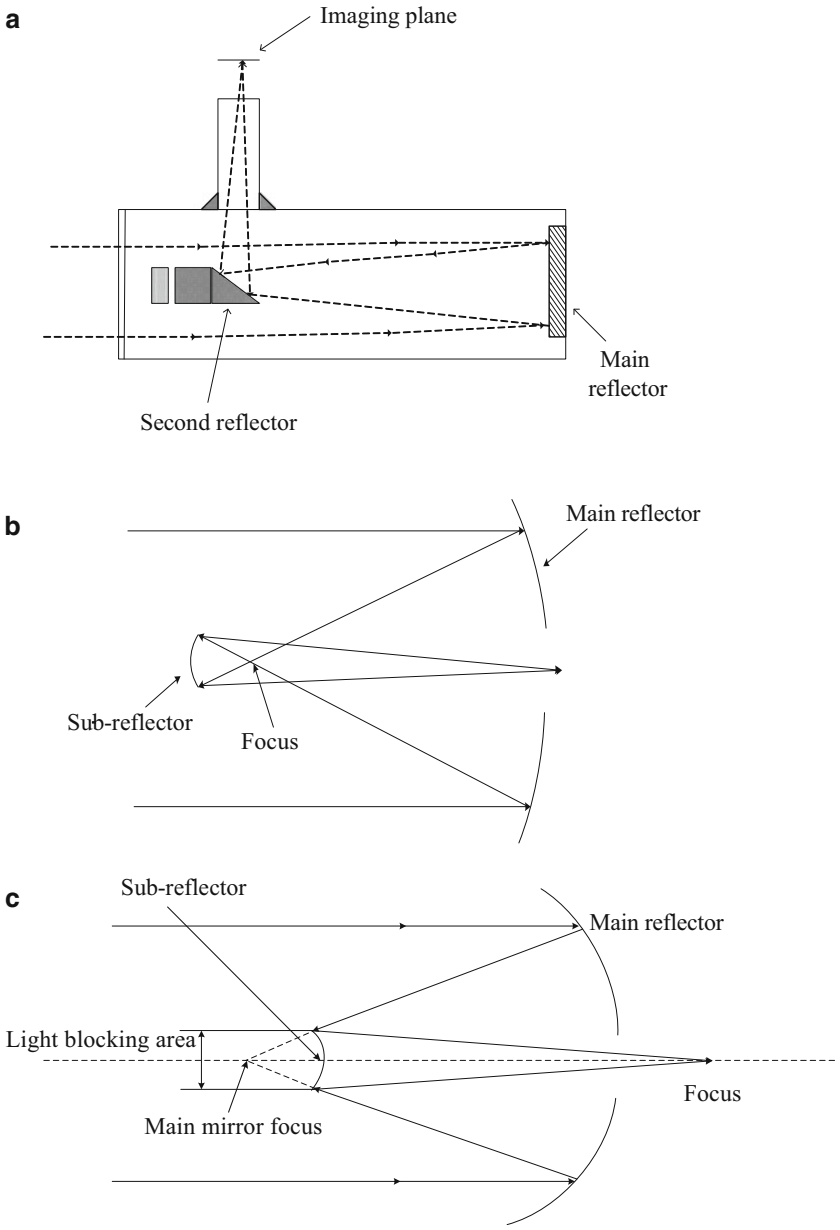

Fig. 10.1 Reflective optical systems. (**a**) Newtonian optical system, (**b**) Gregory optical system, (**c**) Cassegrain optical system

However, the occlusion ratio of the dual-reflection structure wastes optical-signal energy, serious off-axis aberrations exist, and high-quality image points are obtained at the expense of the field of view. Section "Beacon-Free Tracking" of this chapter

presents in-depth research on the defects and problems of the Cassegrain optical system.

The refractive optical system is shown in Fig. 10.2. The front objective is a group of glued lenses. After passing through the objective, the light is imaged in front of the eyepiece, and the image point is received after being magnified by the eyepiece. Refractive telescopes have the advantages of a wide field of view, high contrast, and clarity; however, the objective lens produces chromatic aberrations in refractive telescopes, and the larger the aperture, the more serious the chromatic aberration. Moreover, the lens-tube length determines the focal length, resulting in the large volume of the refracting telescope.

A structural diagram of the reentrant optical system is shown in Fig. 10.3. The reentrant optical system combines the objective lens of a refractive optical system with a reflective optical system. The objective lens is a wave-shaped correction lens with a convex center, concave periphery, and complex shape that corrects the spherical aberration of the spherical primary lens. The reentrant optical system mainly includes the Schmidt–Cassegrain, Maksutov–Cassegrain, and Fresnel optical systems.

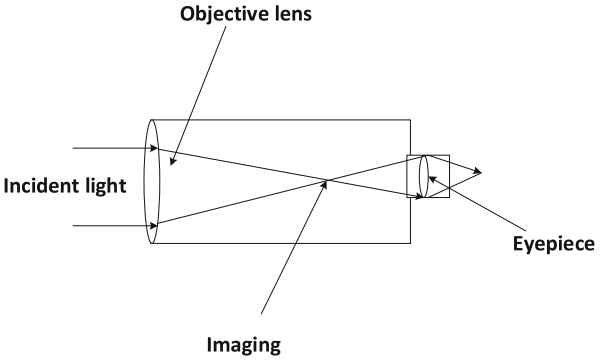

Fig. 10.2 Refractive optical system

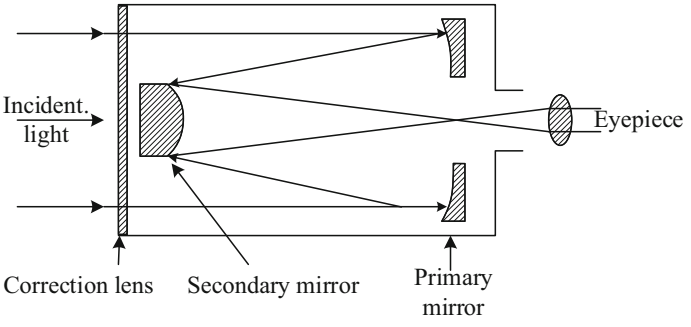

Fig. 10.3 Reentrant optical system

The Schmidt–Cassegrain system is based on the Schmidt astronomical observatory, uses a Schmidt correction lens to correct spherical aberrations, and adopts a convex mirror as the secondary mirror of the optical system, following the Cassegrain structure. It has many deformable structures, such as the double-spherical mirror group, double-aspheric lens group, and a combination of spherical and aspheric mirrors. This type of antenna structure is relatively simple to manufacture, compact in structure, and easy to carry.

A typical feature of the Maksutov–Cassegrain (Maka) system is that the secondary mirror is very small, usually an aluminized circular spot on the correction mirror. The catadioptric structure makes the Maka antenna compact, and a lens-group system with a large aperture and long focal length can be created with a small size. When the Maka antenna is used as a space optical-coupling system, it can produce large-aperture coupling receiving technology and has a strong ability to gather optical power. The long focal length easily meets the requirements of an optical-fiber numerical aperture. At the same relative aperture (D/f), the length of the lens system can be reduced to nearly one-half that of an ordinary lens system, and its advantages cannot be ignored in engineering.

The Fresnel optical system is based on the Cassegrain structure and uses a Fresnel lens to replace the refractive correction lens at the front end. Compared with conventional correction lenses, Fresnel lenses have the advantages of a strong focusing ability, short focal length, thin lens, and light weight. Their optical efficiency is more than 90%, which is suitable for most front-ends of optical systems with a small field of view and high gain [4]. The advantages and disadvantages of these three structures are compared in Table 10.1.

Table 10.1 Comparison of the refractive, reflective, and reentrant structures

Optical-system type	Advantages	Disadvantages
Refractive	Wide field of vision; high contrast and high definition	The chromatic aberration is serious; the aperture has a great influence on the performance; the system is bulky and bloated
Reflective	Multi-focus, different numerical aperture and field-of-view angle; spherical and chromatic aberrations; wide spectrum range; simple optical structure, excellent image quality	The production cost is high, the production process is complex, and the off-axis light differs.
Reentrant	Eliminates the refractive-chromatic, reflective-spherical, and other aberrations. The focal length is longer at the same volume	The chromatic aberration is serious, the pore diameter has a great influence on the performance, and the volume is huge. The production cost is high, the production process is complex, and the off-axis light also differs

Cassegrain Optical Antennas

The Cassegrain optical system includes the following optical antennas: large-aperture, array, free-form surface, antenna based on beam-shaping, off-axis dual-reflection, array Gaussian beam off-axis emitting, and pre-collimated. These structures are the results of studying Cassegrain antennas in free-space optical system over the past decades. This study introduces these structures and compares their advantages and disadvantages.

Large-Aperture Cassegrain Antenna

In 1998, AstroTerra [5] designed and developed an optical transceiver antenna for optical communication with the support of the United States Ballistic Missile Defense Organization (BMDO). The antenna was based on a Cassegrain antenna structure, with a weight of 31.5 pounds, volume of less than 1 cubic foot, and a 100-mm aperture. It aligned the transmitting beam, tracked and aligned the signal light, and realized two-way high-speed satellite–ground communications at a maximum transmission rate of 1 Gbit/s.

From 1999 to 2007, the Cassegrain system was used as the main optical antenna in Japan's orbital inter-satellite laser communication satellite [6] (OICETS), the European Aviation Administration's laser inter-satellite link experiment (SILEX) [7], and the United States' optical communication and sensor demonstration (OCD) [8], with antenna diameters of 260 mm, 250 mm, and 100 mm, respectively. The working wavelengths were 1062 nm, 510 nm, and 830 nm, respectively. The maximum powers were 130 W, 115 W, and 90.4 W, respectively.

In 2001, the National Space Development Agency of Japan developed a free-space laser-communication terminal for inter-orbiting satellites [9]. Its uplink working wavelength was 1552 nm, the downlink working wavelength was 1562 nm, the transmitting-antenna aperture was 150 mm, and the maximum speed was 2.488 Gbit/s. When the reception condition was -71.4 dBm, the bit-error rate (BER) was 10^{-6}, the reception sensitivity was 70 photons/bit, and the maximum communication distance reached 25×10^5 km.

In 2013, NASA developed a moon–earth optical wireless communication platform (LLCD) [10]. Its communication terminal on the Moon used a Cassegrain optical antenna with a 108.5-mm optical aperture and a 1550-nm working wavelength. The communication distance of the system reached 45×10^5 km and achieved a two-way communication rate of 20 Mbit/s for the uplink and 615 Mbit/s for the downlink over this distance.

All the above satellite–ground laser communication projects used the Cassegrain optical antenna as the optical system of the transceiver terminal, with no chromatic aberrations and a wide spectral range. Owing to the continuous increase in communication distance, capacity, and speed, the aperture of the Cassegrain optical antenna continues to expand, and the focal length continues to grow. This overcomes the

problem of low received optical-signal energy caused by the middle occlusion ratio of the Cassegrain antenna system and helps meet the actual demand for higher-power optical-signal reception.

Cassegrain Optical-Antenna Array

In 2004, Pitman [11] designed a multi-aperture distributed optical-antenna array, as shown in Fig. 10.4. The system consisted of nine basic array elements with the same focal length. The basic array element was a Cassegrain optical system with a 35-cm aperture. After the nine telescopes were arranged according to a certain layout, they formed a remote-sensing optical-antenna array with a 1.5-m synthetic aperture and 0.8-m focal length. The entire remote-sensing system was composed of a front telescope array, relay optical system, rear support, and servo-control system.

As a subunit, the system could form a larger antenna array with 54 basic arrays. For a 5000-km beam-transmission distance, the maximum resolution of the antenna was 4 m. In addition, it could provide accurate servo control in different bands, distances, and remote-sensing tasks to meet the requirements of accurate imaging. The aperture antenna-array system increases the effective receiving area and the receiving field of view through the expanded synthetic aperture. Moreover, directional reception and interferometry technology make it possible to meet a variety of practical needs.

Freeform-Surface Cassegrain Antenna

In 2008, Takahashi et al. [12] proposed a free-form fiber-coupled Cassegrain antenna with an aiming tracker. A fiber-coupling device made of a glass buckle and optical fiber seamlessly coupled the beam to a single-mode optical fiber. The signal wavelength was 1562 nm, beacon wavelength was 980 nm, and antenna aperture was 40 mm. The beam inclination angle was less than 20 μrad. A tracking collimator with

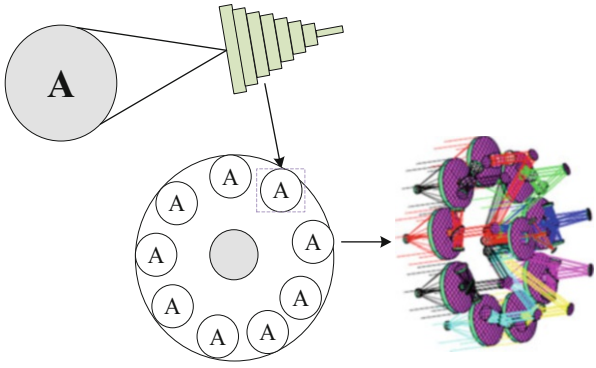

Fig. 10.4 Schematic diagram of a multi-aperture optical-antenna array structure

a response frequency of up to 2 kHz effectively reduced the impact of the angle-of-arrival fluctuation.

In 2011, Li et al. [13] designed a new type of optical antenna for ultraviolet communication. The system structure introduced a double reflector based on a composite paraboloid, which filtered visible and infrared light and reduced the background noise.

In 2019, Gu et al. [14] proposed a design scheme for an unfocused space-laser optical-communication system, based on off-axis free-form surfaces. This scheme adopted a defocused structure to solve the problem of high-power density at the focus of traditional optical-focusing elements when high-power signal sources were used. The simulation results showed that the stellar ratio of the signal beam was greater than 0.8, and the optical field of view was increased by 26.7%, compared to that of a traditional antenna.

Cassegrain Optical Antenna Based on a Beam-Shaping Scheme

In 2002, Kong et al. [15] proposed a design scheme for a ring-beam transmitting optical antenna, as shown in Fig. 10.5. The scheme used two conical or complex-parabolic mirrors to transmit the ring beam, which reduced the beam-energy loss caused by the central block of the card antenna. It reduced the energy loss by up to 45.7%. Owing to the geometric optics and processing level, the accuracy of the prism angle is difficult to guarantee; therefore, the accuracy of this scheme is low, and the error is large.

In 2009, Shishlov et al. [16] designed a Cassegrain optical-antenna structure that could control the beam waveform in a mobile-satellite communication band. As shown in Fig. 10.6, the antenna is composed of two mirrors and a phased-array controller. The main reflector is used to improve the antenna gain, and the secondary reflector rotates in elevation and azimuth to control the beam. The phased array maximizes the radiation direction (Fig. 10.7).

In 2012, Yu et al. [17] proposed a scheme that converted a solid Gaussian beam into a hollow Gaussian beam by correcting a pair of two-dimensional optical-

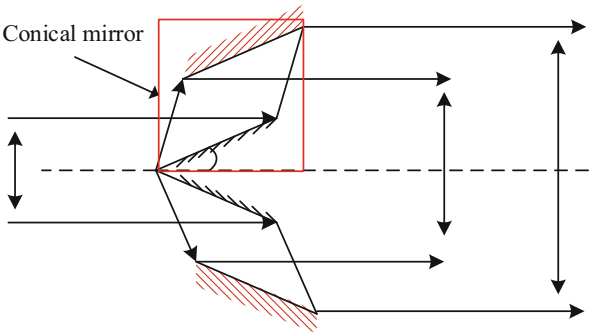

Fig. 10.5 Schematic diagram of a conical-mirror structure

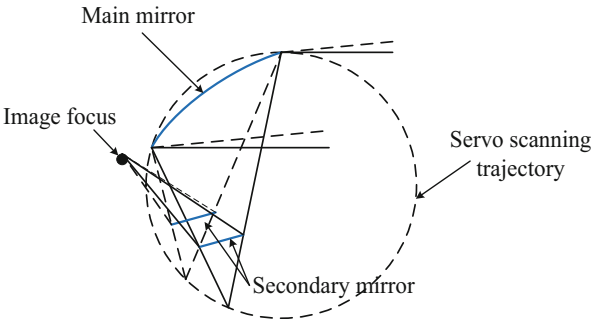

Fig. 10.6 Schematic diagram of a waveform control-card antenna

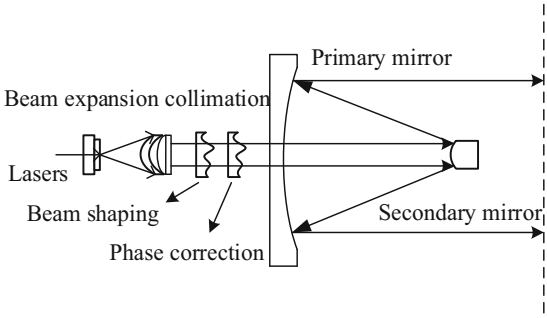

Fig. 10.7 Structural diagram of an annular-beam emission optical antenna

diffraction elements through beam shaping and phase compensation. This avoided the beam-energy loss caused by central occlusion. The emission efficiency of this optical-system structure exceeded 95%.

In 2018, Xu et al. [18] designed a new type of Fresnel optical antenna. As shown in Fig. 10.8, the signal beam is first incident to the phase-modulated Fresnel zone plate at the center of the main mirror, and the outgoing beam is a hollow beam with a focus. The beam is incident on the secondary mirror in the hyperbolic structure; it is then reflected by the primary mirror and emitted parallel to the antenna structure. The system uses a self-designed phase-modulated Fresnel zone plate.

The transmission efficiency of the Gaussian beam, in the secondary-mirror occlusion part at the exit pupil of the antenna, was 92.82%, with an efficiency increase of 31.42%. Compared to the diffraction-element annular Gaussian-beam emission scheme, the zone plate has a simple structure and is easy to operate and realize. Although the emission efficiency is slightly lower, it has good practicability and realizability.

The above four beam-shaping schemes are proposed to compensate for the low light-energy utilization rate of the Cassegrain antenna. The structure and principle of the scheme proposed in Reference [19] are relatively simple, but the requirements for

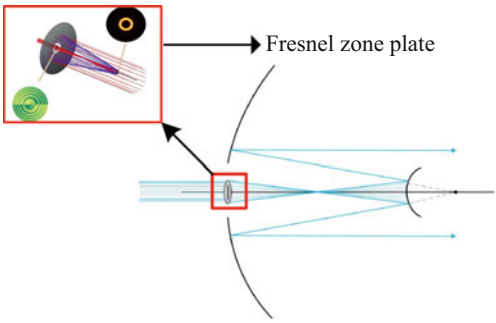

Fig. 10.8 Structural diagram of a ring-beam emitting optical antenna

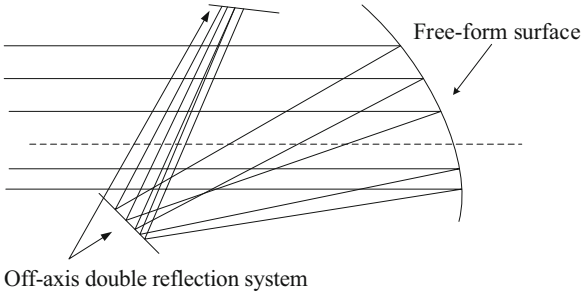

Fig. 10.9 Schematic diagram of an off-axis double-reflection structure with a free-form surface

the transmittance and reflectivity of the prism are very high. It is difficult to meet the manufacturing-process requirements.

The scheme proposed in References [23, 24] uses the phase-shaping principle to output the beam as a circular beam. This is more suitable for practical applications, owing to the good dispersion and temperature-difference characteristics, high diffraction efficiency, high accuracy, and operability of the binary-diffraction element. The scheme proposed in Reference [13] receives optical signals in a larger field of view and adjusts the antenna for different angles and beam conditions to achieve optimal reception. This expands the receiving field of the Cassegrain antenna.

Off-Axis Dual-Reflection Cassegrain Optical Antenna

In 2017, Shu et al. [19] proposed using an off-axis double-mirror reflection structure with a free-form surface instead of a coaxial double-mirror reflection structure for space laser-communication optical antennas. As shown in Fig. 10.9, the light emitted through the free surface accurately entered the first coated mirror of the off-axis double-reflection system, and the reflected light entered the optical-relay system.

In 2019, Tian et al. [20] designed a four-mirror optical antenna with a long exit-pupil distance axis. The exit-pupil position of the optical system coincided with the

position of the fast mirror. This eliminated the optical relay system and overcame the defect that the backscattered light of the optical relay system adversely affected the laser-communication terminal.

According to the above optical antenna structure, we can conclude that the addition of a free-form surface can effectively correct off-axis aberration. Compared to a coaxial transmission system, the modulation transfer function (MTF) of the off-axis reflection system is higher, and it can work closer to the diffraction limit in a large field of view.

With the constant expansion of the field of view, the performance of the coaxial system decreases rapidly, whereas the off-axis dual-reflection structure remains stable and can approach the diffraction limit. In addition, the off-axis dual-reverse structure avoids the problem of low energy utilization caused by the key occlusion of the Cassegrain optical ensemble. This makes it more suitable for spaceborne laser communications and improves the overall performance of the space laser-communication system.

Maksutov–Cassegrain Optical Antenna with Off-Axis Emission of a Gaussian-Beam Array

In 2015, Ke and Wang et al. [21] designed an array of off-axis Gaussian-beam transmitting Maksutov–Cassegrain antennas in response to the optical-signal energy waste caused by the occlusion ratio of the Maksutov–Cassegrain antenna (hereinafter referred to as the Maka antenna). Because the coaxial transmission efficiency of the Maka antenna was low, and the reception efficiency was low because of the secondary-mirror occlusion, the Maka antenna structure was properly modified so that it could emit Gaussian beams off-axis. Moreover, its transmission and reception efficiencies were further improved through the self-coupling phenomenon of the Gaussian-beam array.

The emission scheme for arranging the Gaussian beams proposed is shown in Fig. 10.11. In a rectangular coordinate system, it is assumed that the Gaussian beams are uniformly distributed on a circle with radius r_0, and the angular spacing of the adjacent subbeams is. The subbeam constitutes a radially distributed beam array (Fig. 10.10).

After the derivation and calculation, a Gaussian-beam array coupling-simulation experiment was conducted. According to the experiment and results, if the diverging Gaussian-beam array ($F_0 < 0$), the collimated Gaussian-beam array ($F_0 = \infty$), and the converged Gaussian-beam array ($F_0 > 0$) are horizontally transmitted along the optical axis, the Gaussian beam will always change because of its wavefront curvature as the transmission distance increases. Finally, it evolves from a discrete Gaussian beam into a beam. The farther the distance, the better the beam-coupling effect, and the greater the central-energy attenuation.

Researchers modified the conical aperture of the Maka antenna and used a microlens to control the parameters of the Gaussian beam emitted by a single-mode optical fiber. They designed four Maka antennas with uniformly distributed

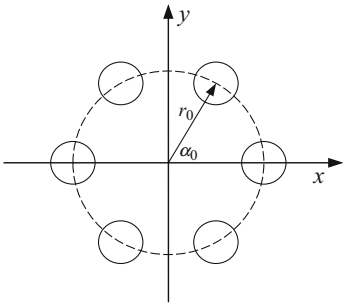

Fig. 10.10 Schematic diagram of a radially distributed beam array [22]

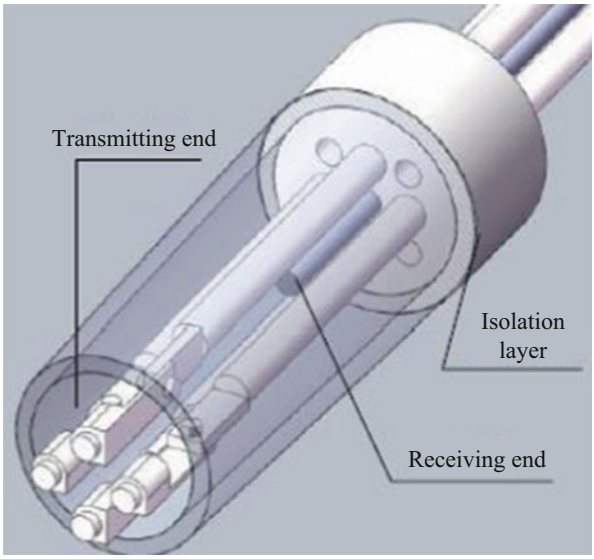

Fig. 10.11 Schematic diagram of an off-axis transmitting antenna with a uniform circular arrangement of Gaussian beams

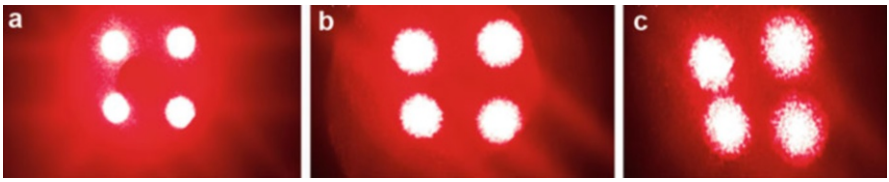
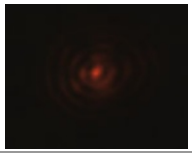
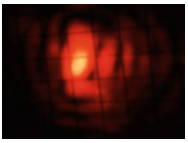
off-axis emissions of Gaussian beams in a ring. The structure is shown in Fig. 10.11 [21].

Experiments were performed on the coupling effect of the off-axis emitting beam array. Figure 10.12 shows the spot emissions of the beam at different transmission distances [21]. The experimental results are listed in Table 10.2. From the experimental phenomenon in Fig. 10.12 and the experimental data in Table 10.2, it can be seen that the farther the distance is, the larger the light spot is, and it gradually approaches the center. This is because the emitting beam has become a divergent Gaussian beam and gradually self-couples.

To meet the requirements of duplex wireless laser communication, Si et al. [23] made certain structural modifications to the Maka antenna: the optical signal was connected to the semiconductor-laser output by four pigtails through the standard







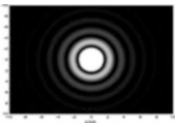


Fig. 10.12 Spot pattern of a Gaussian beam array. (**a**) 10 m (**b**) 50 m (**c**) 100 m

Table 10.2 Experimental results of the off-axis emission of a single Gaussian beam

	Normal launch (experiment)	Off-axis emission (experiment)	Off-axis emission (theory)

interface. A fiber collimator was installed at the rear end of the pigtail to change the divergence angle of the pigtail beam. According to the space position of the transmitting optical fiber, the four pigtails were fixed on the circular transmitting optical-fiber disk to complete the transmitting function, as shown in Fig. 10.13.

In addition, the optical fiber was placed in the center of the receiving optical disk. The received optical signal was coupled into the optical fiber in the center of the receiving optical disk after passing through the through hole of the transmitting optical disk. The receiving optical fiber disk was placed at the focal point of the

Table 10.3 Experimental data of Maka antennas A and B

Distance (m)	Emission optical power (B)	Receive optical power (A)	Coupling efficiency (A)	Emission optical power (A)	Receive optical power (B)	Coupling efficiency (B)
5	16.8 mW	3.1 mW	21.6%	16.8 mW	2.8 mW	20.2%
15		3.0 mW	20.9%		2.9 mW	20.9%
30		2.3 mW	16.1%		2.2 mW	18.8%

Maka antenna in the conical aperture to complete the spatial optical-fiber coupling and optical reception. The three-digit effect is illustrated in Fig. 10.14.

The experimental results of the off-axis emission tests of the Gaussian beam are shown in Table 10.3. Maka antennas A and B were used as transmit and receive antennas, respectively, to test the off-axis transmission optical power and the reception and coupling efficiency. The experimental results showed that the transmitted optical power was 16.8 mW after passing through the collimator. The emitted optical power was 14.9 mW after passing through Maka antenna A, and the transmission efficiency was up to 94%.

Compared with the traditional optical-antenna coaxial-transmission method, the transmission efficiency was significantly improved. This optical antenna structure can solve the optical-power loss problem caused by secondary-mirror occlusion.

Pre-Collimated Cassegrain Optical Antenna

In 2006, Yang et al. [24] designed a new type of aspheric pre-collimated Cassegrain optical antenna for a space laser-communication system. The system aperture was 150 mm and the focal length of the aspheric lens was 250 cm. The system structure compressed the beam to a minimum of six μrad with a 20× magnification, but it also improved the light-emission gain and reduced the background-light noise.

Jiang et al. [25] proposed to use optical devices, such as collimation systems, optical isolators, and splitter prisms, to integrate transceivers after focusing the Cassegrain optical antenna. This is the most common method of transceiver integration.

Further improvement and research on the traditional Cassegrain optical antenna is mainly intended to reduce the impact of the middle obstruction of the Cassegrain antenna structure. Various technologies and structures have been proposed, such as ring-beam emission, hollow-beam emission, off-axis emission of beam arrays, diversity reception, and coaxial aperture synthesis. These technologies have advantages and disadvantages in terms of their structure and function, as shown in Table 10.4.

In recent years, many new optical antennas have emerged, such as the complex parabolic-reflector optical antenna, the combined Galileo and Gregorian optical antennas, complex aspheric-lens combination, and bionic compound-eye structure optical antenna. These new structures inherit the performance of traditional card antennas, but have advantages, such as high gain and aberration elimination.

However, domestic research works mainly focus on numerical simulations of the antenna structure and design schemes [26], lacking practical engineering applications. Only a few researchers have conducted test and application cases, such as the Institute of Optoelectronic Technology of the Chinese Academy of Sciences [27] and Xi'an University of Technology [28].

Beacon-Free Tracking

The signal beam in an optical wireless communication system usually has a very small beam-divergence angle to ensure sufficient detection-signal strength. However, the small divergence angle is not conducive to the acquisition, pointing, and tracking (APT) of the receiver. Therefore, a beacon light with a large beam-divergence angle and a signal light with a small divergence angle are sent along the optical path to facilitate APT at the receiving end. A beacon light requires an independent optical-transmission system, which complicates the optical structure and servo control system of the transceiver; therefore, no independent-beacon optical APT systems exist.

An optical APT system without an independent beacon divides part of the signal light into a spot-position detector to detect the beam position [29]. The terminal-signal and beacon beams of the non-independent beacon optical APT system share

Table 10.4 Research progress on the Cassegrain antenna structure

Antenna structure	Research progress	Advantages and disadvantages
Large aperture	Large-caliber technology	The large-aperture antenna can increase the power of the received optical signal and uses the aperture-average effect to weaken the fluctuation
Array	Large-caliber technology	It breaks through the maximum-aperture limit of a single antenna. The array gain can be obtained through signal coherence. Multiple basic-unit channels can obtain diversity gain and eliminate inter-channel interference
Free-form surface	Free-form surface-mirror technology	The energy loss of the coaxial-reflection antenna is reduced and the transmission efficiency is improved
Antenna structure based on beam shaping	Beam-shaping technology	The divergence-angle collimation shaping can minimize the light spot at the receiving end. The light-field energy-distribution shaping reduces the inherent energy loss of the antenna.
Antenna structure based on beamforming	Off-axis reflection technique	The light-collecting ability of the antenna is improved and its detection range is increased. Considering the technology maturity, system performance, and future communication requirements, the off-axis double-inverse system has higher feasibility and maneuverability
Off-axis emission structure of a Gaussian-beam array	Beam auto-coupling and technology	It effectively solves the transmission-efficiency decline caused by the secondary mirror reflection of the Maka antenna
Pre-collimating	Lens pre-collimation technology	The collimating lens further compresses the divergence angle of the beam, improves the spot quality, and improves the receiving and transmitting efficiency

parts of the optical elements. Therefore, this type of receiving antenna has a small size, light weight, and low power consumption.

In 2007, the Tesat-Spacecom communication satellite launched by the German Aerospace Technology Center used the then-highest level of beaconless capture technology [30]. In 2017, Guo et al. [31] proposed a beacon-free tracking and acquisition method that required 0.135 W of laser emission power, had 30 s of acquisition time, and had a 95% acquisition probability.

In 2018, a satellite launched by the European Space Agency was equipped with the OPTEL-D communication terminal with a 1016-mm receiving aperture and a 1550-nm receiving wavelength. The terminal used a reflective-telescope structure combined with a multi-axis beaconless optical APT tracking system [32]. The beacon-free tracking and aiming system avoids the shortcomings of a beacon optical APT system, does not require an additional beacon optical

antenna, greatly simplifies the complexity of the transmitter and receiver, and is the development trend of future APT systems.

Point-to-Multipoint Communication Optical Antennas

The above antenna structures are suitable for point-to-point optical wireless communication. However, the limited number of communication terminals in point-to-point communication systems cannot carry out high-speed communications and information relays between multiple platforms. This restricts the progress of space laser-communication applications and the development of laser-communication space networking. Therefore, the networking mode of point-to-point laser communication has become a popular research topic.

In 1993, Clarke et al. [33] proposed to use a large field-of-view optical antenna to fully cover low-orbit users and installed a movable micro detector on the antenna focal plane for point-to-multipoint laser communication.

In 2002, the American Transformational Satellite Communications System (TSAT) proposed placing multiple transceivers in different locations to achieve simultaneous multipoint communication [34].

In 2005, Sherman et al. [35] proposed placing an optical-fiber array at the focal plane of a receiving antenna to realize point-to-multipoint space laser communication.

Although these schemes designed one-to-many communication links, the communication quality is not ideal, owing to the limited effect of the optical-fiber numerical aperture on the received signal. In addition, the arrangement of the optical fiber and optical-fiber array has some difficulties. Therefore, the practicability and integrated miniaturization of one-to-many space optical communication antennas must be further explored.

In 2006, Nishi et al. [36] developed a 60-GHz point-to-multipoint wireless-access link with a 156-Mbit/s data rate for short-range applications, such as indoor optical wireless local area networks and intelligent-transportation systems. The total size of the 60-GHz transceiver module was 50 mm $\times$ 75 mm.

In 2011, Jiang et al. [37] proposed a point-to-multipoint optical antenna with a paraboloid-based multimirror splicing structure. The antenna structure is composed of front, middle, and rear lenses whose surfaces are concentrated. The communication target within the 160° field-of-view angle can be imaged on the bottom receiving-end plane, and the signal beam can be transmitted to communicate with other targets in this range. The communication rate of the antenna can reach 2.5 Gbit/s and the pitch angle is $\pm 60°$.

In 2014, Zheng et al. [38] proposed an optical-antenna structure with four mirrors on the orbital surface and proposed a link satellite-networking scheme based on this antenna structure. The antenna structure captures the laser light source within a 50° view angle and 40° pitch angle. The servo system enables it to conduct two-way communication and dynamic tracking between satellites in the same and different orbits. The pitch angles of the antenna devices in Beijing,

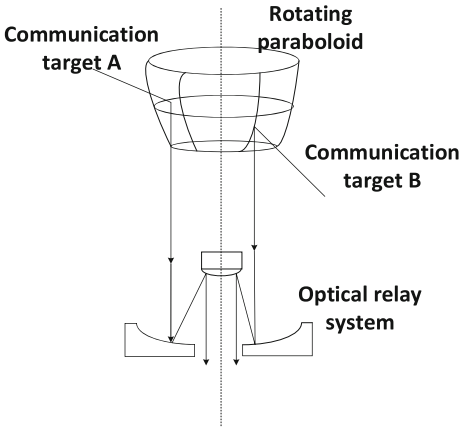

Fig. 10.15 Structural diagram of an optical antenna for rotating paraboloid one-to-many laser communication

Mohe, Lhasa, and Shanghai met the requirements of a 1500-km minimum communication distance.

In 2015, Jiang et al. [39] proposed an optical-antenna design scheme that met the requirements of synchronous duplex laser communication between multiple points, to enable networking communication between multiple platforms in orbit. The structural diagram is shown in Fig. 10.15. The optical antenna consists of a rotating paraboloid mirror and an optical relay system. The aperture of the rotating paraboloid mirror is 200 mm and the pitch angle is 73°.

Communication targets A and B are in different directions. The light is incident onto the optical system along the focal direction of the parabolic surface and along the direction parallel to the principal axis. It then enters the optical relay system.

The antenna has the advantages of a large field of view, wide communication range, simple structure, and high receiving energy. It can realize simultaneous duplex communication between multiple points and can meet the requirements for networking communication between geostationary-orbit satellites (GEO) and their optical ground stations (GEO-OGS) [40].

In this study, Jiang et al. also proposed a point-to-multipoint laser-communication optical tracking scheme that used a rotating paraboloid and a three-concentric-sphere structure as the receiving antenna. It simultaneously communicated with up to three systems in the experiment.

A schematic diagram of the three-concentric-sphere structure is shown in Fig. 10.16. The structure has a 120° field-of-view angle in both the horizontal and pitching directions. The optical antenna can perform simultaneous duplex communication with multiple transceiver terminals on the track of the corresponding working area. When the transceiver terminal moves along the track, out of the working area of the current optical antenna and into the next area, the next optical antenna takes over the transceiver terminal and establishes a communication link.

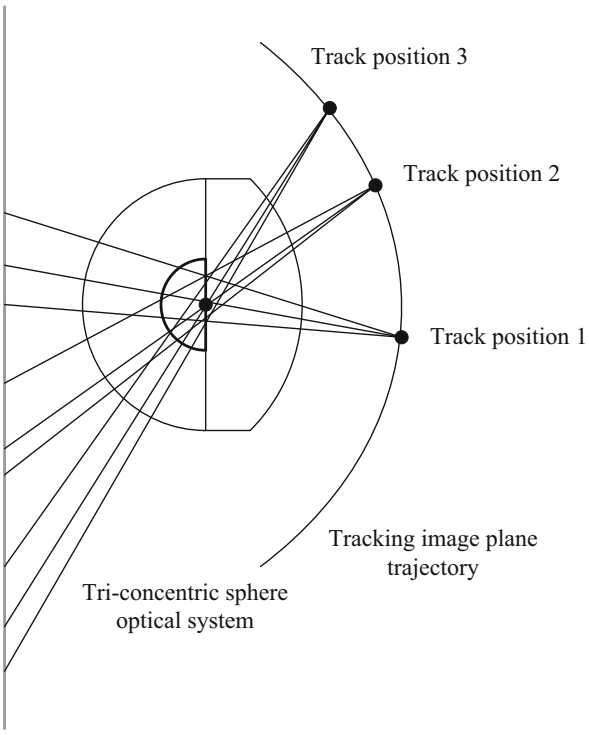

Fig. 10.16 Schematic diagram of a concentric-sphere structure

This scheme omits the complex steps of tracking and aiming and provides a feasible scheme for establishing a multipoint simultaneous duplex tracking communication network.

In 2015, Zhang et al. [41] designed an optical antenna for an optical wireless communication network that could realize synchronous duplex space-laser communication and carry out bi-directional communication between multiple points in a 360° azimuth angle and 90° pitch angle range. The highest transmission rate was 2 Gbit/s.

In 2016, Jiang et al. [42] proposed using a wide-angle beam expander and a double-wedge group to make the optical antenna of a multipoint laser communication system. As shown in Fig. 10.17, a 350-mm wide-angle beam expander expands the field of view and receives optical signals from different directions. The double optical-wedge group with 100-mm *N*-pair apertures can dynamically aim and track *N* different signal sources simultaneously and can carry out one to three simultaneous two-way communications in a low track.

In the communication experiment, the communication distance was 400 km, communication rate was 2.5 Gbit/s, and communication bit-error rate was less than 10^{-7}. The optical antenna flexibly controlled the relative position of the number

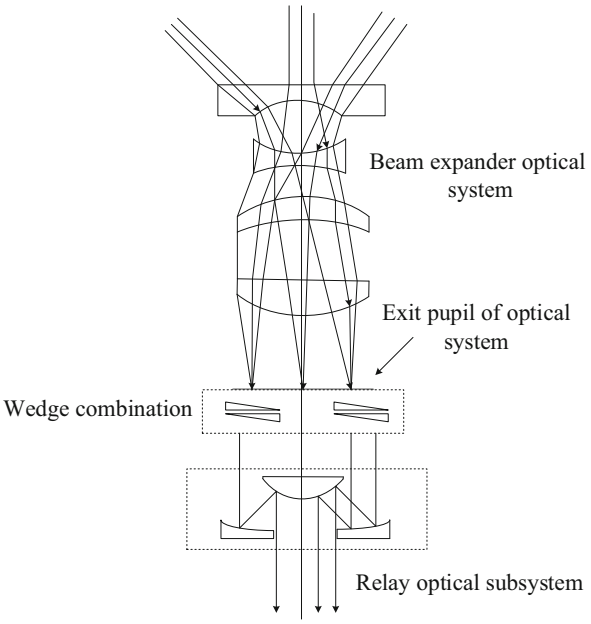

Fig. 10.17 Structural diagram of a combined wide-angle beam expander and double optical wedge

of optical-wedge combinations, according to the number and position of communication targets, and used as much optical-signal energy as possible.

Compared with the three-concentric-sphere structure, the structure of the combined double optical-wedge and rotating-paraboloid optical antenna is slightly complex, and its weight and volume are higher. However, its optical-energy utilization rate is higher, making it more suitable for long-distance optical wireless communication-system networking.

A comparison of the point-to-multipoint antenna structures is presented in Table 10.5.

Establishing a space-to-ground integrated global information network is inevitable. Traditional point-to-point space laser communication cannot communicate simultaneously with multiple terminals, which limits the networking ability of optical wireless communication networks. Therefore, point-to-multipoint optical wireless communication is the only way to develop networking technology.

Summary

This chapter systematically summarized the application and development of optical-antenna technology in optical wireless and space-laser communication systems. In the future, the transmitting/receiving antennas of optical wireless communication systems still need to be developed.

Table 10.5 Progress of optical antennas for point-to-multipoint laser communication

Year	Researcher	Research progress	Advantages and disadvantages
1993	Clarke	Full-coverage optical antenna with a large field of view	(1) The field of view is still small, owing to the numerical-aperture limitation of the optical-fiber and card system (2) The stray light is serious and the device arrangement and combination are difficult, with low application and feasibility. Further research is needed
2002	TSAT	Multi-receiver combined with an optical communication antenna	
2005	Sherman	Focal-plane fiber array with multiple receiving antennas	
2006	Nishi	Indoor optical wireless point-to-multipoint wireless-access optical antenna	
2011	Jiang H	Splicing paraboloid optical antennas with multiple mirrors	(3) Wide communication range, simple structure, high usable aperture, and high beam energy (4) The communication range is long, so it is suitable for multi-terminal networking of aircraft, satellites, and ground terminals
2014	Zheng	Optical antenna with four mirrors on track surface	
2016	Jiang L	Wide-angle beam expander and double-wedge multi-point receiving optical antenna	
2015	Jiang H	Multi-point receiving optical antenna with three-concentric-sphere structure	(5) The concentric sphere has a simple structure, light weight, and miniaturization, which is suitable for short-range and flexible laser communication networks
2015	Zhang	Design scheme of an optical antenna for optical wireless communication network	

1. The theory and technology of point-to-multipoint optical antennas should be investigated to enable optical wireless communication networks.
2. The traditional APT beacon requires an independent optical antenna for transmission, which complicates its structure. The beacon-free optical scheme saves a light source, which simplifies the transmitter structure, and can meet the miniaturization and integration requirements of future optical devices.
3. Multi-emitting and multi-receiver optical antennas should be investigated to further improve the flexibility of optical wireless communication networks. This can enable a space-to-ground three-dimensional laser-communication network and expedite the practical application of wireless laser communications.

wireless communication is an emerging communication technology with advantages of high speed, large capacity, and good security. However, the traditional optical wireless communication system has the limitation of single-to-single communication mode, which can't satisfy the demand of multi-user simultaneous communication. Optical antenna plays the role of transmitting and receiving coupled optical signals in optical wireless communication, and a pair of multipoint transmitting antennas can expand the applications of optical wireless communication. The development of one-to-multipoint optical antennas at home and abroad is summarized, and the basic principle of one-to-multipoint optical antennas is introduced. Several existing one-to-multipoint optical antennas design schemes are discussed. Finally, the development trend of this field and the future development direction are prospected.

Introduction

An optical antenna is a telescopic system that can be divided into three categories, depending on the angle of incidence of the optical antenna:

1. Reflective telescopic systems, which reflect incident light
2. Refractive telescopic systems, which refract light
3. Reflexive telescopic systems, which refract and reflect light [1]

Transmitting antennas concentrate the energy from a light by gathering it into a small angular range and transmitting it into the atmosphere to extend the communication distance. Receiving antennas, on the other hand, use various optical elements to increase their receiving area. They improve the signal-to-noise ratio by receiving as much light signal and energy as possible to reliably receive the signal. The amount of received energy has a direct impact on the bit-error rate (BER) of the system [2].

The selection of transmitting and receiving antennas is very important and directly affects the communication quality of the entire system. In practical applications, multiple transmit and receive antennas are typically used to improve the communication quality and stability for multi-channel transmission and reception.

Point-to-point communication systems have a limited number of communication terminals, which greatly limits the interstellar and space-to-ground transmission of high-capacity and high-rate information. This seriously affects communication relays, network formations, and applications. Therefore, the development of point-to-multipoint communication has become an inevitable trend in the future.

Optical Antennas

Optical antennas are classified as shown in Fig. 11.1. Reflective telescope systems are widely used in astronomy, earth science, and other fields because of their special construction, which can be applied to various wavelength bands, including visible light, infrared, and others.

Refractive telescope systems are typically used for optical wireless communication in the visible and near-infrared wavelengths. Their simple construction and low cost make them widely used in some low-cost short-range communication systems.

The Catadioptric telescope system, on the other hand, is developed by combining the advantages of the above two telescope systems. Owing to its aberration correction, the Catadioptric telescope system is not only suitable for optical wireless communication in visible and near-infrared wavelengths but also performs particularly well in long-range optical wireless communication in complex atmospheric environments [3].

Reflective Telescope Systems

Reflective telescopic systems use mirrors, both spherical and aspherical. They use the principle of specular reflection, rather than lens refraction, to achieve optical imaging, and have multiple focal points, so they can produce different relative apertures, field-of-view angles, and focal lengths. Reflective telescope systems have low energy-absorption loss, light weight, a large aperture, and no chromatic aberration.

Therefore, reflective telescope systems are typically used as receiving systems. According to their design characteristics, common reflective telescope systems include various types, such as the Newtonian, Cassegrain, Gregorian, and off-axis triple-reflector [5].

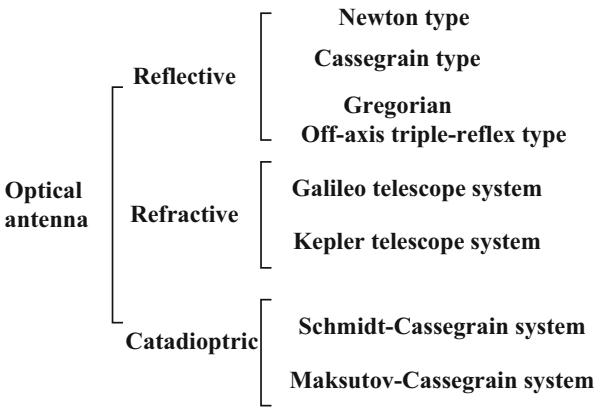

Fig. 11.1 Optical antenna classification [4]

Newtonian Telescopic System

The Newtonian telescope system is shown in Fig. 11.2. It mainly consists of three parts: a parabolic primary mirror, a planar secondary reflector, and a collimating lens [6]. Compared with other telescopic systems, the Newtonian telescopic system has a large relative aperture to adequately receive light and therefore is widely used in optical systems with large apertures. It has a simple structure, no dispersion, and a small spherical aberration.

However, the Newtonian telescope system also has some disadvantages. The structure adopts an open design, and air can circulate freely. This leads to the possibility of airflow interference inside the telescope, thus affecting the image quality. The production cost is high and there is coma for off-axis light.

Cassegrain Telescope System

The Cassegrain-type telescope system is shown in Fig. 11.3. It is a telescopic optical system with a double-reflection structure, consisting of two parts: a parabolic primary mirror and a hyperbolic secondary mirror. In this telescope system, the focuses of the primary and secondary mirrors coincide, thus eliminating spherical aberration and providing high-quality imaging results. In addition, the Cassegrain telescope system is small, compact, and free of chromatic aberration and has an adjustable aperture.

Because the primary and secondary mirrors of the Cassegrain-type telescope system are located on the same optical axis, a certain degree of occlusion exists, caused by the size of the secondary mirror. Consequently, the system field of view is relatively small and the mirror barrel is long [7]. The advantages of Cassegrain-type optical systems, such as compactness and the absence of chromatic aberrations, make them widely used in laser communication, astronomical observation, and remote sensing. Their advantages, such as a short length and light weight, make

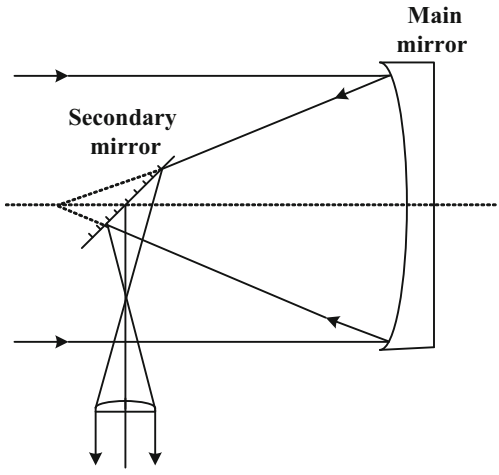

Fig. 11.2 Newtonian telescopic system [6]

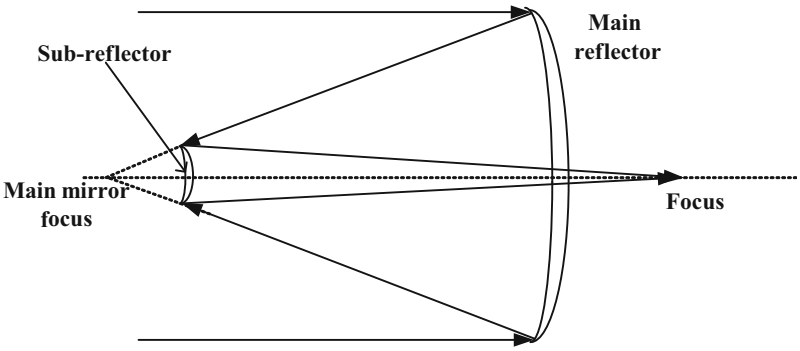

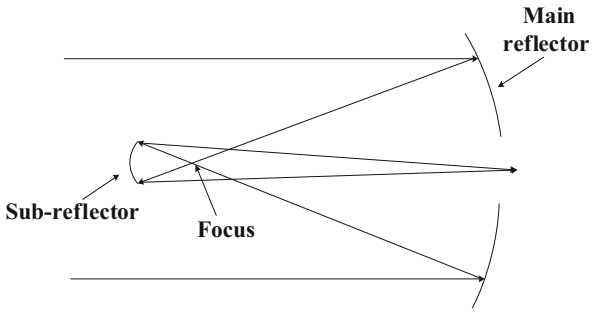

Fig. 11.3 Cassegrain telescope system [11]

Fig. 11.4 Gregorian telescope system [13]

them widely used in the fields of satellites and unmanned aerial vehicles (UAVs) [8–10].

Gregorian Telescope System

The Gregorian-type telescope system is shown in Fig. 11.4. It is a common reflecting telescope, which mainly consists of two parts: a parabolic primary mirror and a concave ellipsoidal secondary mirror. In this telescope system, the focuses of the parabolic primary mirror and concave ellipsoidal secondary mirror coincide, which can eliminate spherical aberrations.

However, the large axial size of the Gregorian-type telescope system can be limiting in some applications and the fabrication process is demanding; hence, there are few practical applications [12]. It is commonly used in astronomical observation, satellite communication, and other fields.

Off-Axis Triple-Reflex Telescope System

The off-axis triple-reflex telescope system is shown in Fig. 11.5. It is a non-coaxial optical system using three aspherical mirrors as the initial structure for off-axis optimization [14]. Its most important features are that it overcomes the chromatic

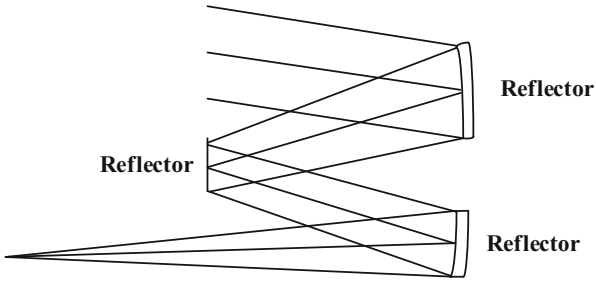

Fig. 11.5 Off-axis triple-reflex telescope system [16]

Table 11.1 Comparison of the advantages and disadvantages of reflective systems

Reflective type	Advantages	Disadvantages
Newton	Simple structure, no dispersion	Open structure, air circulation, maintenance difficulties, high cost, existence of coma
Cassegrain	No chromatic aberration, good image quality, short system length, small size, light weight, compact structure	Small field of view with central occlusion
Gregorian	No spherical aberration	Large axial dimensions, secondary-mirror blocking
Off-axis triple-reflex	Large caliber, long focal length, no chromatic aberration, no central obscuration	Difficult to assemble

aberration and central occlusion of conventional telescopes and has a very high imaging quality.

In addition, the aperture of the off-axis triple-reflex telescope system can be made very large, while its long focal length effectively improves the field of view of the optical system. Owing to the non-coaxial structure, the off-axis triple-reflex telescope system has a very flexible mirror layout, which can be used in many scenarios. It is widely used in the fields of astronomical telescopes, military reconnaissance, and satellite detection. However, its assembly and commissioning are difficult and require more delicate processes and techniques to ensure the optical performance [15] (Table 11.1).

Refractive Telescope Systems

Refractive telescope systems usually consist of an objective lens and an eyepiece. The objective lens converges light onto the focus point and magnifies the image through refraction. The eyepiece receives the image point and magnifies it further to obtain a clearer image [17].

Refractive telescope systems have the advantages of a wide field of view, high contrast, and high clarity. The chromatic aberration present in the system can be addressed by using multiple sets of lenses, but accordingly, it leads to increased cost and loss of luminous flux. In addition, refractive telescope systems are larger, owing to the long length of the lens barrel.

Refractive telescope systems are widely used in astronomical observation, Earth observation, remote sensing, and atmospheric laser communications [17]. They can be used as both transmitting and receiving optical systems. They mainly include Galileo and Kepler telescope systems [18].

Galileo Telescope System

The Galileo telescope system is shown in Fig. 11.6. It is an optical system consisting of a convex-lens objective lens and a concave-lens eyepiece. The objective lens of this system collects the light from the distant object and focuses it at the focal point behind the objective lens, while the eyepiece magnifies the image behind the objective lens and forms a visible virtual image [19].

This system has the advantages of a short distance between the objective lens and eyepiece, a short barrel, aberration elimination, and ortho-imaging. The disadvantages are that the system has a small field of view and no real exit pupil.

Kepler Telescope System

The Kepler telescope system is shown in Fig. 11.7. It mainly consists of an objective lens and an eyepiece, both of which are convex lenses, with a focus point between the objective lens and the eyepiece. To obtain an extended beam that is less affected by the Gaussian-type intensity distribution, it is necessary to include a small-aperture diaphragm in the optical path so that the peak portion of the Gaussian-type intensity distribution passes through [17].

However, this optical antenna still has some drawbacks. For example, a certain amount of light energy is blocked when the small-aperture diaphragm is added, producing a strong light effect. This problem can be solved by adding a spatial filter to distribute the laser energy more uniformly [21].

Table 11.2 compares the advantages and disadvantages of refractive telescope systems.

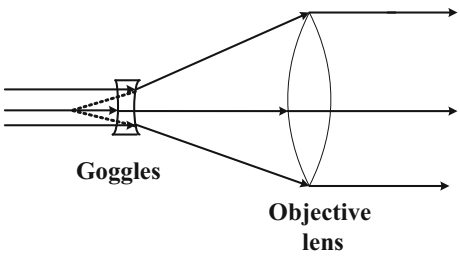

Fig. 11.6 Galileo telescope system [20]

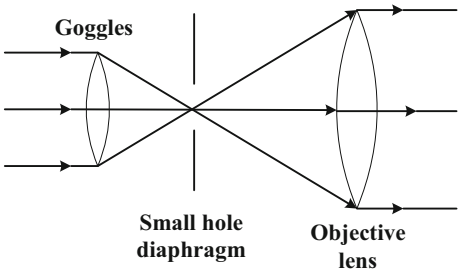

Fig. 11.7 Kepler telescope system [20]

Table 11.2 Comparison of the advantages and disadvantages of refractive systems

Reflective type	Advantages	Disadvantages
Galileo	Short distance between objective lens and eyepiece, short lens barrel, positive image	Smaller field of view and no solid exit pupil
Kepler	A diaphragm can be placed at the focal-point overlap to eliminate stray light effects	Light energy is frequently blocked, strong light effect, relatively long tube length

Catadioptric Telescope System

A Catadioptric telescope system combines refractive and reflective optical systems. To correct the spherical aberration of the primary mirror, the system often uses a wavy correction lens with a convex center, concave side, and complex shape to form the objective lens of the system [17].

The Catadioptric telescope system has many advantages, such as a small optical-system size and high optical performance. It is widely used in the astronomy, military, and aviation fields. The Schmidt–Cassegrain and Maksutov–Cassegrain systems are two common examples of reflexive optical systems [22].

Schmidt–Cassegrain System

The Schmidt–Cassegrain system is shown in Fig. 11.8. It consists of two reflecting surfaces, a concave parabolic primary mirror, and a convex hyperbolic secondary mirror [23]. The Schmidt–Cassegrain system has many deformed structures, such as a double spherical-mirror set structure, double aspheric-lens set structure, and combined spherical and aspheric mirror structure [17]. The primary reflector has a shorter focal length, which is more compact than a conventional parabolic reflector, and can obtain a much higher gain than other types. However, the system suffers from problems, such as secondary-mirror occlusion and the difficulty of making large-aperture Schmidt correction plates.

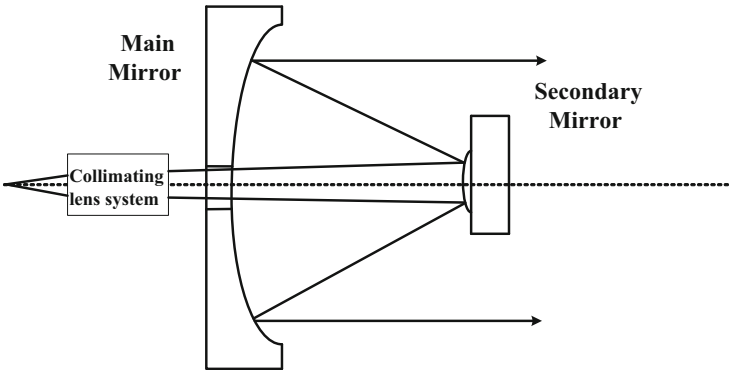

Fig. 11.8 Schmidt–Cassegrain system [23]

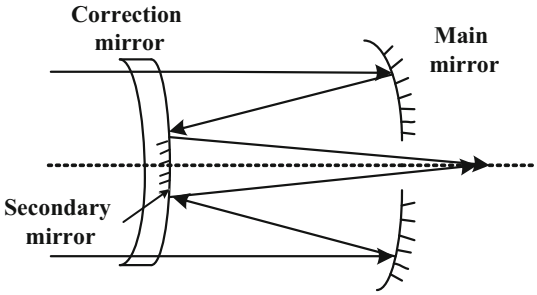

Fig. 11.9 Maksutov–Cassegrain system [25]

Maksutov–Cassegrain System

The Maksutov–Cassegrain (Mak-Cass) system is shown in Fig. 11.9. It employs a large-curvature meniscus-type correction lens and an aluminized dot on the correction lens as a secondary reflector [24]. Moreover, it adds an aspherical lens to the Schmidt–Cassegrain system. After the light passes through the primary and compensating lenses, it passes through the aspherical lens for compensation to achieve higher optical performance. When the Mak-Cass antenna is used as a spatial optical-coupling system, it has large-aperture coupled reception and an improved ability to converge optical power [17].

A typical feature of the Mak-Cass telescope system is the use of a fold-and-reverse structure, which makes its subreflector very small and more compact. This greatly reduces the size and weight of the antenna and enables large-aperture and long-focal-length imaging [25]. However, the telescope system suffers from obscuration problems, leading to a large loss of energy. Mak-Cass telescope systems are widely used in the military, industrial, and aeronautical fields.

Table 11.3 compares the advantages and disadvantages of Catadioptric telescope system.

Table 11.3 Comparison of the advantages and disadvantages of reflexive systems

Reflexive type	Advantages	Disadvantages
Schmidt–Cassegrain	Compact system for higher gain, excellent image quality, no coma or dispersion	Poor ball presence, large volume, high cost
Maksutov–Cassegrain	Compact, long focal length, large aperture	Large volume, small field of view

Problems of Point-to-Point Antennas

Traditional optical wireless communication research and experiments typically use point-to-point antennas, which face the following problems.

1. Distance: Generally, point-to-point antennas must be applied in closer locations. In more distant locations, the communication quality is reduced.
2. Weather influence: Optical transmissions are susceptible to atmospheric influence, such as fog, rain, haze, etc. Such weather conditions can cause a large amount of optical-signal loss, which, in turn, affects the communication quality. Bad weather can also make deployment and maintenance more difficult.
3. Line-of-sight obstacles: Because light propagates in a straight line, it cannot bypass obstacles in the communication path. It must have a clear line of sight between the two sides of the communication, limiting its use and scenarios.
4. High interference: Light signals are susceptible to daylight and other light sources and are also susceptible to electromagnetic waves.
5. High cost: Because of the special devices and optical components required for optical wireless communication, it is more expensive.

Foreign and Domestic Research Progress

In 1953, the United States officially launched the Star Wars program, which promoted the rapid development of space laser communication. Since then, Germany, the United Kingdom, Japan, and other countries have also been involved in this field and started related work [26].

In 1993, Clarke et al. [27] proposed the use of a large field-of-view optical antenna to achieve all-round coverage of near-Earth targets with a small movable detector on its focal plane to realize point-to-multipoint optical communication.

In 2002, the Transformational Satellite Communications System (TSAT) [28] proposed to place multiple receiving terminals at different locations to achieve simultaneous transmissions from multiple locations.

In 2002, Sherman M P et al. [29] proposed an optical wireless communication system, as shown in Fig. 11.10. The telescope in this system had an aspherical mirror design, such as the Ritchey–Chrétien (RC) telescope shown in (a). It featured a concave primary mirror and convex secondary mirror, both of which had a hyperbolic shape. The mirror had a large focal plane, which allowed the automatic

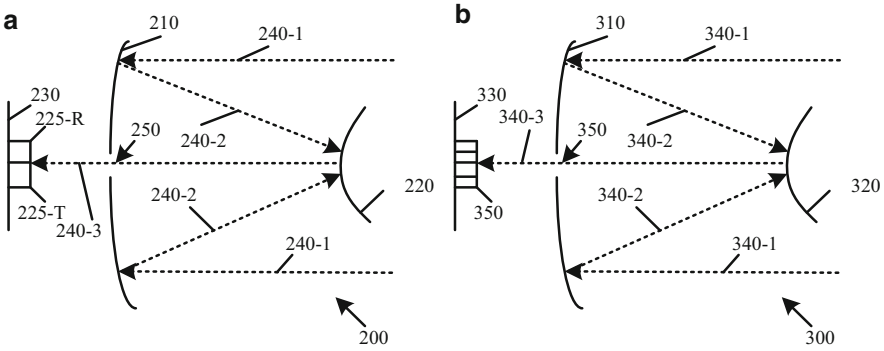

Fig. 11.10 Optical Wireless communication system [29]·(**a**) RC optical telescope (**b**) Point-to-multipoint communication system

matching of fixed or stationary mirrors between transmitter and receiver, thus greatly reducing production costs. An $N \times N$ fiber array could be established on the focal plane of the RC optical telescope for point-to-multipoint communication, as shown in (b).

In 2006, Zhou L et al. [30] proposed a new optical-antenna array for interstellar laser communication and performed a statistical analysis of the causes of the degradation of its alignment-error performance to verify the feasibility of the new optical-antenna array. Compared with ordinary antennas, it had the advantages of a small size and adaptive pointing.

In 2008, Zhang C et al. [31] proposed a novel multipoint ground-reception scheme to improve the communication quality. The problems of communication-link interruption and increased BER were mitigated by channel redundancy.

In 2008, Zhang W L et al. [32] proposed a theoretical structure for one-to-many and many-to-one synchronous communication using semiconductor lasers.

In 2011, Li K et al. [33] proposed a one-to-many network communication scheme using the sea surface as a laser diffuse-scattering medium. They applied the Kirchhoff approximation theory to analyze the transmission characteristics of ocean diffuse communication.

In 2011, Jiang H L et al. [34] proposed an optical antenna suitable for simultaneous multipoint duplex communication. The working principle and implementation method of an optical antenna with three concentric spheres in laser-communication networking were studied. Through theoretical analysis and experiments, the acquisition, pointing, and tracking (APT) control model of the multi-reflector splicing from optical transceiver was studied to help lay the foundation for the application of space laser-communication-link networking.

In 2012, Jiang H L et al. [35] proposed a multi-target inter-synchronous laser-communication technology and applied it to the key technologies of optical antennas, relay optical systems, transceivers, and APT. It was based on a rotating paraboloid with a multiple-reflector splicing structure to provide a new technical idea for optical wireless communication-link networking.

In 2012, He Y J et al. [36] designed a multipoint bi-directional laser-communication optical antenna based on a splicing mirror. The antenna broke through the structural limitations of traditional antennas and could be applied to space laser-communication networks as node terminals.

In 2013, Sun X D [37] proposed an eccentric cross-gimbal coarse-tracking structure scheme, which used a rotating paraboloid as the base and a spliced mirror. By studying the construction of a one-to-many communication optical terminal, a servo control unit was designed for the system to achieve accurate alignment and tracking functions.

In 2013, Xiao P [38] proposed a new all-optical capture technique for one-to-many laser-communication systems and discussed the capture method of this technique in depth. The parameters and capture methods of the all-optical capture technique were analyzed in detail, and a model was established according to the capture strategy.

In 2013, Yu X N et al. [39] established a servo control system for capture, targeting, and tracking to realize a one-to-many space laser-communication network.

In 2014, Yu X N et al. [40] proposed a single-beam tracking system for laser-communication networking, which could accurately track the spot position of interstellar laser communication. It laid the foundation for the next stage of realizing many-to-many laser-communication networking.

In 2014, Jiang H L et al. [41] proposed a simultaneous dynamic-communication technology between multiple points, which provided technical support for the formation of an integrated information network between heaven and earth.

In 2014, Meng L X et al. [42] proposed a general idea about optical antennas to simultaneously track multiple targets and established an information-transmission network. The kinematic model was simulated to obtain the ideal field of view of the optical antenna, which provided a theoretical basis for subsequent development.

In 2014, Meng L X et al. [43] proposed a scheme using a multi-mirror reflector, with a rotating paraboloid as the substrate, as an optical antenna to establish a one-to-many laser-communication network. The system adopted an eccentric cross-tracking frame design, and the problems of decreasing optical-energy utilization and system stability were effectively solved.

In 2014, Meng L X [44] proposed a rotating paraboloid-based multi-mirror stitching capture and tracking system with dynamic-optics principles to establish tracking and scanning models. Experimental results showed that this system could rapidly capture and accurately track multiple targets with an azimuth angle of 360° and a pitch angle of ±15°.

In 2014, Zheng Y et al. [45] proposed a four-reflector optical antenna structure and a link-satellite networking scheme based on the optical antenna structure and conducted an optical dynamic study on the antenna. This antenna structure was capable of laser-source capture within a 50° field of view and a 40° pitch angle. This scheme achieved link-satellite networking and improved the communication efficiency.

In 2014, Zhao K H et al. [46] proposed an optical-antenna structure capable of simultaneously tracking and communicating with multiple targets. This is the core

structure of one-to-many laser-communication networking technology, and the tracking performance is the key factor for measuring its technical reliability. To verify the tracking performance of the optical antenna, the priority was the design and development of an optical-antenna tracking-performance test system.

In 2014, Zhang L J et al. [47] proposed the use of Kalman-filter prediction to track an optical spot. Simulation results showed that the Kalman filter could well predict the velocity and motion direction of a moving object within the specified error. This could be used to control the spot position of the optical lens and provide a theoretical basis for realizing multi-point communication.

In 2014, Zhang L J [48] proposed a multi-point synchronous tracking technique for satellite space laser-communication networking. A research method combining theory and experimental tests was used to design an overall scheme for one-to-multipoint laser communication.

In 2015, Zhao K H et al. [49] designed a complete test system to verify the tracking performance of an optical antenna to ensure the reliability of one-to-many laser-communication networking technology. The tracking performance was tested by providing a laser signal to the optical antenna as the target source. In the actual communication, the optical antenna tracked the moving target reliably and ensured the communication quality of one-to-many laser communication.

In 2015, Yu X N et al. [50] discussed the design and development process of servo antennas in one-to-many laser-communication networks and conducted splicing and tracking experiments. The success rate of the splicing reliability reached 90% and the tracking error was less than 50 μrad, which guaranteed the reliable operation of the communication networking system.

In 2015, Jiang H L et al. [51] proposed an overall optical scheme for a pair of simultaneous point laser communications, deduced the workflow of the APT system, and analyzed the relationship between the off-target amount and the rotation of the reflector, during the capture alignment and coarse tracking.

In 2015, Jiang L et al. [52] proposed a “one-to-two” laser-communication networking technique and also calculated the power margin of the interplanetary laser-communication link. The experimental results showed that the technique could achieve a 200-km communication distance and 2.5-Gbit/s communication rate, providing a new technical approach for intra-flight communication networking in formations.

In 2015, Zhang T et al. [53] proposed a new optical-antenna design method, which was capable of one-to-many laser communication. They derived the operating range of multiple optical antennas and their inter-platform communication, providing a feasible design solution to achieve multi-point inter-communication.

In 2015, Ke X Z et al. [54] designed a transceiver optical antenna based on the Cassegrain telescope. It used the effective area as the transmitting and receiving area of the antenna to separate the optical path, thus improving the transmitting efficiency of the antenna.

In 2016, Zhang T [55] proposed several design schemes for laser-communication grouping in antenna systems. Among them, a new theory of optical properties was derived, based on the rotating-paraboloid antenna, which achieved greater dynamic

communication within an azimuth of 360°, as well as two-way communication between multiple platforms.

In 2016, Zhang T et al. [56] proposed a novel laser-communication networking system that enabled efficient laser communication by precisely focusing the laser through a confocal reflection technique. The system could be used for networked communication between different platforms and had various advantages, such as a simple structure, light weight, and easy miniaturization.

In 2016, Ma G D et al. [57] investigated and modeled the tracking-antenna performance in one-to-many laser communication using a joint machine–electric simulation. The simulation results showed that the performance and error of the tracking antenna could be obtained accurately and quickly after the joint-simulation approach, and the servo-drive error was also reduced.

In 2016, Jiang L et al. [58] proposed to use the combination of a wide-angle beam expander and dual optical-wedge set as an optical antenna for a multipoint laser-communication system. This antenna expanded the beam angle and eliminated the optical offset; it could be used for dynamic tracking and signal reception of the target. This optical antenna design provided a new technical method for space laser-communication networking technology.

In 2017, Zhang T et al. [59] proposed two different schemes to solve the problem of communication-platform networking: one based on the rotating paraboloid model and another for a laser-communication networking antenna system.

In 2017, Zhao Y et al. [60] proposed an underwater optical wireless link based on orbital angular momentum (OAM) to solve the problem of underwater one-to-many data-information transmissions. This technology had a high speed, low power consumption, and interference resistance.

In 2019, Li X et al. [61] proposed an optical-antenna structure with high carrying capacity, and the precise design of the connection of various optical elements ensured the accuracy of the optical antenna position. The experimental results showed that the imaging quality after the bearing was significantly improved, compared with that before the bearing, which helped lay the foundation for one-to-many laser communication.

In 2019, LOU N [62] proposed a wireless laser-communication abutment design, which could carry out multipoint laser communication to multiple bands. To effectively transmit and receive laser communication, a complete set of laser-communication equipment containing a relay system and splitting system was designed.

In 2020, Cao H Y [63] proposed a new networking scheme, which used three independent single-reflector-type follow-up units to adjust the optical axis to ensure the optical system for accurate targeting. It provided a strong support for the development of one-to-many laser-communication networking technology.

In 2020, Wang S D [64] designed a bearable optical antenna that could efficiently transmit data and could be used for inter-satellite platform communication. The optical antenna was designed using an orthogonal test optimization method for the main mirror to achieve high-quality imaging and a stable carrying capacity.

In 2020, Song G et al. [65] proposed that an optical frequency comb (OFC) could be used instead of a laser or laser array as a carrier source for a pair of multiple optical wireless communication systems.

In 2020, Wang J Y et al. [66] proposed a dual-mirror linkage-control scheme for reflector-spliced optical antennas for multi-target tracking. The optical-signal energy utilization was improved. Meanwhile, the reflector-spliced optical antenna of this technique achieved efficient and accurate target capture and real-time multi-target tracking, which greatly improved the performance and reliability of the optical detection system.

In 2021, Wang J Y et al. [67] designed a multi-target APT system, based on an optical antenna and fast-steering mirror (FSM), and used a mirror-linked control method to improve the utilization efficiency of the optical antenna. A principle prototype was developed and dynamic demonstration experiments were conducted for point-to-multipoint laser communication.

In 2021, Wang T et al. [68] designed a "one-to-two" space laser-communication system to realize high-speed laser data transmissions of multiple nodes in space information networks.

In 2021, Bai Y Y et al. [69] explored a "one-to-four" space laser-communication system, elaborated its working principle, and studied in depth the networking and control mode of the system. In this system, the optical-transceiver design relied on a mathematical model based on the Jetlink control technology. It provided an effective solution to communicate between multiple points in space laser communication.

In 2021, Fan T et al. [70] described the principle of a networked "one-to-four" main optical-transceiver system. By designing a fuzzy self-anti-disturbance control method, the precise tracking control of the main optical transceiver was realized, which greatly improved the stability and reliability of the laser-communication system.

In 2021, Li X M et al. [71] conducted a theoretical analysis of the support parameters of an integrated SiC/Al pendulum mirror to reduce the impact of planarity errors on the reflector surface shape. By optimizing the design, the pendulum-mirror surface-shape accuracy requirements for one-to-many laser-communication networks were met. In the same year, Li et al. [72] designed an integrated compact pendulum mirror that could realize one-to-many space laser communication in a large range. Higher requirements were imposed on the structural dimensions of its components to improve the reflection efficiency of the pendulum mirror.

In 2021, Zhao B Q et al. [73] studied the servo performance of the reflector optical antenna in a one-to-many laser-communication network and simulated and analyzed the optical closed-loop performance of the velocity and position loops. The simulation results showed that the optical closed-loop strategy of the velocity loop had a larger error in the tracking computation compared with the optical closed-loop strategy of the position loop. However, its servo bandwidth was larger than that of the position loop and had a stronger anti-disturbance capability.

In 2021, Xu M et al. [74] proposed a pair of multiple laser-communication optics, based on which, a principle prototype was designed and fabricated and experiments were conducted. The performance results showed that the principle prototype had

good multidimensional detection performance. A principle prototype of integrated multi-dimensional space-target detection with laser communication with a 250-mm optical aperture was developed.

In 2022, Zhang K Q et al. [75] established a corresponding coarse-tracking system model for a pair of multi-network optical-communication coarse-tracking servo control systems and designed a model-predictive controller (MPC) for this model to effectively improve the system tracking-control performance.

In 2023, Ding C et al. [76] used a pulse-width modulation technique combined with the data-routing and forwarding function of a laser-relay station for optical wireless communication networking. They demodulated the received signal using a high-speed digital-to-analog converter to improve the stability of the optical wireless communication system. The system was more flexible and had higher communication quality than the point-to-point laser-communication system, while the system achieved one-to-many optical wireless communication without adjusting the transmission angle.

In 2023, Hu Y B et al. [77] established a two-way tracking and targeting model for satellite laser-communication optical terminals to realize "one-to-four" network communication. The concept of equivalent composite control was introduced to further improve the tracking accuracy without changing the parameters and stability of the original calibration-control system.

In 2023, Wang L H et al. [78] designed a scheme to simultaneously stabilize multiple optical axes using a single gyroscope. They proposed a method to solve the attitude of the axes for the miniaturization, weight reduction, and networking of a simultaneous point-to-multipoint laser-communication optical transceiver.

One-point-to-multipoint optical wireless communications have their own advantages and disadvantages between the various structures, according to the integration of their respective characteristics that are categorized as shown in Table 11.4.

One-to-Many Optical Communication

At present, research on optical wireless communication systems is mainly focused on single-point-to-single-point communication structures. Although this structure form can meet the demand in some scenarios, in practical applications, multiple terminals will need to communicate with each other. In this case, the traditional single-point-to-single-point transmission form can no longer meet the communication needs. It must establish a complete communication network for efficient information transmission through a pair of multi-laser communication systems to achieve a higher practical value.

Basic Principles of One-to-Many Optical Communication

In multi-target communications, the visual range of the optical antenna is critical. Only with a sufficiently wide visual range can a system communicate with multiple

Table 11.4 Research progress in one-to-multipoint optical wireless communication

Year	Researchers	Key technologies	Study results

2023	Ding	Optical wireless communication networking	

targets simultaneously without compromising the communication quality. Current-optical-communication systems commonly use independent-aperture optical systems, which cannot communicate with multiple targets simultaneously [79].

The challenge of simultaneous communication to multiple targets can be solved if an optical system can be designed such that incident light from any angle in space (over a wide range) can pass through the system and be focused on the same point. The design of such an optical system requires full consideration of optical principles and relevant mathematical models, as well as detailed design and testing, to ensure its efficiency and reliability in practical applications.

By comparing the optical properties of various surfaces, it was found that the rotating paraboloid had the unique property that all reflected beams were parallel to the rotation axis, after the incident light was reflected by the rotating paraboloid. It could be used to design various optical devices, such as optical antennas, reflectors, etc. The optical principle is shown in Fig. 11.11.

As shown in Fig. 11.11, assume that the equation of the parabola is

$$y^2 = 4px. \tag{11.1}$$

$P(x_0, y_0)$ is a point on the parabola. If we apply it to (11.1), $y_0^2 = 4px_0$. The axis of symmetry of this parabola is the X-axis; that is, $y = 0$. The tangent line through point p is

$$y_0 y = 2p(x + x_0) \rightarrow 2px - y_0 y + 2px_0 = 0. \tag{11.2}$$

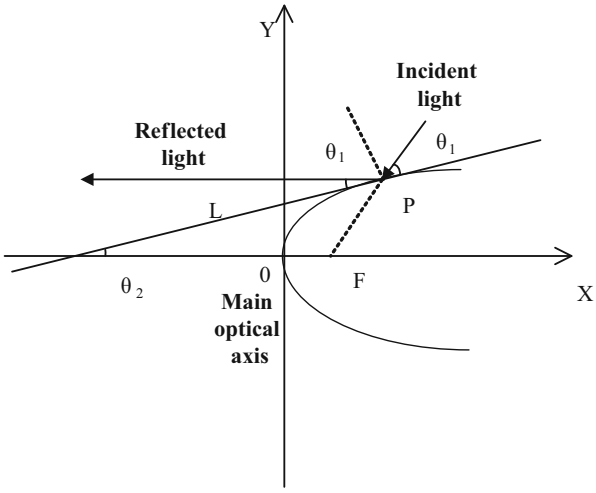

Fig. 11.11 Schematic diagram of the parabolic optics principle [44]

Point F is the focus of the rotating paraboloid with coordinates $(p, 0)$, and the equation of line PF is

$$y = \frac{y_0}{x_0 - p}(x - p) \rightarrow y_0 x - (x_0 - p)y - py_0 = 0. \tag{11.3}$$

With the basic principle of reflection, equations can be obtained:

$$\begin{aligned} \cos\theta_1 &= \frac{|2py_0 + (x_0 - p)y_0|}{\sqrt{4p^2 + {y_0}^2}\sqrt{{y_0}^2 + (x_0 - p)}} \\ &= \frac{|x_0 y_0 + py_0|}{\sqrt{4p^2 + 4px_0}\sqrt{4px_0 + {x_0}^2 - 2px_0 + p^2)}} \\ &= \frac{|y_0(x_0 + p)|}{\sqrt{4p(p + x_0)}\sqrt{(x_0 + p)^2}} \\ &= \frac{|y_0|}{\sqrt{4p(p + x_0)}} \end{aligned} \tag{11.4}$$

$$\cos\theta_2 = \frac{|-y_0|}{\sqrt{4p^2 + {y_0}^2}} = \frac{|-y_0|}{\sqrt{4p^2 + 4p{x_0}^2}} = \frac{|y_0|}{\sqrt{4p(p + x_0)}}. \tag{11.5}$$

From Eqs. (11.4) and (11.5), we obtain $\cos\theta_1 = \cos\theta_2$. Because θ_1 and θ_2 are both acute angles, $\theta_1 = \theta_2$. Assuming that the incident light is a straight line, PF, there exists a reflected light parallel to the axis of symmetry. By exploiting the optical properties of the paraboloid, the receiving antenna can receive light beams from different directions, thus enabling the simultaneous tracking and communication of multiple targets. Figure 11.12 illustrates the working principle of a pair of multiple optical-communication optical systems.

The system is divided into three parts: the optical antenna, relay optics, and splitting system [35]. In the optical wireless communication system, the optical-antenna part undertakes the task of signal acquisition and transmission. When multiple optical signals arrive at the optical antenna, they pass through a multi-reflector splicing and servo system so that the light is incident along the optical axis into the relay-optics system. The optical-antenna part generally adopts structures, such as a Cassegrain telescope system, off-axis two-inverse telescope system, and refractive system, to achieve a common laser-transceiver aperture [80].

The relay-optics part is mainly responsible for converging the received communication light and expanding the transmitted beacon and communication light. The splitting-system part is mainly responsible for separating the received beams for separate processing and directing them to the corresponding detectors for detection, thus realizing multi-point laser communication [44].

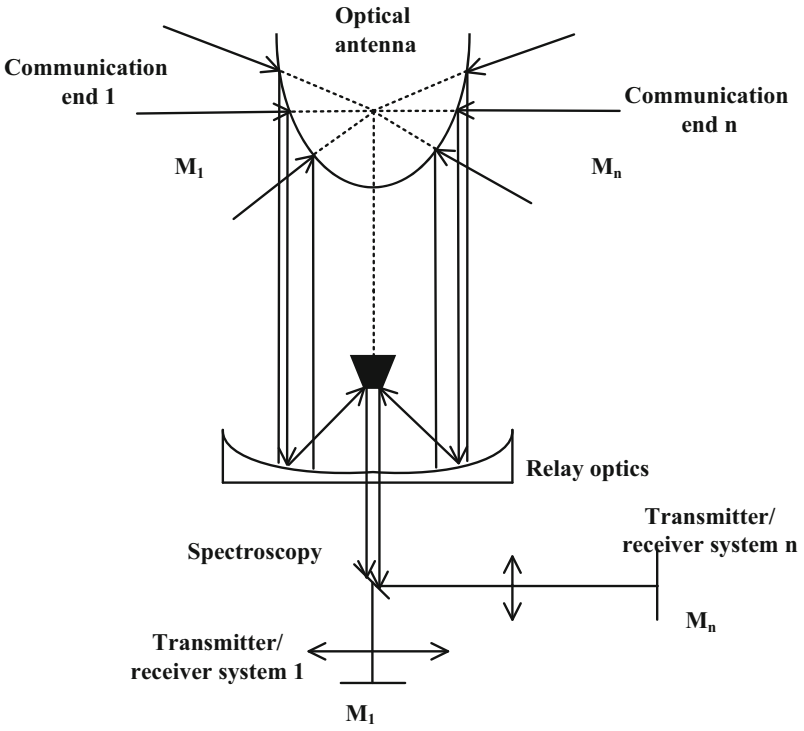

Fig. 11.12 One-to-many optical-communication system working-principle sketch [44]

Acquisition, Pointing, and Tracking (APT)

In space laser communication, owing to the small beam-dispersion angle and long transmission distance, precise tracking techniques must be adopted to ensure the transmission and reception quality of the laser signal. Here, APT technology becomes particularly critical and directly affects the quality of the space laser communication [81].

1. Acquisition: When the beacon light from the transmitter is received, the beam is usually focused on the center of the detector to identify the target. To identify the target in an uncertain area, a scanning operation is required to find and capture the target's beacon-light signal, thus laying the foundation for subsequent targeting and tracking [82].
2. Pointing: After capturing the beacon-light signal, it must be transmitted through the receiver. To meet the communication requirements, the transmitter and receiver should be aligned with each other so that the optical axis is consistent.
3. Tracking: Owing to the relative motion between the communicating and receiving ends, a precise connection must always be maintained to ensure that communication is maintained between satellites or between satellites and ground stations. Because of the relative motion between the communicating and

receiving ends, together with the influence of other factors, such as spot flicker and platform vibration caused by atmospheric turbulence, the system must control the error by tracking the aiming after it is completed to ensure that the accuracy is within the allowed range [82].

In optical communication, the signal-transmission loss results in a narrow communication beam. To ensure that the signal energy is accurately received by the receiver, the communication beam needs to be precisely controlled so that it is aligned with the system optical axis and remains within the error range. In this process, APT technology plays an important role. It plays a crucial role in interplanetary laser communication because it has very high precision and therefore becomes an essential technical means to ensure the success of communication [83].

In a one-to-many space laser-communication system, the workflow of the APT system consists of five main stages, namely,

1. Guidance pointing
2. Capture alignment
3. Coarse tracking
4. Fine tracking
5. Communication [84]

These are performed sequentially to achieve high-precision tracking and communication for one-to-many laser communication.

The main task of guidance pointing is to clarify the objectives and requirements of inter-multipoint communication and to determine information about the target. The main task of capture alignment is to determine the corresponding working reflector, based on target information, and achieve capture alignment so that the beam can be incident parallel to the subsequent optical system.

The main task of coarse tracking is to track a large field of view, based on the capture alignment, and to perform closed-loop tracking so that the beam is successfully incident to the center of the field of view [85]. The main task of fine tracking is to track the target on the basis of coarse tracking and suppress the residual error from coarse tracking so that it meets the communication requirements.

Coarse tracking requires a wide search range and fast target locking, while precision tracking requires high accuracy, a smaller search range, and advance calculation. The main task of communication is to achieve two-way communication with stable tracking [52].

Optical Principle of One-to-Many Communication

According to the one-to-many optical principle, terminals can be mainly classified into the following types: multi-optical terminal combination, multi-reflector, TSAT grouping, dual optical-wedge grouping-combination, fiber-array structure, multi-transmitting and multi-receiving structure, three-concentric-sphere structure, and rotating-paraboloid structure [86].

Multi-optical Terminal Combination Type

The structure of the multi-optical terminal combination type is shown in Fig. 11.13. It uses a single optical transceiver to realize one-to-many laser communication by combining multiple optical transceivers [87]. The optical transceiver mainly consists of an APT system, communication transceiver system, and optical subsystem.

The APT system consists of coarse and fine composite axes, in which the coarse-tracking structure is realized by the reflector, while the fine-tracking structure is realized by a piezoelectric ceramic oscillator, and the coarse and fine detection share the same CCD camera to realize variable resolution and variable frame-rate control for fast capture and high-precision tracking.

The communication transceiver system includes communication transceiver and receiver units with a bi-directional-rate asymmetry function. Optical subsystems usually include multiple units, such as shared Cassegrain telescope units, optical relays, and two-color beamsplitters [48]. These units work together to enable efficient and reliable signal transmission and processing in optical-communication systems.

By combining multiple optical-terminal units, the communication coverage and capability can be increased, making multi-target communication more convenient and efficient. However, the weight limitation of optical transceivers means that multiple combined optical transceivers must occupy extensive space and resources, increasing the cost and complexity of the system. In practice, they are mostly used in large-platform laser communication.

Multi-reflector Type

The multi-reflector type is shown in Fig. 11.14 and consists of multiple reflectors and a main optical transceiver. The multi-reflector type is innovative technology for space laser-communication networking. Multiple mirrors are placed at different

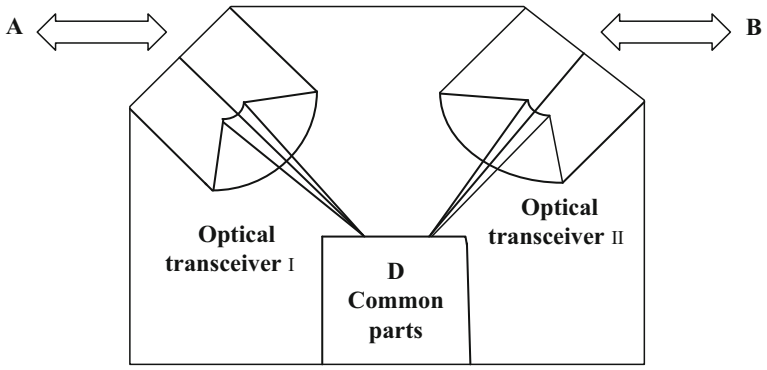

Fig. 11.13 Multi-optical terminal system diagram [87]

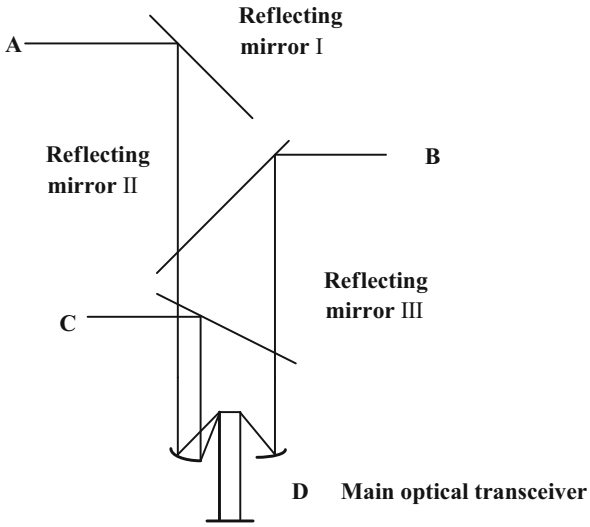

Fig. 11.14 Schematic diagram of a multi-reflector structure system [86]

angles at the front of the optical antenna of the optical transceiver to communicate in different orientations [45].

In the multi-reflector type, each reflector is single-point-to-single-point, and there are no redundant optical components. It has better flexibility and scalability, compared with the traditional optical-communication network built with multiple optical terminals, but it can only be used for "one-to-three" or "one-to-four" laser communications. The number of communications is still limited by the energy utilization and the difficulty of plating the reflector-film system [45]. The multi-reflector type can realize high-speed and high-bandwidth optical communication and has broad application prospects.

TSAT Networking

In 2016, the United States launched the Transformational Satellite Communications System (TSAT), a networking program designed to provide global military high-bandwidth communications and secure high-speed data-transmission capabilities [88].

The TSAT space segment consists of five satellites, of which the laser link is the backbone, integrating the geostationary satellite system, Optical Relay Communications Architecture (ORCA), Advanced Polar System (APS), and Tracking and Data Relay Satellite System (TDRSS). They cover the area between the 65° north and south latitudes and are the next generation of secure broadband satellite communication systems [89].

Compared with traditional microwave communication, the TSAT network introduces inter-satellite laser links. The communication bandwidth is improved and is

expected to reach a communication rate of 10–40 Gbit/s. The scheme covers a wide range of communication means for interplanetary and interstellar applications [90]. Its main advantages are a fast communication speed, high bandwidth, and wide coverage, while various communication means complement each other and play an important role in improving military communication and intelligence exchange, etc. The TSAT networking plan provides new ideas and technical support for the development of the satellite-communication field and has broad application prospects.

Double Optical-Wedge Group Combined Type

The combined double optical-wedge group structure is shown in Fig. 11.15. It uses a combination of a wide-angle beam expander and a double optical-wedge group as the optical antenna to achieve dynamic tracking and signal reception of the target [58]. A wide-angle beam expander is an optical component used to receive the signal light and transmit it to different communication targets. Although it has the advantage of a large field of view, it also has difficulty dynamically tracking moving communication targets.

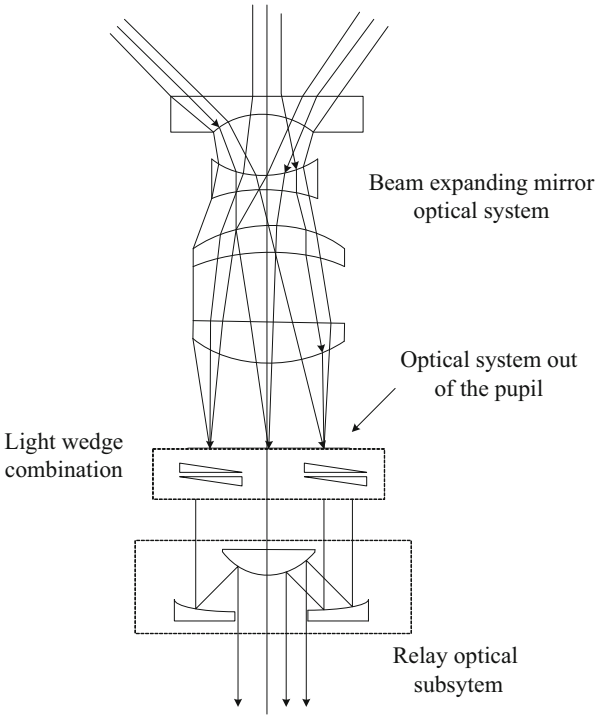

Fig. 11.15 Schematic diagram of the combined optical structure of the double optical-wedge group [58]

To address this problem, a double optical-wedge set is placed at the exit pupil of the optical system. In addition, the system uses a relay-optics subsystem to focus and optimize the signal light [91]. With this structural modification, the system can simultaneously track and receive signals from multiple targets, thus improving the application range of the system.

The combined double-wedge system can control the angle of the outgoing beam and improve the light-energy utilization by adjusting the rotation angle of the double wedge, according to the number and position of the targets. In addition, it has a low cost, has simple structure, and can dynamically track and receive signals from multiple targets. It is widely used in the field of multi-target laser-communication systems, such as communication between aircraft and aircraft and between artillery positions, and has broad application prospects [58].

Fiber-Array Type

The structure of the fiber-optic array is shown in Fig. 11.16. It consists of three parts: the overall optical path, the fiber end face, and the transmitter–receiver end. The overall optical path consists of a transmitting telescope and a receiving telescope. The fiber end face is an $N \times N$ fiber array. The transmitter end is an RC optical telescope that can be used for optical wireless systems, and the receiver end is a point-to-multipoint communication system.

In 2002, Lucent Technologies, Inc. (USA) [92] provided an improved optical telescope for optical wireless communication systems, which had the advantages of high bandwidth, wide link range, and high reliability, compared with the conventional design. The structure used a cassette system that automatically aligned the transmitter and receiver, positioning the $N \times N$ fiber array in the focal plane of the RC optical telescope, thus enabling point-to-multipoint communication with a single optical telescope [93].

Although this structure successfully expanded the field of view, the limitations of the card-based system and the numerical aperture of the fiber resulted in a still smaller field of view, more-severe stray light, and more-difficult transceiver arrangement; it needed to be further optimized [86]. In addition, interactions and interference that occur between fibers when transmitting through fiber arrays need to be overcome. Therefore, future fiber-array technology needs to be further improved and optimized to enhance its transmission efficiency and stability.

Multi-transmission, Multi-receiver Structure

A one-to-many laser communication system proposed by TeraBeam, USA, is shown in Fig. 11.17 [94]. In this system, light source 210 and light receiver 520 are optically coupled by optical input 240 and transmit the light to fiber 270. Optical input 240 is coupled to transmit the light received from light source 210 to reflective surface 230b, which reflects emitted light 260 in the form of a beam, 261, to the corresponding remote location.

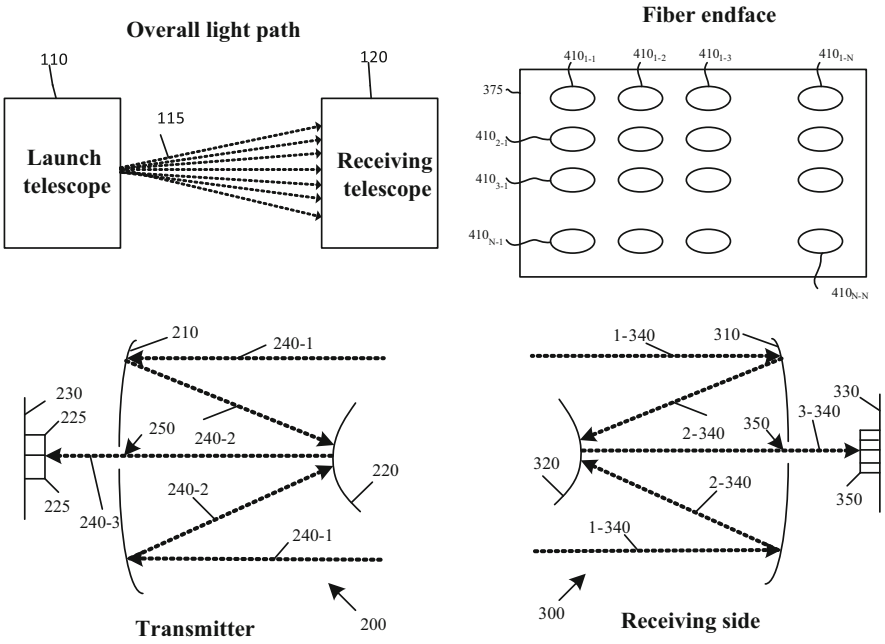

Fig. 11.16 Fiber-array type structure [92]

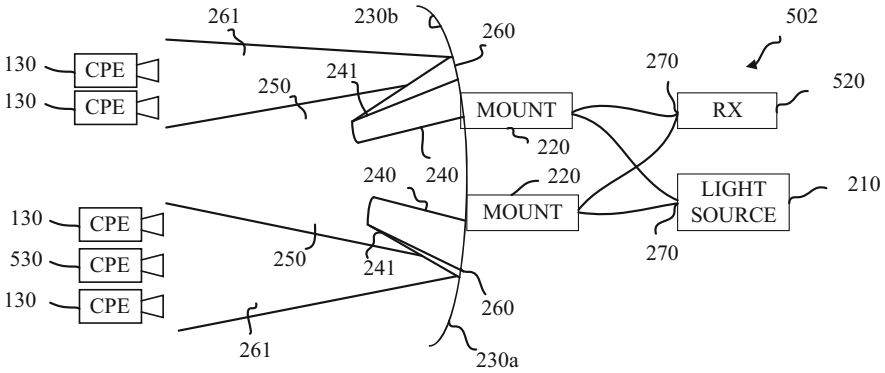

Fig. 11.17 Schematic diagram of one-to-many laser communication in free space [94]

Customer Premise Equipment (CPE) 130 at the remote position receives light beam 261 and returns the light signal back to reflecting element 230a, which is reflected to terminal 240 of 241. When the light signal is returned, it is coupled through optical receiver 520 to optical input 240; it is demodulated by optical receiver 520, converted into an electrical signal, and made available to the connected device.

A technique for tracking movement over long distances is provided by adjusting the position of node unit 250 and can be received simultaneously using optical receiver 520, thus enabling the design of a one-to-many laser-communication networking structure.

Although the structure can expand the field of view, the expansion has some limitations and APT system tracking is not easily achieved. In addition, the layout of nodal units and their adjustment become more difficult because multiple nodal units are involved; hence, the design needs further optimization and improvement.

Three-Concentric-Sphere Structure

The three-concentric-sphere structure, shown in Fig. 11.18, is designed by embedding three concentric-sphere structures into the lens to form a monolithic structure. Each concentric-sphere structure contains a lens and a reflective surface, and these surfaces work together to make a lens with both horizontal and pitch fields of view. By combining multiple such lens structures, multiple-target tracking and communication transmitting and receiving can be achieved. The system can reach a 120° field of view in both the horizontal and pitch directions, enabling it to be used in application scenarios with large field-of-view requirements, such as satellite communications.

By placing the unit-transceiver terminal on a tracking track, it is possible to transmit and receive communications to and from multiple targets. When the target

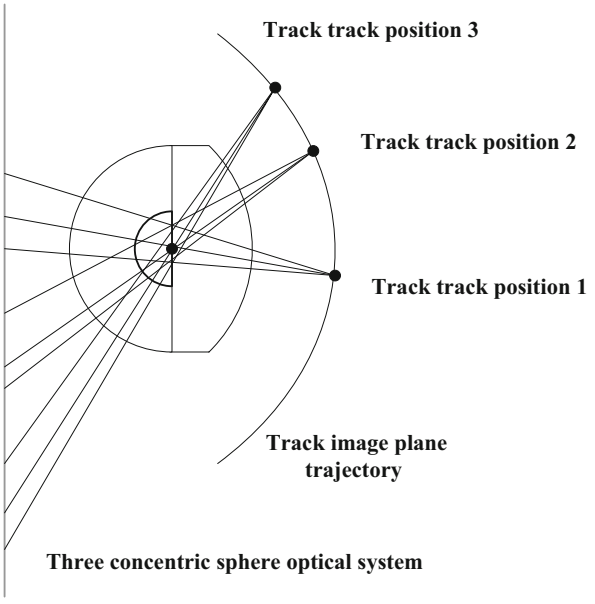

Fig. 11.18 Schematic diagram of the three-concentric-sphere structure [17]

moves into the jurisdiction of another subsystem, the system can quickly "take over" and handle the tracking and communication tasks, thus enabling a seamless communication connection [95]. It has a more efficient tracking and targeting capability than conventional optical antennas and identifies and tracks targets more quickly, thus making the work easier and more efficient.

This structure can be used to realize multi-point space laser communication in a defined orbit, which makes laser-communication networking simpler and more convenient. In addition, the optical antenna has a simple and lightweight structure, which is suitable for short-range laser-communication networks. During use, the structure can maintain good stability and high reliability and successfully work in complex environments [96].

Rotating-Paraboloid Structure

The rotating-paraboloid structure is shown in Fig. 11.19. It consists of a communication target, optical-relay system, detector, and transmitter. The rotating-paraboloid structure is obtained by using a reflective rotating paraboloid as the base surface type [97]. Its advantage is that it has a very wide horizontal communication range. The communication rays are directed to the focal point of the parabolic surface from different directions and are incident on the rotating-paraboloid structure. After the action of the rotating paraboloid, the light rays are emitted in a direction parallel to its axis and then incident onto the optical-relay system.

This reflective rotating paraboloid can achieve a horizontal communication range of 360° and a pitch communication range of 100°. Owing to the rotating-paraboloid structure, the antenna can be flexibly rotated and adjusted to adapt to different communication scenarios and is widely used in radar, aircraft, satellite receiving stations, and other fields. The rotating-paraboloid structure, with a compact design, wide communication range, and high communication efficiency, provides stable communication transmissions. This makes multi-target communication easy and efficient, enabling simultaneous one-to-many laser communications [86].

Development Trends

One-to-many wireless laser communication is a high-speed, high-quality communication method that has become a key technology for many applications. Its future development trend mainly includes the following points:

1. Networking: As the performance of optical wireless communication systems continues to gradually improve, from the current point-to-point mode to point-to-multipoint, building optical wireless communication networks is a direction of rapid development.

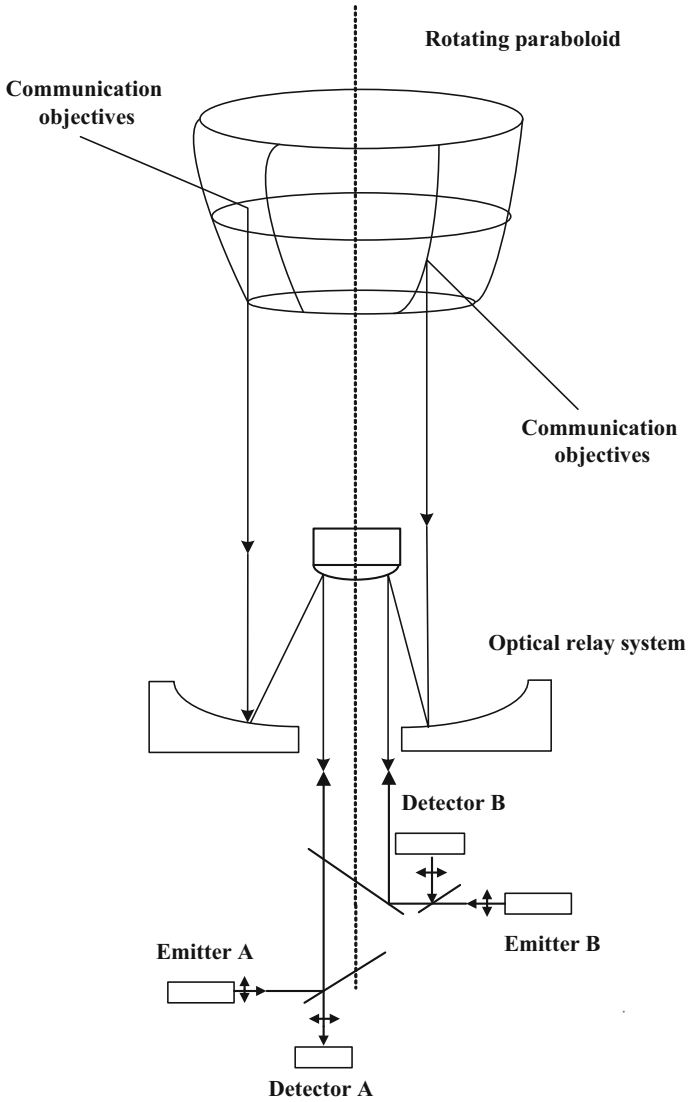

Fig. 11.19 Schematic diagram of the rotating-paraboloid structure [97]

2. High speed: With the development of technology, the transmission rate of one-to-many laser communication will gradually increase to achieve more efficient transmissions.
3. Security: To ensure the security of communications, the future will introduce more secure data-encryption technology to strengthen security measures.
4. Applicability: In the future, one-to-many laser-communication technology will be applied in a wider range of fields, such as military, medical, intelligent

transportation, etc., to provide communication services with a high transmission rate, high reliability, and high stability.

Generally, one-to-many laser-communication technology will become popular and become one of the main communication means in various fields, while more efficient and secure technologies and applications will be continuously introduced.

Summary

Space laser-communication networking requires capabilities, such as one-to-multi-point communication, dynamic communication, and duplex communication. In this chapter, the basic characteristics of different types of optical antennas were introduced and the current status of one-to-many laser communication at home and abroad and its development were discussed.

Moreover, several different types of structures were presented, namely, the multi-optical terminal combination type, multi-reflector superposition type, TSAT networking, dual-optical wedge group combination type, fiber-array structure, multi-transmitting and multi-receiving structure, three-concentric-sphere structure, and rotating-paraboloid structure. The features are compared in Table 11.5.

One-to-many communication technology has become an important research direction in the field of optical wireless communication, with broad application prospects. The future research directions of optical wireless communication systems with one-to-many optical antennas are likely to take the following paths:

1. Research on the tracking-control technology of one-to-many wireless laser communication should be strengthened.

Table 11.5 Comparison of the characteristics of each structure

Designation	Strengths and weaknesses
Multi-optical-terminal combination type	Fast capture and high-precision tracking; high weight
Multi-reflector superposition type	Low energy efficiency; not widely available
TSAT networking	High-bandwidth information communication capability
Double optical-wedge group combined type	Large field of view, dynamic tracking
Fiber-array structure	Large focal plane; small field of view, serious stray light, more difficult to arrange transceiver devices
Multi-transmit, multi-receive structure	Field of view is still limited and APT system tracking is more difficult to achieve
Three-concentric-sphere structure	Simple structure, light weight, and miniaturization
Rotating-paraboloid structure	Wide communication range, simple structure, long communication distance

2. One-to-many optical wireless communication should move toward greater coverage, higher transmission rates, and wider application prospects, and multipoint-to-multipoint communication, based on one-to-many communication, should be investigated.
3. The one-to-many optical wireless communication system optical-antenna design is a key technology to achieve one-to-many communication. This technology provides the feasibility and possibility for establishing optical wireless communication grouping networks.
4. Building an integrated global information network in space and air is an inevitable development trend, and wireless laser-communication networking technology is the most effective means to achieve this goal.
5. Traditional wireless laser communication can achieve point-to-point communication; however, it is difficult to meet the communication needs of multiple devices, thus limiting the development of optical wireless communication networking. One-to-many optical wireless communication technology can effectively solve the problems that point-to-point communication cannot solve.

Abstract

Optical wireless communication refers to the technology of transmitting information in free space using light waves as a carrier, which has the advantages of high bandwidth, low cost, and high security. The acquisition, pointing, and tracking (APT) system is the premise of establishing an optical wireless communication system. A simple, reliable, and dynamic APT system can overcome the impact of mechanical platform vibration and external environment changes on the optical wireless communication system. Therefore, it is necessary to conduct in-depth theoretical and experimental research on the APT system, so as to design a capture, aiming, and tracking method suitable for optical wireless communication. This chapter analyzes the domestic and foreign research achievements in capturing, aiming, and tracking, and introduces the work done by Xi'an University of Technology in the field of automatic aiming. It mainly includes the progress of initial acquisition system, non-common visual axis control system,

Introduction

Optical wireless communication uses light waves as carriers to transmit information in free space. It offers the advantages of high bandwidth, low cost, and high security. An acquisition, pointing, and tracking (APT) system is the basis for establishing an optical wireless communication system. An APT system with simple, reliable, and good dynamic performance can overcome the impact of mechanical-platform vibrations and external environment changes on optical wireless communication systems. Therefore, it is necessary to conduct more in-depth theoretical and experimental research on APT systems to design an acquisition, pointing, and tracking method suitable for optical wireless communication.

This chapter analyzes the research results on acquisition, pointing, and tracking at home and abroad and introduces the work of Xi'an University of Technology in automatic aiming. It includes the progress of the initial acquisition system, non-common axis-of-sight control system, beam detection system, etc. In addition, outfield experiments of 1.3 km, 5.2 km, 10.2 km, and 100 km distance links are introduced, which verify the effectiveness of the APT system. Finally, the development of APT in optical wireless communication is projected.

Optical wireless communication has the advantages of both microwave and optical fiber communications [1]. It is an important means to realize space-based, air-based, and land-based communication links [2] and has broad development prospects in military-security communication, emergency-rescue communication, and other fields.

However, owing to the influence of mechanical jitter and various uncertain factors in the atmospheric channel (such as atmospheric turbulence, rain, snow, and dust), the spot position of the receiver may be offset or even lost. This increases the bit error rate of the system and ultimately leads to a decline in performance, causing difficulties in establishing and maintaining optical wireless communication links [3]. Therefore, it is necessary to establish a set of acquisition, pointing, and tracking (APT) systems to prevent communication link interruptions.

In an optical wireless communication system, the optical elements on the transmitter and receiver platforms are required to share the same axis of view in real time. This process is typically referred to as automatic aiming [4]. A structural diagram of

the optical wireless APT system is shown in Fig. 12.1. The APT system includes coarse and fine tracking and aiming structures and servo units. After the initial pointing of the transmitter and receiver is completed, the signal and beacon lights pass through the beam-combining mirror, are collimated, and are output through the transmitting antenna.

The acquisition device at the receiving end starts to scan the synthetic beam to complete the acquisition work. The beam splitter at the receiving end guides the beams through the receiving end to the tracking and communication detectors. When the light beam shines on the photosensitive surface of the detector at the receiving end, the sight axes at both ends of the transmitter and receiver are aimed by the drive of the servo mechanism.

Finally, according to the real-time feedback spot information at the receiving end, the coarse tracking structure adjusts the direction of the beam to make it perpendicular to the center of the detector. The fine tracking structure further eliminates the tracking residual that was not eliminated by the coarse tracking structure, to ensure the real-time collimation of the line of sight (LOS) at both ends of the transmitter and receiver.

This chapter introduces the research progress and course of APT in optical wireless communication systems at home and abroad, summarizes the research achievements of Xi'an University of Technology in this field, and looks forward to the application prospects and research directions of APT systems in optical wireless communication, according to existing research theories.

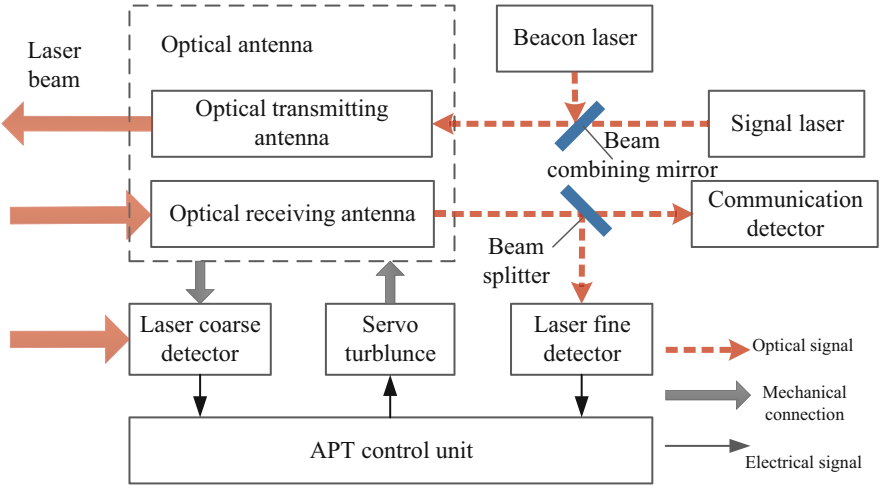

Fig. 12.1 Schematic diagram of an optical wireless communication APT system structure [5]

Foreign Research Progress

An APT system is an indispensable part of an optical wireless communication system. Its role is to ensure that the beams of the transmitter and receiver are fully aligned in real time, to establish a stable optical wireless communication link. The development of APT systems has been almost synchronous with the development of optical wireless communication systems.

In the 1970s, the Jet Propulsion Laboratory (JPL) in the United States conducted experimental research on space-based optical wireless communication systems. The Deutsches Zentrum für Luft- und Raumfahrt (DLR), European Space Agency (ESA), National Space Development Agency of Japan (NASDA), and other institutions successively carried out satellite–ground experiments on air–ground optical communication links.

In 1985, NASDA developed the laser utilizing communication equipment (LUCE) system, in which the detection system used for alignment and tracking consisted of a charge-coupled device (CCD) and a four-quadrant detector. The experiment showed that the aiming and tracking accuracies of the system were better than 1 mrad [6] in a strong vibration environment.

In 1994, the JPL developed the optical communication demonstrator (OCD) system that realized fast, accurate aiming and stable beam tracking with a data-transmission rate of 250 Mbit/s [7].

In 1994, the Ministry of Posts and Telecommunications (MPT) of Japan developed laser communication equipment (LCE). The coarse tracking structure of the system adopted area array CCD detection, and the coarse tracking accuracy was 32 μrad. The precision tracking structure used a four-quadrant detector to measure the position information of the beam; its accuracy reached 2 μrad, and it had a jitter compensation capability of 200 Hz [8].

In 1999, Biswas designed a satellite laser communication terminal (LCT) that used an independent transmitting and receiving antenna. The capture sensor used an area array CCD, and a servo turntable for aiming and tracking. The frame rate of the CCD operation in tracking mode reached 1.6 kHz [9].

In 2002, the ESA established an inter-satellite optical communication link using the semiconductor laser inter-satellite link experiment (SILEX) system. The system used a coarse and fine composite axis alignment system composed of a direct current (DC) stepper motor and a fast mirror. Its tracking accuracy reached 2 μrad [10].

In 2004, Guelman adopted a two-level hierarchical system control, with the lower layer controlling the pan, tilt, and zoom (PTZ) of the electro-optical transceiver. The upper layer was a fast closed-loop control system to control the beam width and direction, and realized laser communications between an unmanned aerial vehicle (UAV) and the ground [11].

In 2004, the Lincoln Laboratory of the Massachusetts Institute of Technology and JPL jointly developed the Mars laser communications demonstration system (MLCD). The system adopted a photon-counting detector and telescope receiving-array structure. A combined aiming and tracking system was adopted to improve the aiming accuracy, and the system communication rate reached up to 10 Mbit/s [12].

In 2010, the DLR designed a beacon-free laser communication terminal (LCT). In the process of aiming and tracking, a beacon light was not used, and a servo turntable control mirror with only two dimensions was used for spiral scanning and signal light acquisition. This reduced the complexity of the airborne laser communication terminal. The average tracking error was 226 μrad [13].

In 2012, Schmidt et al. designed a small laser communication terminal consisting of an objective lens providing a wide field of view and a driver for controlling the beam-steering mirror. The system provided a wide field of view of 46°, based on fast aiming [14].

In 2013, the DLR conducted an air-to-ground optical wireless communication experiment. The airborne laser terminal included a coarse aiming structure and fine aiming mechanism. Experiments showed that the system could reduce the influence of turbulence and microvibration on the tracking accuracy to 200 μrad [15]. In the same year, the DLR conducted an airborne laser communication experiment between the "Wind" fighter and a ground terminal. The communication link distance was 50 km, the data-transmission rate was 1.25 Gbit/s, and the APT system terminal carried by the aircraft achieved stable tracking at 79 km [16].

In 2016, Quintana et al. designed a tracking system consisting of a coarse tracking module, composed of a CCD camera, and a fine-tracking module, composed of a spatial light modulator and a position-sensitive detector (PSD), and applied the system to an air–ground laser communication experiment. A 2-Mbit/s optical communication link was established within 300 m, with a bit error rate of approximately 2×10^{-4} [17].

In 2020, Antonello et al. designed a high-precision aiming and tracking system for in-orbit laser communications. The system adopted coarse and fine aiming structures with a weight of 1.8 kg. By simulating an external interference environment, the aiming error of the system was found to be less than 10 μrad [18].

A summary of the foreign research progress is presented in Table 12.1. As research on optical wireless communication APT systems has been conducted, their application scenarios have gradually developed from ground stations to airborne and inter-satellite optical communication platforms. The accuracy requirements of the tracking and pointing systems have also increased.

Domestic Research Progress

Since the 1990s, many scientific research institutions and universities in China have conducted in-depth research in the field of optical wireless communication and have made certain progress in rapid aiming systems, composite axis control systems, and airborne laser communication systems. At present, the main research institutions in China include the Changchun University of Technology; Harbin Institute of Technology; Changchun Institute of Optics, Fine Mechanics and Physics, Chinese Academy of Sciences; University of Electronic Science and Technology; Wuhan University; and Xi'an University of Technology.

Table 12.1 Foreign research progress

Year	Researcher/ organization	Research progress	Benefits/parameters
1985	NASDA	LUCE system	Tracking accuracy better than 1 mrad
1994	JPL	OCD system	250-Mbit/s communication rate
1994	MPT	LCE system	Tracking accuracy better than 32 μrad and 2 μrad
1999	Biswas	LCT system	1.6-kHz CCD working frame rate
2002	ESA	Composite aiming system applied to SILEX	Tracking accuracy was 2 μrad
2004	Guelman	Composite APT system	Composite shaft system adopted for the first time
2004	MIT NASA	OLCD system	10-Mbit/s communication rate
2010	DLR	Laser communication terminal	226-μrad average tracking error
2012	Schmidt	Small laser communication terminal	Capture field of view was 46°
2013	DLR	Experiment on ground-to-air laser communication	Distance: 79 km; transmission rate: 1.25 Gbit/s
2016	Quintana	Airborne laser communication system	Communication rate: 2 Mbit/s
2020	Antonello	Satellite laser communication system	Aiming error less than 10 μrad

In 1999, Liu et al. designed an automatic aiming scheme for optical wireless communication systems. In this scheme, a reflector was used as the beam stabilizer to eliminate the optical axis deviation at both ends of the transmitter and receiver, caused by beam drift and mechanical vibrations in the system [4].

In 2000, Jiang et al. designed a prototype of a wireless laser communication system. The transmitter used a semiconductor laser with an 855-nm wavelength. The maximum communication rate of the system was 2048 Kbit/s [19].

In 2002, Hu et al. designed a free-space optical communication ground demonstration system. The system used a tracking mechanism composed of a DC torque motor to achieve stable high-precision and broadband operation. The field experiment results showed that the system acquisition time was 180 s, and the tracking and pointing accuracies in the azimuthal and pitch directions were 38.6 μrad and 40.4 μrad, respectively [20].

In 2005, Ai et al. designed a space light APT scheme that used a CCD sensor as an image processor and a digital signal processor to control and drive the composite axis system to realize tracking. The experimental results indicated that the relative error of the angle measurement was approximately 1.3% [21].

In 2007, Jiang et al. optimized the bandwidth of a composite axis coarse tracking servo system and simulated an interstellar optical wireless communication experiment. When the servo bandwidth was 16 Hz, the coarse tracking and fine tracking errors were 60 μrad and 4 μrad, respectively [22].

In 2008, Zhang et al. designed an APT experimental device for deep-space noncooperative targets and analyzed the motion characteristics of the system's tracking structure, and the factors affecting the acquisition and tracking time after the satellite deviated from the center of the spot. The results showed that during the acquisition and tracking process, the angular velocity of the motor met the change rule of acceleration before deceleration. The angular acceleration of the motor and the detection accuracy of the detector directly affected the acquisition and tracking time of the system [23].

In 2008, Pan et al. designed an automatic pointing system for uplinks and downlinks. By adjusting the angle of the tilt mirror, the transmitter was aimed at a CCD goniometer, and the aiming accuracy of the optical axis at both ends of the transmitter and receiver reached 20.52 μrad [24].

In 2011, Ma et al. realized optical communication between the "Ocean 2" satellite and the ground. The experimental results showed that the system uplink and downlink single-channel data rates were 2 Mbit/s and 504 Mbit/s, respectively [25].

In 2011, Song et al. analyzed the impact of external constraints on an airborne laser communication system and conducted an optical wireless communication experiment between two aircraft. The aircraft flew at a height of 700 m, with a communication rate of 1.5 Gbit/s [26].

In 2012, Ai et al. designed a precise tracking system and conducted a 2-km laser communication experiment. The system was primarily composed of a complementary metal-oxide semiconductor (CMOS) camera, fast mirror, and host computer, which were used to compensate for the coarse tracking residual caused by atmospheric turbulence and platform vibration. The experimental results showed that the standard deviation of the spot offset could be controlled to 6 μrad [27].

In 2013, Qian et al. proposed a design scheme for a new type of spot detection camera that was based on a detector with a higher pixel duty ratio and reduced the impact of noise on the detector-positioning accuracy. The experimental results showed that the positioning error of noise in the system could be reduced to less than 0.007 pixels using this scheme, which met the system requirements [28].

In 2015, Meng et al. designed a two-stage (i.e., coarse and fine) composite tracking mechanism for airborne laser communication systems that could eliminate platform vibration. The simulation results showed that the coarse and fine tracking accuracies of the system were better than 23.97 μrad and 8.03 μrad, respectively [29].

In 2017, Zhang et al. designed a composite tracking system for airborne laser communication experiments using a single-loop proportional–integral–derivative (PID) algorithm to control the fast reflector. Experimental results showed that the tracking accuracy of the system was 10 μrad [30].

In 2017, Xu et al. proposed a fast-tracking method using a liquid-crystal optical phased array. A PID algorithm was introduced to control the actuator to deflect the incident beam and point it to the center of the detector for fast tracking. The experimental results showed that the system tracking accuracy under a stable tracking state was less than 13.6 μrad [31].

In 2018, Yu et al. studied the hysteresis characteristics of a piezoelectric tilt mirror in a space laser communication APT system. To overcome the influence of hysteresis on the positioning accuracy of the precision aiming system, a mathematical model of the improved Prandtl–Ishlinskii play hysteresis operator was proposed, and the system parameters were identified using the least-squares method. The experimental results showed that the tracking error of the system using this method was reduced by 80% [32].

In 2019, Cai et al. conducted a study on the coarse and fine pointing of a single-detection composite axis system and enabled the coarse and fine pointing of the transmitter and receiver by establishing a decoupling model. Experimental results showed that the tracking accuracy of the system using this method reached 10.69 μrad [33].

In 2019, An et al. from the 34th Research Institute of the China Electronics Technology Group Corporation designed an airborne laser communication system. The system adopted a combination of coarse and fine tracking methods and conducted an airborne laser communication experiment with a communication distance of 6.7 km and a communication rate of 1.25 Gbit/s through speed and position closed-loop control [34].

In 2020, Ren et al. studied the application of a four-quadrant detector in beam acquisition and tracking systems and achieved stable tracking by calculating the spot position on the four-quadrant detector. Experimental results showed that the tracking accuracy of the system using this scheme was better than 3 μrad [35].

In 2021, Li et al. designed a backpropagation (BP) neural network position detection algorithm and a multielement array position detection method to meet the performance requirements of coarse and fine tracking. The experimental results showed that the angular resolutions of the spot position detection system were 0.187 μrad and 0.903 μrad, respectively [36].

In 2022, Zhong proposed a new scanning acquisition method. The system used a fast mirror as an actuator, overcoming the problem of large overlapping areas in traditional scanning methods. The experimental results showed that the acquisition time of this method was approximately 35 s less than that of the traditional non-beacon scanning method, and the acquisition probability could reach 92.3% [37].

A summary of domestic research progress is shown in Table 12.2.

Research Progress in the Automatic Aiming of Optical Wireless Communication Systems at Xi'an University of Technology

To maintain the real-time collimation of an optical transceiver line of sight (LOS), it is necessary to design a fast and high-precision APT system [29]. A typical optical wireless communication APT system is shown in Fig. 12.2 [1]. The main controller completes the initial orientation according to the positions of the transmitter and receiver ends, and the image-processing unit calculates the deflection angle of the two-dimensional turntable according to the spot position information. The angle

Table 12.2 Domestic research progress

Year	People	Research progress	Benefits/parameters
1999	Liu and Shu	Automated pointing system	Stable effective bandwidth was 50 Hz
2005	Ke and Liu	Automated acquisition system	Established an APT system simulation model
2005	Ai and Zhou	Space optical APT system	Angle measurement error was about 1.3%
2007	Jiang and Tong	Bandwidth optimization design of a coarse tracking servo	Coarse and fine tracking accuracies were about 60 μrad and 4 μrad, respectively
2008	Pan and Zhang	Automated pointing system	Pointing accuracy was 20.52 μrad
2011	Ke and Hu	Beacon light spot detection system	Used PSD and CCD to design an APT system
2011	Song and Chang	Airborne laser communication experiment	Communication rate: 1.5 Gbit/s
2013	Qian	Spot detection camera	Impact of noise on positioning error was reduced to 0.007 pixel
2015	Meng and Zhao	Compound tracking system	Coarse and fine tracking accuracies were better than 23.97 μrad and 8.0 μrad
2016	Ke and Yang	Coaxial aiming detection method	Angle tracking accuracy was 34.6 μrad
2016	Ke and Zhao	Initial capture system	A position calibration point method was designed
2017	Zhang and Qiu	APT system applied to airborne laser communication	Tracking accuracy was 10 μrad

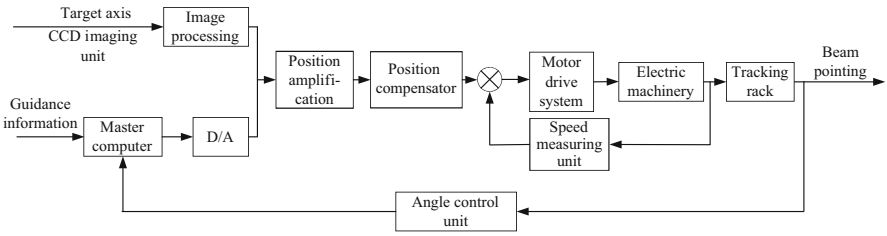

Fig. 12.2 Typical wireless laser communication APT system diagram [1]

control system feeds back the deflection angle information of the two-dimensional turntable in real time. The main controller then sends a control command to the motor to drive the two-dimensional turntable according to the feedback information to realize stable beam alignment and tracking.

Since 2000, Professor Xizheng Ke of Xi'an University of Technology has conducted in-depth theoretical research and experimental verification of typical optical wireless transmission technologies, such as optical wireless communication APT-system design, initial beam acquisition, precise spot aiming, and far-field spot image detection.

In 2005, Liu established and analyzed a simulation model for an APT system in atmospheric laser communication and designed an automatic beam acquisition system [30].

In 2011, Hu designed a beacon light spot detection scheme using a CCD [31].

In 2016, Yang proposed a coaxial aiming detection method, designed aiming control and tracking systems according to the method, and conducted field experiments [32]. In the same year, Zhao designed an initial acquisition system and conducted a 1.3-km outfield experiment [33]. In the same year, Xu designed a spot detection system and proposed a corresponding image-processing algorithm [34].

In 2017, Li proposed an optical axis aiming scheme that could effectively improve the detection and aiming accuracy of the system [35].

In 2019, Yan designed a spot tracking system and conducted a 5.2-km outfield tracking experiment. The experimental results showed that the tracking accuracy of the system could reach 5.4 μrad [36].

In 2020, Jing designed a spot image detection method and carried out a 100-km laser communication experiment [37]. In the same year, Zhang embedded a high-precision actuator in an APT system to achieve high-precision aiming and tracking, designed a focusing system, and carried out field experiments at 10.2 km and 100 km [38].

In 2021, Liang designed an APT system that could be carried on a UAV and carried out an airborne laser communication experiment by simulating an airborne experimental platform, with a tracking accuracy of 2.42 μrad [39]. In the same year, Ke et al. proposed a rapid aiming method. This method did not require the control signal to feed from the receiver back to the transmitter and could simultaneously establish uplinks and downlinks. Field experiments of 1.3 km and 10.2 km were conducted [40–41].

Coarse- and Fine-Grading Control System

A coarse- and fine-grading control system is composed of a two-dimensional pan–tilt and piezoelectric micromotion platform [42]; its structure is shown in Fig. 12.3. The coarse tracking structure adopts a two-dimensional PTZ TGMZ-01 with an azimuth adjustment range of 0°–360° and a pitch range of −70°–70°. The angle adjustment in the two directions is controlled by a servomotor, and the control algorithm adopts an incremental PID algorithm.

The precision tracking structure adopts a piezoelectric micromotion platform, and its azimuth and pitch angles can vary from 0 mrad to 0.2 mrad, and from 0 mrad to 0.4 mrad. The test results for the coarse tracking system are shown in Fig. 12.4. An incremental PID algorithm was used for control to suppress the positioning error of the system. The error suppression performance of the system was tested when the target angle increment was 0.03°.

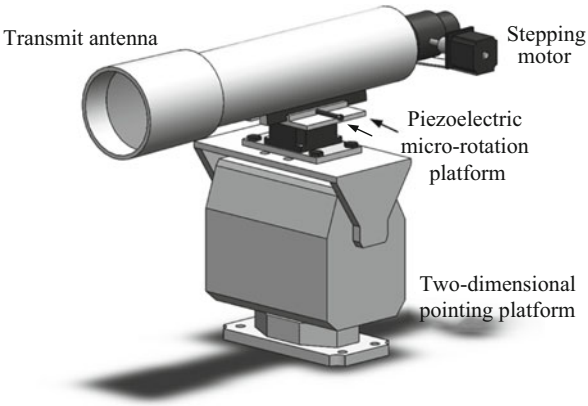

Fig. 12.3 Coarse- and fine-grading control system [42]

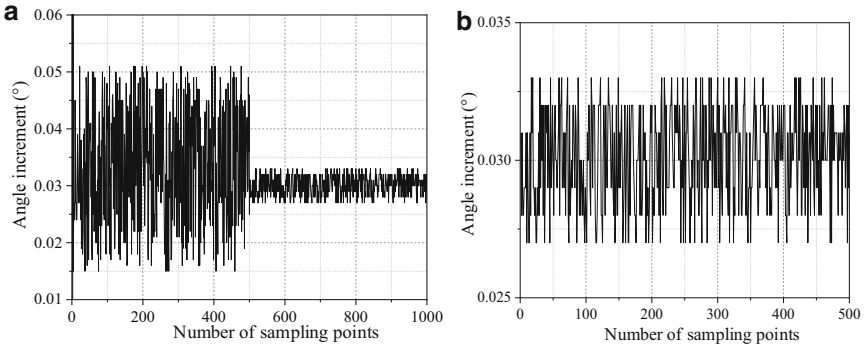

Fig. 12.4 Angle increment (**a**) before and (**b**) after error suppression [43]

Figure 12.5 shows the response curve of the coarse tracking structure. The figure shows that the system has no overshoot or large-amplitude oscillations and that the control performance is ideal.

The relationship curve between the input voltage and angle of the piezoelectric micromotion platform is shown in Fig. 12.6, where Fig. 12.6a is the θ_x relation curve of the voltage and angle in the x direction and Fig. 12.6b is the θ_z curve of the voltage and angle in the z direction. The linearities $\delta = (\Delta y_{\max}/y) \times 100\%$ available in the θ_x and θ_z directions are 0.15% and 0.14%, respectively. The results are approximated

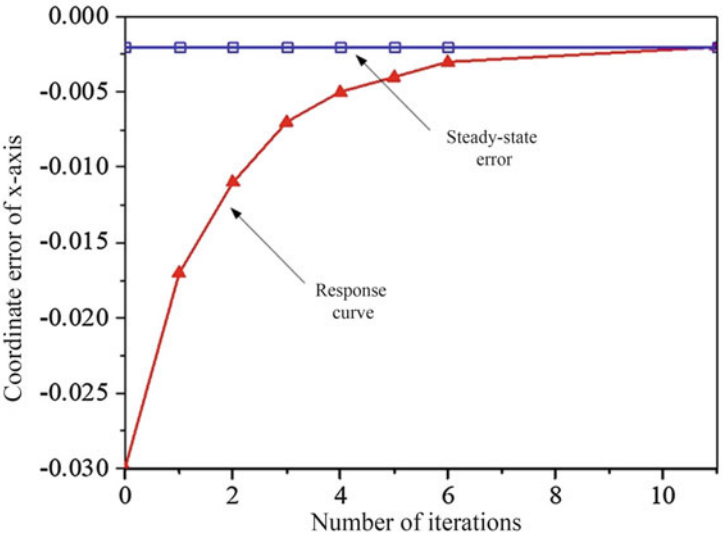

Fig. 12.5 Two-dimensional PTZ response curve [43]

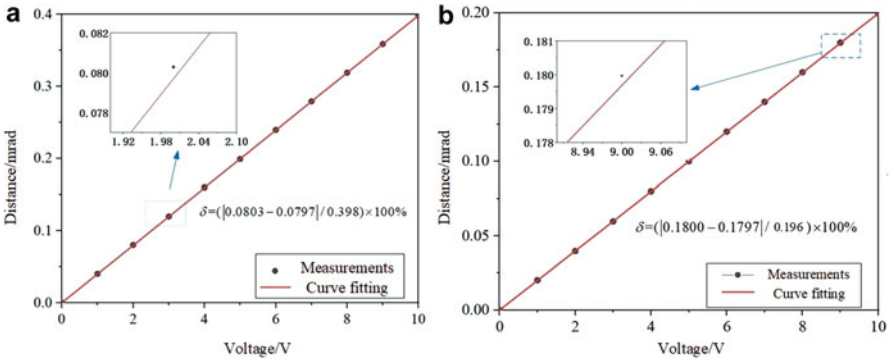

Fig. 12.6 Relation curve between input voltage and angle. (**a**) θ_x-direction control voltage and angle; (**b**) linear error curve of θ_z direction [43]

using a linear relationship. Δy_{max} is the maximum deviation between the input voltage, angular-displacement relationship curve, and ideal fitting curve. y is the full-scale output value [43].

Beam Detection System

The optical path diagram of a beam-aiming detection system is shown in Fig. 12.7. The beam was divided into communication and position detection beams after passing through a light splitting prism. The former was used to transmit information, and the latter was irradiated on the optical rear projection screen to the image.

The four beam detection cases are shown in Fig. 12.8. α represents the angle between the incident beam and the visual axis of the antenna, and ρ represents the beam offset. By defocusing the system, the problem of the system being unable to detect the beam offset can be overcome.

Automatic Tracking Control System for Space-Based Relay Optical Wireless Communication

Figure 12.9 shows the schematic diagram of a UAV-relay APT system with an integrated transceiver. The six-rotor UAV is equipped with a two-dimensional reflector and an optical receiving unit to capture, aim, and track the signals sent from the ground terminal, to enable the two ground terminals to realize two-way communication through the UAV relay platform. When ground terminal 1 is the transmitting terminal, ground terminal 2 is the receiving terminal, and vice versa. Thus, UAV-relay laser communication with an integrated transceiver can be realized [44].

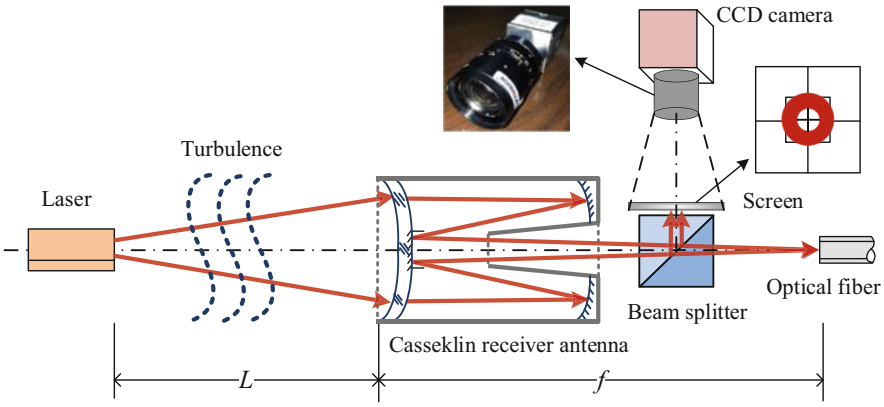

Fig. 12.7 Schematic diagram of the beam detection system structure [5]

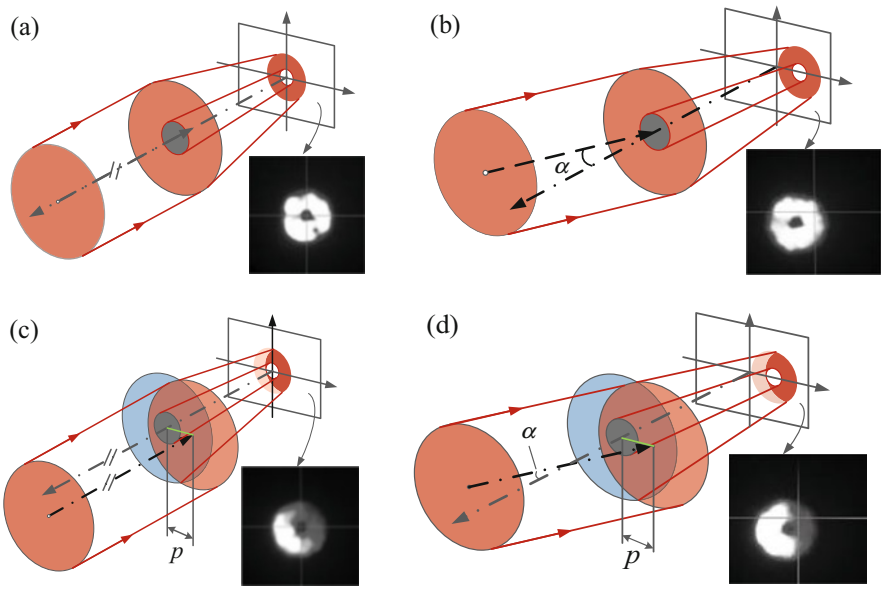

Fig. 12.8 Four beam detection cases [5]. (**a**) $\alpha = 0, p = 0$; (**b**) $\alpha \neq 0, p = 0$; (**c**) $\alpha = 0, p \neq 0$; (**d**) $\alpha \neq 0, p \neq 0$

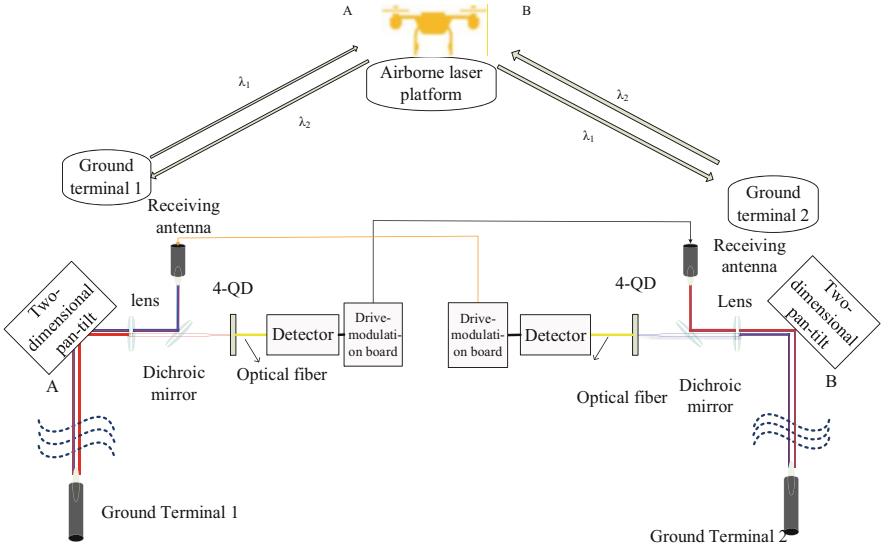

Fig. 12.9 Integrated transceiver UAV-relay APT system [45]

In the experiment, the signal wavelength was 650 nm, transmitted optical power was 2 mW, and communication rate was 10 Mbit/s. The transmitting end used on–off

keying (OOK) modulation to load the video signal onto the light source and collimate the transmission output through a transmitting antenna. The two-dimensional reflector focused the laser beam through the lens onto the through-hole four-quadrant detector to complete the coarse aiming process [46]. The detector then converted the received optical signal into photoelectricity, the signal was demodulated, and the image information collected by the transmitter was observed on the computer.

Figure 12.10 shows the signal waveform at the receiving end. The signal output by the transmitter is a 10-Mbit/s square wave signal. From the waveform of the signal at the receiver, it can be observed that the signal is not significantly distorted and is still a relatively complete square wave signal. The test results show that the system satisfies the performance index for working at 10 Mbit/s.

Figure 12.11 shows the distribution of the spot center coordinate positions during the aiming process. The image was re-aimed after 4500 spot drifts. The re-aimed images of the spot were collected, and the center position coordinates of the spot were obtained through image processing. The black "+" in the figure refers to the position of the bull's eye, and the blue coordinate points refer to the positions of the light spot center deviating from the bull's eye at the time of aiming. After the calculation, the aiming accuracy of the system reached 2.42 μrad.

Field Experiments for Acquisition, Aiming, and Tracking in Optical Wireless Communication

1.3-km Far-Field Experiment

The assembly structure diagram of the 1.3-km far-field experimental system is shown in Fig. 12.12. The transmitting end was located on the eighth floor of the teaching building on the Jinhua Campus of Xi'an University of Technology. The receiving end was located on the 11th floor [5] of Kaisen Fujing Yayuan, East 2nd Ring Road, Xi'an, China, with a communication link distance of 1.3 km. The experimental system was based on a NexStar 8SE astronomical telescope. A camera was placed before and after the receiving antenna for capturing and tracking, and the entire system was placed on a single-arm platform.

The spot data measured in the experiment are shown in Fig. 12.13. In the light spot tracking process, the light spot drifted out of the tracking threshold 11 and two times in the azimuth and pitch directions, respectively. After the system was adjusted, the light spot returned to its coordinate origin [43].

5.2-km Far-Field Experiment

A schematic diagram of the 5.2-km far-field experiment system is shown in Fig. 12.14. The computer processed the spot image information collected from the CCD camera and obtained the spot position coordinates. After receiving the data, the transmitter directed the optical antenna according to the spot position error information to achieve stable beam tracking.

Figure 12.15 shows the spot data measured during the tests. Figure 12.16a and b show the drifts of the spot positions in the azimuth and pitch directions, respectively, with a data sampling time of 12 h. Figures 12.17a and b show the statistical data of the spot position error measured in the test in the azimuth and pitch directions, respectively.

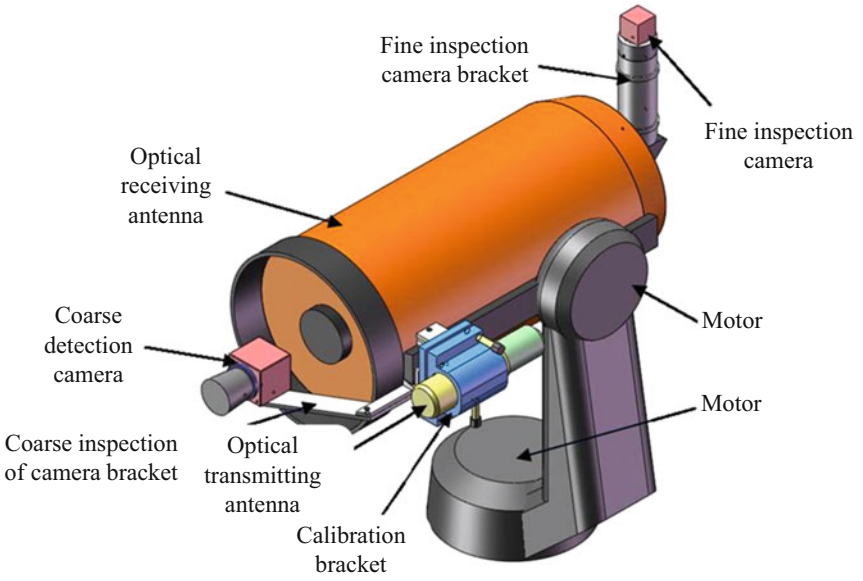

Fig. 12.12 Assembly structure diagram of the 1.3-km far-field experimental system [5]

As shown in Fig. 12.16, from the results of the light spot drift, the light spot in the azimuth and pitch directions drifted out of the threshold 23 and 14 times, respectively. The light spot returned to the center point of the CCD camera after adjustment by the tracking system.

10.2-km Far-Field Experiment

The 10.2-km far-field experimental system assembly is shown in Fig. 12.17; it is composed of a laser light source, optical fiber amplifier, transmitting antenna, two-dimensional aiming platform, and its driver. The receiving end is composed of a receiving antenna, infrared CCD camera, and its controller.

During the experiment, the spot image was sampled every 1 min, and the spot position at the sampling time was obtained after image processing. The azimuth and pitch deviations of the spot refer to the difference between the spot position centers in the two different states.

The detection curves of the light spot images under different weather conditions are shown in Figs. 12.18, 12.19, and 12.20. The results show that the range of spot offsets is 50–110 pixels [48].

Figure 12.21a and b show the fitting curves of the light spot center during the experiment [48]. The results show that the center position coordinates of the light spot change with different external environment factors, such as temperature, humidity, and wind speed.

100-km Far-Field Experiment

The system assembly photos of the 100-km far-field experiment are shown in Fig. 12.22. The experiment adopted a coarse- and fine-grading control system. The transmitter was located in Erlangjian Scenic Spot, Gonghe County, on the south bank of Qinghai Lake, at an altitude of 4015 m. The receiving end was located in Quanji Township, Gangcha County, on the north bank of Qinghai Lake, at an altitude of 3955 m [43]. The optical wavelength of the signal was 1550 nm and the system adopted a double-transmitter and single-receiver structure.

The 100-km outfield experiment used the rectangular scanning method to capture the beam, and the aiming and tracking process was similar to that in the 10.2-km far-field experiment. The change curve of the spot center position is shown in Figs. 12.23 and 12.24. It can be seen from the change of the spot center position that the tracking and aiming of the system is more difficult, owing to the influence of atmospheric turbulence and the increase in communication link distance.

Non-common Visual Axis Two-Dimensional Mirror Rapid Aiming System

Basic Principle

Figure 12.25 shows the capture, alignment, and tracking system controlled by the transmitter image calibration and receiver using a two-dimensional mirror. The coarse alignment calibration from the transmitting antenna to the two-dimensional

reflector uses the calibration camera at the transmitting end to point to a designated area at the receiving end, directly calibrates the position, and adjusts the transmitting antenna with the image as feedback.

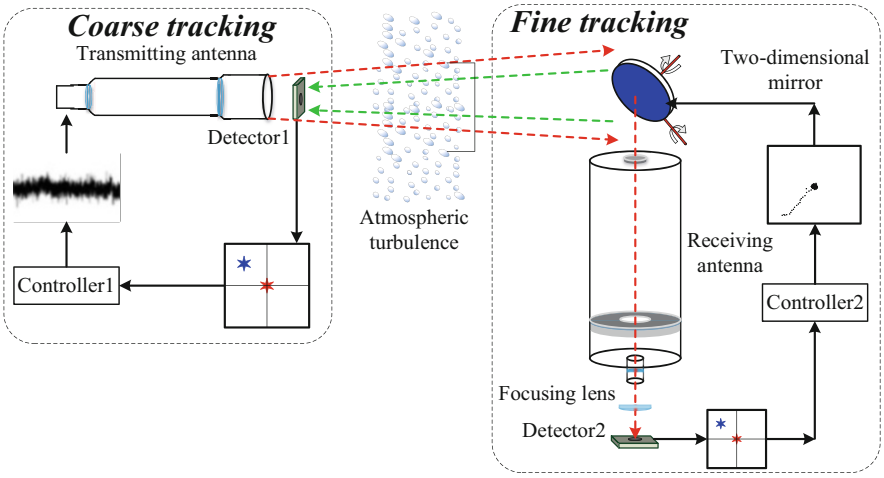

Fig. 12.25 Image calibration at the transmitter; acquisition, alignment, and tracking system controlled by the two-dimensional mirror at the receiver [50]

The short-axis fine alignment from the two-dimensional mirror to the receiving antenna adjusts the two-dimensional mirror according to the feedback information from the detector at the rear of the receiving antenna. The model can be operated at either end, and no auxiliary communication is required for data interaction at the receiving or sending ends. This alignment method is convenient and less affected by the environment.

A beam acquisition, alignment, and tracking system with a non-common axis of view is used to quickly establish the optical wireless communication link, which is divided into three stages: acquisition (image calibration at the transmitter), alignment, and tracking.

1. Acquisition stage: The transmitter gradually approaches the two-dimensional reflector of the receiver by adjusting the azimuth and pitch angles of the transmitter antenna and calibrating the camera imaging. It is only necessary to find the target point to combine the center of the camera's field of view with the center of the image target of the captured long-range two-dimensional reflector, which completes the long-distance beam alignment.
2. Alignment stage: After the beam is aligned with the two-dimensional mirror at the receiving end, the two-dimensional mirror scans the beam within a certain range by controlling the stepper motor. When the optical signal is captured by the spot detection unit at the receiving end, the two-dimensional mirror stops scanning. Then, the position information of the spot is detected and calculated by computer software to adjust the two-dimensional mirror, thus gradually approaching the position of the reference point.
3. Tracking stage: The error is corrected in real time according to the beam position detection results. When a light spot drifts out of the preset threshold range, the position deviation is corrected. If the external interference suddenly increases, such that the system fails to track and the spot target is lost, the two-dimensional mirror scans again until the spot target appears in the field of view of the detector.

Coarse Tracking and Control Model

In Fig. 12.26, the coarse tracking at the transmitter uses a zoom camera as the image detection device, and the calibration principle is shown in Fig. 12.28. The zoom camera at the transmitting end is located at the position of the image in the Fig. 12.26, whereas the calibrated object at the receiving end is located at the position of the object in the picture.

Assuming that when the zoom capacity of the camera reaches its maximum (i.e., when the maximum focal length is reached), if the calibrated object can present an image that can be resolved on a single pixel point, the observation distance is at its limit. Assuming that the size of a pixel in the calibration camera is x_{pixel}, the maximum zoom length of the camera is f, and the size of the calibration object at the receiving end is d, the maximum limit distance L that the camera can calibrate can be expressed as

$$L = \frac{f}{x_{\text{pixel}}} \cdot D. \tag{12.1}$$

When the camera resolution x_{pixel}, zoom ability f, and other limitations make it impossible for the calibration camera to observe calibration point 1 in Fig. 12.27, the

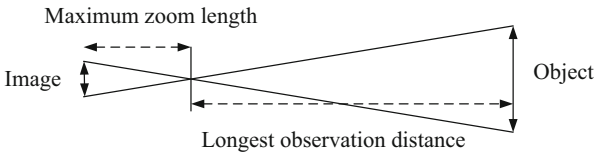

Fig. 12.26 Coarse tracking mark imaging model [50]

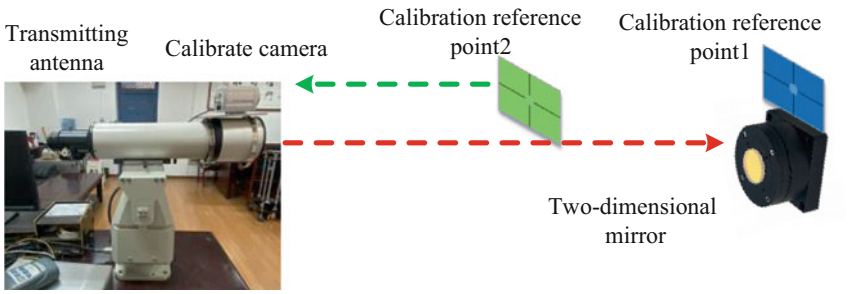

Fig. 12.27 Schematic diagram of the calibration principle using a coaxial reference system [50]

traditional alignment method can be used to align the beam. When the beam is aligned, calibration point 2 should be placed at the limit observation distance close to the camera and used as the reference point for the coarse alignment and tracking of the beam.

Because the calibration camera and optical antenna are mechanical structures with optical axes parallel to each other, calibration point 2 can also be aligned and tracked after calibration point 1 to coarse align and track the beam to the two-dimensional mirror. When the observation distance limit of the calibration camera is insufficient, a near-point coaxial reference system can be selected.

Two-Dimensional Mirror Model

After coarse aligning the beam, the spatial coordinate system shown in Fig. 12.28 is established to study the scanning track of the beam on the exit surface after passing through the two-dimensional reflector.

Assume that the vector of the incident ray is recorded as A, and the angle between the incident ray and the normal of the two-dimensional reflector is α. The vector direction of the incident ray is considered as the x' axis, and the spatial coordinate system of the incident ray is established (x', y', and z'). The vector of outgoing light is marked as A'.

Considering the vector direction of the outgoing ray as the z axis, the spatial coordinate system (x, y, and z) of the outgoing ray is established. The normal vector of the mirror is N, and the deflection angles of the two-dimensional mirror in the transverse and longitudinal directions are θ_1 and θ_2, respectively.

With the reflection ray coordinate system (x, y, and z) as the main coordinate system, vectors A and N are expressed as:

$$\mathbf{A} = \begin{bmatrix} A_x \\ A_y \\ A_z \end{bmatrix} = \begin{bmatrix} -\sin(2\alpha) \\ 0 \\ -\cos(2\alpha) \end{bmatrix} \tag{12.2}$$

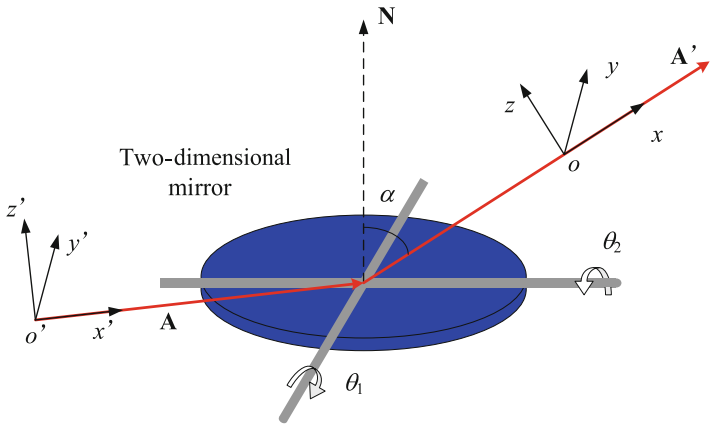

Fig. 12.28 Geometric optical model of the two-dimensional mirror [50]

$$\mathbf{N} = \begin{bmatrix} N_x \\ N_y \\ N_z \end{bmatrix} = \begin{bmatrix} \sin(\alpha + \theta_1) \cdot \cos\theta_2 \\ \sin\theta_2 \\ \cos(\alpha + \theta_1) \cdot \cos\theta_2 \end{bmatrix}. \tag{12.3}$$

According to the reflection law, each vector is expressed as:

$$\mathbf{A}' = \mathbf{A} - 2(\mathbf{A} \cdot \mathbf{N}) \cdot \mathbf{N} = \mathbf{MA} \tag{12.4}$$

$$\mathbf{N}(\theta) = \mathbf{N} \cdot \cos\theta + \mathbf{C}(\mathbf{C} \cdot \mathbf{N}) \cdot (1 - \cos\theta) + (\mathbf{C} \times \mathbf{N}) \cdot \sin\theta. \tag{12.5}$$

In Eq. (12.5), C denotes the unit direction vector corresponding to any rotational axis direction. Equations (12.2), (12.3), and (12.4) are substituted into Eq. (12.5) to obtain the matrix representation of M:

$$\mathbf{M} = \begin{bmatrix} 1 - 2N_x^2 & -2N_xN_y & -2N_xN_z \\ -2N_xN_y & 1 - 2N_y^2 & -2N_yN_z \\ -2N_xN_z & -2N_yN_z & 1 - 2N_z^2 \end{bmatrix}. \tag{12.6}$$

The outgoing-ray matrix is expressed as:

$$\mathbf{A}' = \begin{bmatrix} A'_x \\ A'_y \\ A'_z \end{bmatrix} = \begin{bmatrix} \sin(2\alpha) \cdot \left(2 \cdot \cos^2\theta_2 \cdot \sin^2(\alpha + \theta_1) - 1\right) + \cos(2\alpha) \cdot \cos^2\theta_2 \cdot \sin(2\alpha + 2\theta_1) \\ \cos(2\alpha) \cdot \cos(\alpha + \theta_1) \cdot \sin(2\theta_2) + \sin(2\alpha) \cdot \sin(\alpha + \theta_1) \cdot \sin(2\theta_2) \\ \cos(2\alpha) \cdot \left(2 \cdot \cos^2\theta_2 \cdot \cos^2(\alpha + \theta_1) - 1\right) + \sin(2\alpha) \cdot \cos^2\theta_2 \cdot \sin(2\alpha + 2\theta_1) \end{bmatrix}. \tag{12.7}$$

Therefore, the coordinates of the two points on the scanning path of the light spot are expressed as:

$$x = L\frac{A'_x}{A'_z} = L\frac{\sin(2\alpha)\cdot\left(2\cdot\cos^2\theta_2\cdot\sin^2(\alpha+\theta_1)-1\right)+\cos(2\alpha)\cdot\cos^2\theta_2\cdot\sin(2\alpha+2\theta_1)}{\cos(2\alpha)\cdot(2\cdot\cos^2\theta_2\cdot\cos^2(\alpha+\theta_1)-1)+\sin(2\alpha)\cdot\cos^2\theta_2\cdot\sin(2\alpha+2\theta_1)} \tag{12.8}$$

$$y = L\frac{A'_x}{A'_z} = L\frac{\cos(2\alpha)\cdot\cos(\alpha+\theta_1)\cdot\sin(2\theta_2)+\sin(2\alpha)\cdot\sin(\alpha+\theta_1)\cdot\sin(2\theta_2)}{\cos(2\alpha)\cdot(2\cdot\cos^2\theta_2\cdot\cos^2(\alpha+\theta_1)-1)+\sin(2\alpha)\cdot\cos^2\theta_2\cdot\sin(2\alpha+2\theta_1)}. \tag{12.9}$$

In Eqs. (12.8) and (12.9), L is the linear distance from the beam reflection point to the *xoy* plane.

According to Eqs. (12.8) and (12.9), let $L = 1$ m describe the scanning track of the two-dimensional mirror under different incident angles α, and different scanning angles θ_1 and θ_2, as shown in Fig. 12.29. From Fig. 12.29a and b, it can be seen that, under the same scanning parameters in the two directions of scanning angles θ_1 and θ_2, the greater the incident angle α, the greater the radian of the track curve scanned by the two-dimensional mirror.

Compared with Fig. 12.29c and d, when the incident angle α is the same, the smaller the scanning angles θ_1 and θ_2, the larger the area of the beam scanning path. The value of the incident angle α determines the radian of the scanning path of the two-dimensional mirror to the beam, whereas the parameters of the scanning angles θ_1 and θ_2 determine the size of the scanning area.

Therefore, to make the transmitting antenna and receiving antenna realize non-collinear axis alignment in the two-dimensional reflector spot tracking system, we should select reasonable scanning angles θ_1 and θ_2 for the two-dimensional reflector, according to the incident angle of the beam on the two-dimensional reflector surface of the receiving end in the actual field experiment.

Fine Tracking and Its Control Model

As shown in Fig. 12.30, fine beam tracking can be achieved using the classical integral control. Taking the deviation of the actual spot from the position of the reference center point as feedback, the displacement value is converted into the angle-driving value of the motor to track the beam. The k^{th} iteration can be expressed as:

$$\begin{bmatrix}\theta_1(k+1)\\ \theta_2(k+1)\end{bmatrix} = \begin{bmatrix}m(k)-m_c\\ n(k)-n_c\end{bmatrix}\cdot T\cdot k_{\text{i}} + \begin{bmatrix}\theta_1(k)\\ \theta_2(k)\end{bmatrix}. \tag{12.10}$$

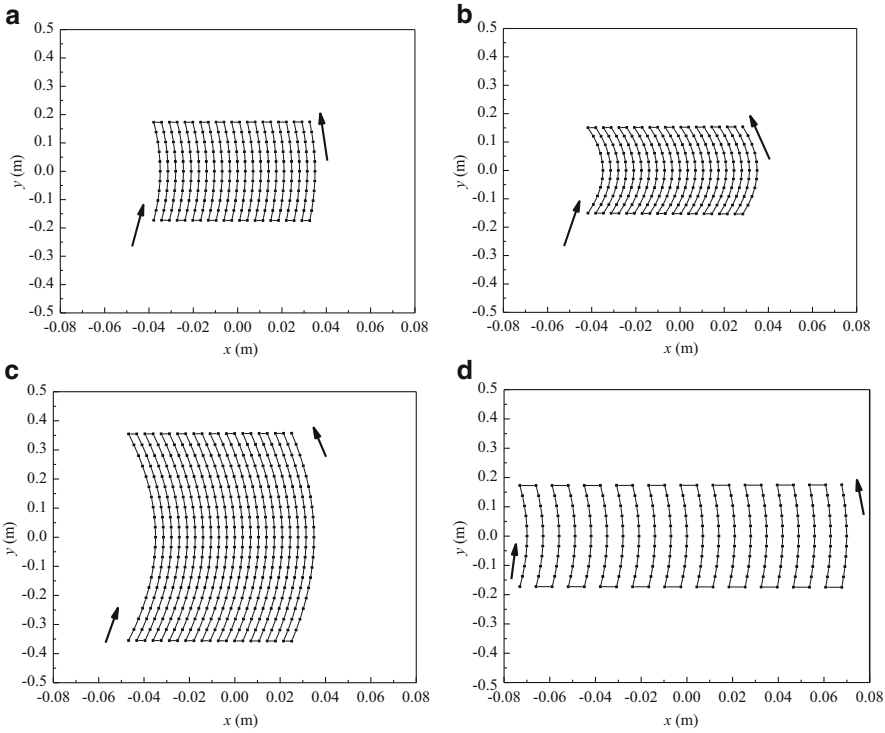

Fig. 12.29 Exit light spot trajectory under different incident angles and scanning angles [50]. (**a**) $\alpha = 15°$, $\theta_1 = -2°–2°$, $\theta_2 = -6°–6°$; (**b**) $\alpha = 30°$, $\theta_1 = -2°–2°$, $\theta_2 = -6°–6°$; (**c**) $\alpha = 15°$, $\theta_1 = -2°–2°$, $\theta_2 = -12°–12°$; (**d**) $\alpha = 15°$, $\theta_1 = -4°–4°$, $\theta_2 = -6°–6°$

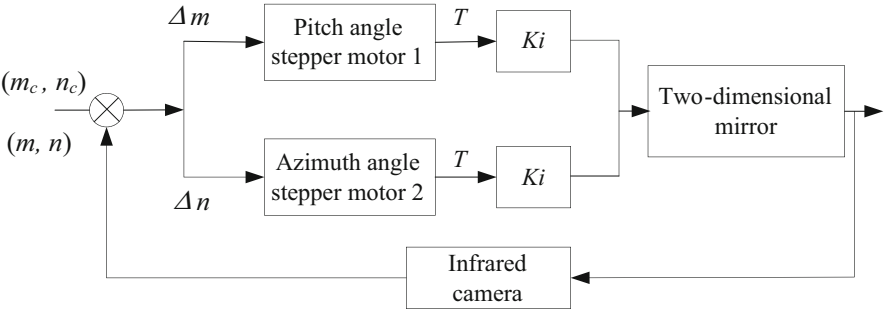

Fig. 12.30 Schematic diagram of the beam tracking algorithm using a two-dimensional mirror [50]

In Eq. (12.10), T is the proportion coefficient from the unit pixel displacement of the infrared camera to the unit step angle of the stepping motor, and k_i is the integral coefficient. (m_c, n_c) is the position of the central reference point of the detector,

$[m(k), n(k)]$ is the actual spot-imaging position, and $[\theta_1(k), \theta_2(k)]$ is the offset angle of the pitch and azimuth angles of the stepper motor, relative to the initial position in the k^{th} iteration.

A far-field experimental communication link using this system is shown in Fig. 12.31. The transmitting and receiving ends were located on the sixth teaching floor in Xiaozhai Village, Bailuyuan, Xi'an City, and Jinhua Campus, Xi'an University of Technology, respectively, with a communication link length of 11.3 km.

As shown in Fig. 12.32, the beam tracking curve of the position coordinates of the two-dimensional mirror is shown, where X represents the pitch direction, Y represents the azimuth direction, and the two-dimensional mirror is adjusted four and two times in the pitch and azimuth directions, respectively.

When the light spot gradually moves to the camera center point, the mean value, variance, and power spectral density (PSD) of the change in the light spot center

Fig. 12.31 Diagram of the 10.2-km optical wireless communication experimental link [50]

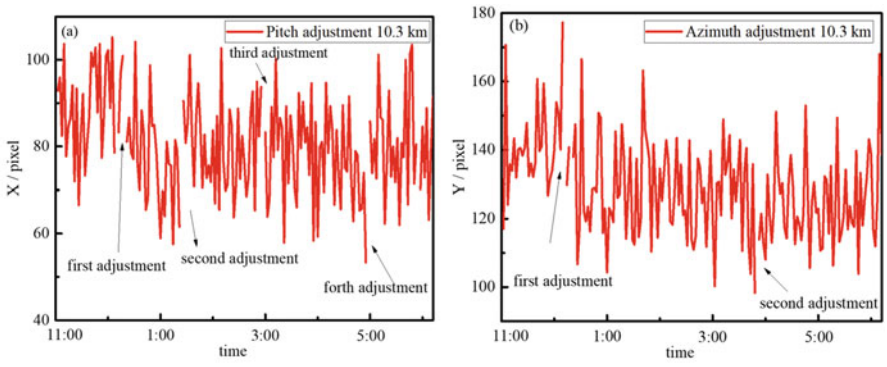

Fig. 12.32 Beam tracking curve (2021.8.24 23:00–2021.8.25 6:00). (**a**) Pitch direction; (**b**) azimuth direction [50]

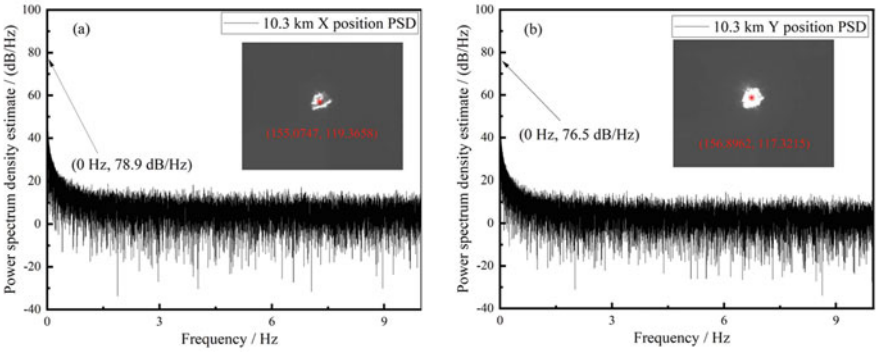

Fig. 12.33 Power-spectral density estimation. (**a**) *X* direction; (**b**) *Y* direction [50]

coordinate in the pitch and azimuth directions are calculated. The results are presented in Fig. 12.33. From the results, it can be observed that the drift in the center position coordinate of the light spot in the azimuth direction is greater than that in the pitch direction.

Figure 12.34 shows the motion track of the light spot and the corresponding PSD during the tracking process. It can be seen from the results that the variance of the light spot in the pitch and azimuth directions is 16.4970 pixel^2 and 9.0287 pixel^2, respectively.

Figure 12.35 shows the signal waveforms at both ends of the transceiver. The transmitter power is 200 mW. When the tracking process is completed, the signal waveform output by the detector for the photoelectric conversion is 74.4 mV.

Chapter Review

This chapter summarized the research progress of Xi'an University of Technology in APT and introduced the working principles and experimental analyses of the initial acquisition system, coarse- and fine-grading tracking system, beam detection system, space-based relay optical wireless communication automatic tracking control system, and receiving and transmitting non-coaxial two-dimensional reflector rapid aiming system. The application scenarios are summarized as follows.

Sections 12.3.1–12.3.3 respectively described the initial acquisition system, coarse- and fine-grading control system, and beam detection system, according to the actual requirements of each stage of acquisition, aiming, and tracking. The initial acquisition system rapidly acquired the position through position calibration, without the need for the positioning devices in traditional acquisition systems, thereby reducing the acquisition time and system design costs.

The coarse- and fine-grading control system used a two-dimensional pan–tilt + piezoelectric micromotion platform as the tracking and aiming actuator. It suppressed the aiming and tracking residual errors not eliminated by the coarse

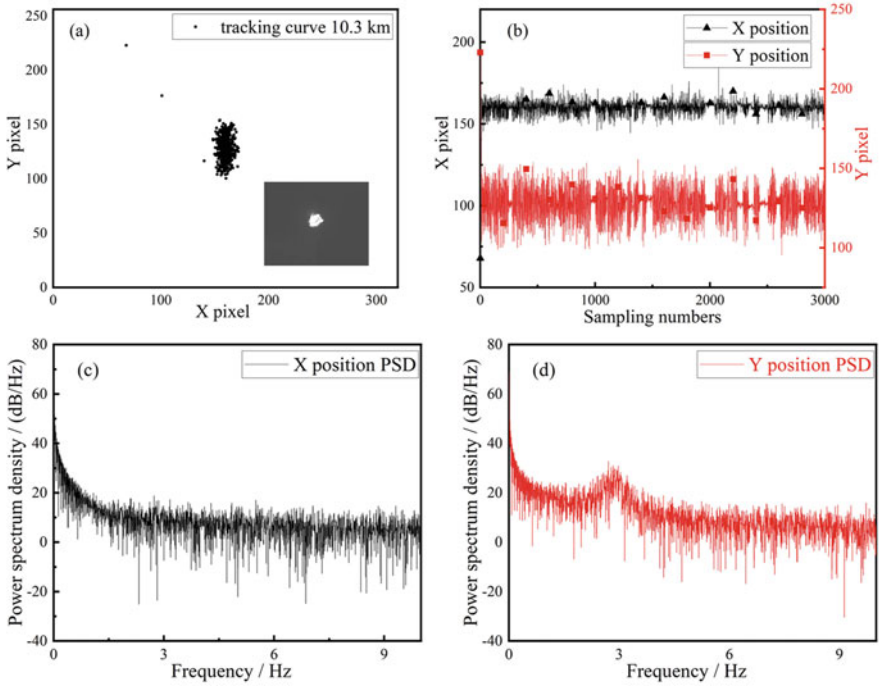

Fig. 12.34 Spot tracking curve and PSD. (**a**) Spot tracking curve; (**b**) direction-tracking curve; (**c**) power spectral density estimation in the *X* direction; (**d**) power spectral density estimation in *Y* direction [50]

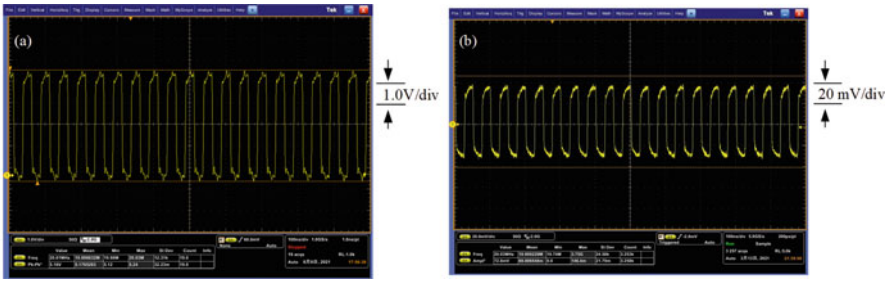

Fig. 12.35 Signal waveform at both ends of the transceiver. (**a**) Transmitting signal; (**b**) receiving signal [50]

tracking and aiming mechanism, and further improved the tracking and aiming accuracy. Its application scenarios were described in detail in section 12.3.5.4. The beam detection system could calculate the beam deviation in the pitch and azimuth directions during the test using data such as the centroid and spot centroid.

The transmitter of the rapid aiming system of the non-coaxial two-dimensional reflector was calibrated by the camera. The receiver scanned the beam by

controlling the two-dimensional reflector and tracked the beam with the spot position information as the feedback signal. Traditional long-axis collimation transmits the positional information of a light spot at a detector over a long distance, which is easily affected by atmospheric turbulence. This system used the image as feedback information to adjust the angle of the transmitting antenna without data transmission. It achieved rapid aiming with little influence from the external environment.

From the optical wireless far-field communication experiments at different distances, it could be observed that, with an increase in the communication link distance, the requirements for the servo bandwidth, degrees of freedom, and resolution in the pitch and azimuth directions of the APT system were higher, which is also the main reason for limiting the working distance of the APT system.

For example, in the 10.2-km far-field experiment, the transmitter completed the aiming and tracking using only the two-dimensional aiming pan–tilt as the actuator, and its resolution was approximately 18.45 μrad. In the 100-km far-field experiment, to meet the corresponding accuracy requirements, the coarse- and fine-grading control system composed of a two-dimensional pan–tilt and piezoelectric micromotion platform was used to complete the aiming and tracking. The resolution of the piezoelectric micromotion platform was about 0.01 μrad.

Summary

With the progress in science and technology, increasing demand for high-speed and large-capacity communication, and improvement in the level of optics, information science, control science, and other disciplines closely related to optical wireless communication, the development direction of optical wireless communication APT systems mainly includes the following aspects:

1. APT terminals with high integration, low power consumption, small size, and lightweight.
2. The control system should adopt a high closed-loop bandwidth to overcome the impact of mechanical vibration generated by the platform equipped with the APT system on beam tracking.
3. Coarse and fine composite axis technology should be adopted to achieve a high dynamic range and high-precision acquisition and tracking.
4. Based on research on point-to-point optical wireless communication structures, an optical wireless communication network between the transmitter and multiple receiving targets should be constructed, and an optical wireless communication APT system that meets the point-to-point requirements should be designed.
5. In a space laser communication link, to obtain the position of the receiving end quickly and accurately without prior information, the transmitting and receiving ends can use scanning methods to search for and capture the uncertain area. When the spot detection camera at the receiving end detects the spot position, the acquisition is considered successful. Using the corresponding control algorithm,

the angle and angular velocity changes of the two-dimensional PTZ are controlled, and the centroid of the spot is maintained at the center of the camera's field of view to achieve fast and accurate target tracking.

This chapter systematically analyzed the development and application of APT systems in optical wireless communication and introduced the research progress and achievements of Xi'an University of Technology in this field. It included an experimental analysis and verification of the performance of the designed initial acquisition system, coarse- and fine-grading control system, and beam detection system. The experimental results showed that the system could effectively and rapidly acquire and aim at the target. The tracking and aiming accuracies of the system were greatly improved, and the effectiveness and reliability of the APT system were also improved.

Abstract

This chapter summarizes the research progress of spatial light to optical-fiber coupling technology in aims to improve the coupling efficiency in optical wireless communication, and introduces the research work of Xi'an University of Technology in this field, including the automatic alignment in spatial light to optical-fiber coupling, optical mode conversion in free space, adaptive optics wavefront correction in spatial light to optic fiber coupling, and design of the Maksutov–Cassegrain integrated transceiver antenna. In addition, the research progress of coupling performance by using lens array to single-mode fiber and Maksutov–Cassegrain receiving antenna in atmospheric turbulence are introduced. Finally, the development of spatial light to optical-fiber coupling technology in optical wireless communication is prospected.

Optical wireless communication · Fiber coupling · Automatic alignment · Mode conversion · Wavefront correction

Introduction

To improve its efficiency, the domestic and foreign research progress of spatial optical-fiber coupling technology in optical wireless communication is introduced, including automatic spatial optical-fiber coupling alignment technology, free-space optical mode-conversion technology, spatial optical-fiber coupling with adaptive-optical wavefront correction technology, and Maksutov–Cassegrain (Maka) antenna integrated transceiver technology.

The performance of coupling a lens array and a single lens to a single-mode fiber in atmospheric turbulence is introduced, as well as the spatial opto-coupling performance of the Maka antenna as a receiving antenna in atmospheric turbulence. Finally, the development of spatial optical-fiber coupling technology for optical wireless communication is discussed.

Foreign Research Progress

A signal light can be more easily and effectively coupled from free space to fiber with active and passive fiber-coupling components, providing efficient light field mixing for coherent-optical communications. All optical networks can transmit by coupling spatial optics into an optical fiber. This technology can simplify optical wireless communication and improve its communication rate. It is possible to control the characteristics of a signal beam in the optical fiber, promote the modularization of optical wireless communication systems, and improve system interchangeability [1], with a wide range of application prospects in military and civilian fields.

In optical wireless communication systems, the optical-fiber coupling efficiency is an important factor restricting the development of optical communication. The diameter of a single-mode fiber core is approximately 10 microns, which increases the difficulty of spatial optical coupling into optical fibers. The arrival-angle undulation under the influence of atmospheric turbulence, static-angle deviation of optical fibers, etc. will affect the coupling efficiency of optical fibers [2]. Therefore, improving the efficiency of spatial optical coupling into optical fibers and improving the system stability has become an important topic in the optical wireless communication field.

With the vigorous development of optical wireless communication, researchers at home and abroad have achieved significant research results as they have actively explored spatial optical-fiber coupling technology.

From 1990–2000, spatial light single-mode-fiber coupling technology was mainly used in the field of astronomy. In 1988, Stuart S et al. studied the coupling of starlight into a single-mode fiber. They calculated that 80% of the incident power at the pupil could be coupled to a single-mode fiber located on the central axis of the focal plane. At $D/r_0 = 4$ (D: coupling-lens diameter, r_0: atmospheric coherence length), the coupling power increased by a factor of 3.6 [3].

Since then, space optical-fiber coupling technology has been gradually applied in the field of light detection and ranging (lidar). In 1994, Wright et al. added an erbium-doped fiber amplifier (EDFA) before the fiber-coupling module of a lidar system, which increased the fiber-coupling efficiency by 20.0% [4]. In 1998, Winzer et al. applied the coupling efficiency expression of a derived monochromatic light to a fiber, after passing it through a lens and coupling it to the fiber lidar field. The numerical simulation results showed that the maximum coupling efficiency of the system was 42.0% [5].

Atmospheric turbulence has a significant impact on the efficiency of coupling spatial light to optical fibers, and different degrees of fading occur. Most scholars use adaptive optics to compensate for wavefront distortion and correct the light wave of the coupling end face to a Gaussian-distributed plane wave, thereby improving the fiber-coupling efficiency.

In 1998, Ruilier et al. studied the use of adaptive optics to improve the coupling efficiency of space-light single-mode fibers under the influence of atmospheric turbulence [6].

In 2002, Weyrauch et al. used a deformation mirror to study adaptive fiber coupling, determined the position error of the fiber by coupling the change in optical power, and combined it with the stochastic parallel gradient-descent (SPGD) algorithm to further improve the efficiency of spatial optical-fiber coupling. A maximum coupling efficiency of 60.0% was obtained in single-mode fiber coupling and 70.0% in multimode fiber coupling [7].

In 2005, Dikmelik et al. experimentally analyzed the influence of atmospheric turbulence on spatial optical-coupling efficiency and calculated that when the coupling efficiency was less than 5.0%, the communication distance could reach approximately 100 m under strong turbulence conditions. Under medium turbulence conditions, the communication distance reached approximately 800 m. Under weak turbulence conditions, the communication distance exceeded 1000 m [8].

In 2006, Toyoshima et al. analyzed the optimal relationship between the Airy spot size and fiber-mode field size on the spatial optical-fiber coupling efficiency under random angular jitter caused by atmospheric turbulence. The results showed that when the ratio of the normalized random angular jitter to the mode field radius was greater than 0.3, the average bit-error rate (BER) of the system decreased significantly [9], from approximately 10^{-1} to 10^{-4}.

In 2019, Carrizo et al. corrected the wavefront phase to increase the power coupled into a fiber by iteratively updating the phase of a single focal-plane speckle. The experimental results showed that under turbulent conditions, the power increased by 60.2% in less than 60 iterations of power measurements [10].

In satellite–ground laser communication, the influence of atmospheric turbulence on the laser-carrier signal transmission is critical. Scholars have conducted in-depth research on the principles and methods needed to overcome the influence of atmospheric turbulence on satellite–terrestrial laser communication.

Generally, the caliber of an optical system is round, and the Fran and Fei diffraction images are called Airy spots. The image of each object point is a diffuse spot, and the two diffuse spots cannot be distinguished when they are close, which limits the system resolution. The larger the spot, the lower the resolution. This is a limitation of physical optics and is caused by the diffraction of light.

In 2008, Fidler et al. studied the effect of phase distortion caused by atmospheric turbulence on the coupling efficiency of laser beams coupled to single-mode fibers in different scenarios of geostationary satellites, high-altitude platforms, and optical land stations, and proved that the performance of geostationary satellite-to-high-altitude platform communication can approach the diffraction limit when correcting the tilt component [11].

In 2010, Hiderki et al. studied the fiber-coupling efficiency loss of satellite–ground laser communication links under the influence of atmospheric turbulence. The fiber-coupling loss was more than 10 dB [12].

In 2012, Takenaka et al. studied a fast mirror that could operate at high frequencies under atmospheric turbulence conditions and verified the tracking performance of its spot position in a satellite–ground laser communication experiment. The results showed that the coupling efficiency of the satellite–ground laser-communication link faded between 10 dB and 19 dB, which was consistent with the theoretical calculation results of 17 dB [13].

In 2016, NASA conducted a satellite–ground laser experiment to test the optical systems of two ground stations. When the beam was coupled into a single-mode fiber, it was affected by atmospheric turbulence, so it was compensated by an adaptive-optical system with a double-deformation mirror design. The results showed that, under ordinary atmospheric conditions, the average coupling efficiency was higher than 50.0% [14, 15].

Because a single-mode fiber has an extremely small core and difficult optical-coupling requirements, to further improve the efficiency of spatial optical-fiber coupling, automatic coupling alignment control systems are used to adjust the position of the fiber to the best coupling position in real time to reduce the coupling efficiency loss to a certain degree.

In 1990, Lincoln Laboratory developed an active coupling method for fiber nutation using free-space optical communication. A spatial-optical single-mode fiber was automatically aligned, which reduced the coupling efficiency loss [16].

In 2001, Sayan et al. obtained a coupling efficiency of approximately 50.0% by determining the change in the incident beam angle through the feedback of a position sensor in an optical code-division multiple-access experiment with multichannel multiplexing, and adjusting a fast-tilting mirror to compensate for the error [17].

Microlens technology also plays a key role in improving the spatial optical-fiber coupling efficiency by changing the spot size and adding control algorithms. Thus, lens technology is also widely used in fiber coupling to improve the coupling efficiency.

In 1995, Modavis et al. established a Gaussian theoretical model based on a laser and a light field, analyzed the coupling performance of deformed fiber microlenses between laser diodes and single-mode fibers, and experimentally measured the average coupling efficiency of the lenses as 79.0% [18].

In 2002, Oswald et al. discussed the coupling efficiency of plane-wave coupling into a single-mode fiber with a misalignment error relative to the focal point of the lens. Studies showed that a collimation system reduced the error and the coupling efficiency reached 61.0% [19]. In the same year, Sherman et al. designed a radio optical communication system that could position an $n \times n$ optical array on the focal plane of a Ritchey–Chretien (RC) telescope with an aspheric mirror. This enabled point-to-multipoint communication with a single optical telescope [20].

In 2010, Danuel et al. designed a method for spatial light coupling using an optical-fiber array. Piezoelectric ceramics were used to drive the microlens position to adopt a control algorithm with the maximum output energy. The experimental results showed that the output optical power increased by 39 dB, and the coupling efficiency of the optical fiber was improved [21].

In 2018, Hottinger designed a single-mode fiber-coupled angle sensor based on a microlens. It detected the change in light energy in the fiber, determined the fiber position error, and improved the coupling efficiency [22].

In recent years, scholars have extensively researched the coupling efficiency of multimode fibers, low-mode fibers, and specially designed fibers to improve the low coupling efficiency of space beams caused by small single-mode fiber cores.

In 1997, Keming et al. investigated a technique for coupling the output of a high-power diode laser into a multimode fiber that included two microlenses for beam shaping. Experiments showed that the overall coupling efficiency of the diode laser to fiber was 71.0% [23].

In 2007, Horton et al. investigated the effect of diffraction on the coupling efficiency of single-mode and low-mode fibers. The results showed that the low-mode fiber had a higher maximum coupling efficiency (>90.0%) [24]. In 2013, NASA conducted a lunar–Earth laser communication demonstration experiment, in which a multimode optical fiber was used to couple spatial light. The results showed that the coupling efficiency of the space-light multimode fiber under atmospheric turbulence could reach 92.0% [25, 26].

Because the signal light has different degrees of efficiency loss in the process of coupling into a single-mode fiber after transmission through a multimode fiber, Carl M et al. proposed a new device that improved free-space light coupling to a single-mode fiber in 2016. It consisted of an optical-fiber cone that acted as a mode filter to filter out high-order modes and then coupled other modes into the single-mode fiber, resulting in a power loss of 42.0% [27].

The relevant foreign research progress is presented in Table 13.1.

Table 13.1 Foreign research progress

Year	Person/Organization	Research progress
1988	Shaklan/National Optical Astronomy Observatory	Starlight was coupled into a single-mode fiber
1990	Boroson/MIT Lincoln Laboratory	Active coupling scheme based on fiber nutation for laser communication
1995	Modavis/Corning, Inc.	Established theoretical models of scalar diffraction and Gaussian pattern shapes of laser and optical-fiber fields
1998	Winzer/Institut fur Nachrichtentechnik und Hochfrequenztechnik	Optimized the receiving aperture size to improve the coupling efficiency
2002	Oswald/Vienna University of Technology	Collimation system increased the coupling efficiency
2002	Weyrauch/US Army Research Laboratory	Studied adaptive fiber coupling with a deformable mirror
2002	Smolyaninov/University of Maryland	EDFA was coupled to a single-mode fiber as a receiving preamplifier
2005	Dikmelik/Johns Hopkins University	Coherent fiber arrays improved the fiber-coupling efficiency
2006	Toyoshima/Johns Hopkins University	Coupling efficiency of space light caused by atmospheric turbulence
2007	Horton/MIT Lincoln Laboratory	Effect of diffraction on coupling efficiency of single-mode and low-mode fibers
2010	Hiderki/University of Electro-Communications	Maximum fiber-coupling efficiency in the presence of random angular jitter
2010	Danuel/Johns Hopkins University Applied Physics Laboratory	Added an algorithm to a microlens to improve coupling efficiency
2012	Takenaka/Space Communication System Laboratory	Jitter error was compensated to improve fiber-coupling efficiency
2013	NASA	Lunar–Earth laser communication demonstration experiment
2014	Carl/Heinrich Hertz Telecommunications Institute	Conical fiber added between multimode and single-mode fibers to improve coupling efficiency
2016	NASA	Adaptive-optical system was used to compensate atmospheric turbulence and the beam was coupled into a single-mode fiber
2018	Hottinger/Astronomie der Universitat Heidelberg	Angle sensor was used to align spatial optical-fiber coupling
2019	Carrizo/Institute of Communication and Navigation	Phase of each focal-plane speckle was iteratively updated to correct the wavefront and improve the coupling efficiency

Domestic Research Progress

Domestic scholars have also carried out in-depth research and made great progress in space optical-fiber coupling technology. Owing to the complexity of space optical-channel transmissions, the intensity of atmospheric turbulence affects the coupling efficiency of space optical fibers.

In 2006, Xiang et al. studied the efficiency of spatial-light coupling to a single-mode fiber and analyzed the change in optical power under the influences of multiple factors. They found that the uplink had little effect on the optical coupling efficiency. For the downlink, the relative power decreased when it was affected by the aperture average effect and increased when it was affected by turbulence [28].

In 2009, Ma et al. studied the influence of arrival-angle fluctuation on fiber-coupling efficiency and obtained the optimal design parameter value of a fiber-coupling optical system with random jitter. When the ratio of the aperture radius to the fiber-mode field radius $\beta = 1.121$, a maximum coupling efficiency of 81.0% was obtained [29].

In 2018, Liu et al. studied the effect of fiber-alignment error and random angle jitter on fiber-coupling efficiency and obtained a maximum coupling efficiency of 62.0% [30].

In 2021, Song et al. established a model to calculate the transient coupling efficiency. They obtained the coupling efficiency change rule with the ratio of the aperture radius to atmospheric coherence length, as well as the change in geometric coupling parameters [31].

Owing to the phase distortion of the beam wavefront caused by atmospheric turbulence, the coupling efficiency of a space optical fiber is significantly reduced, which seriously affects the communication quality. To suppress the influence of atmospheric turbulence on the coupling efficiency of space optical fibers, scholars have used adaptive-optical systems to further improve the coupling efficiency.

In 2010, Wu et al. proposed a method that combined adaptive-optics technology with coherent fiber array technology to improve the efficiency of spatial optical coupling. The results showed that this method improved the efficiency of signal light coupling into optical fibers after atmospheric turbulence from 3.0% to 39.0% [32].

In 2011, Han et al. proposed a model-free blind-optimized wavefront correction technique to improve the spatial optical-coupling efficiency under the influence of atmospheric turbulence. Their results showed that the coupling efficiency of the single-mode fiber improved from 6.0% to approximately 60.0% [33].

In 2012, Yang et al. used the wavefront phase mode to compensate for a beam affected by atmospheric turbulence and coupled it into a single-mode fiber, achieving a coupling efficiency of approximately 81.0% [34].

In 2013, Xiong et al. used a 37-unit adaptive-optical system to compensate for atmospheric turbulence aberrations. Studies showed that the coupling efficiency increased by 20.0% when the Strehl ratio increased from 0.16–0.35 [35].

In 2014, Luo et al. found that the fiber-coupling efficiency was affected by the wave difference caused by a single aberration. The average coupling efficiency

increased from 30.1–61.7% after using an adaptive fiber-optic source collimator for compensation [36].

In 2015, Li Feng team developed an adaptive optical-fiber coupler and combined it with the SPGD algorithm to select several systems under different atmospheric turbulence conditions for closed-loop control. The results showed that when optimal SPGD control parameters were selected, the fiber-coupling efficiency was significantly improved, from 40.0% before convergence to 76.0% after convergence [37].

Atmospheric turbulence not only distorts the beam wavefront phase but also degrades the beam mode, resulting in an incomplete match with the receiving single-mode-fiber mode field. The energy distribution of a beam can be concentrated by means of a mode-conversion method, and the converted fundamental mode form can be collected by a single-mode fiber, to improve the coupling efficiency. In 2015, Qi et al. used a spatial-light modulator (SLM) to convert LP01 mode into a high-order mode. This method was simple, easy to implement, had low device requirements, and high repeatability [38].

In 2017, Tu et al. designed a multiplexer/demultiplexer based on a three-core fiber and supported LP01, LP11a, and LP11b spatial-mode transmissions. The power conversion between the LP11a and LP01 modes and between the LP11b and LP01 modes was simulated and analyzed, and the mode-conversion efficiency was 90.0% [39].

In 2018, Shin et al. proposed a new optical waveguide LP01–LP02 mode converter using a combination of two pyramidal structures. The conversion efficiency of this mode converter was 90.0%, which greatly reduced the crosstalk with other modes [40].

The coupling process is demanding and difficult, owing to the small core of a single-mode optical fiber. Research on automatic spatial optical-fiber coupling alignment technology has solved this problem to a great extent. In 2007, Gao et al. completed automatic coupling through a closed-loop control system they designed. Experiments showed that this method significantly reduced the automatic alignment time and achieved a maximum coupling efficiency of 510.2% [41].

In 2017, Wu et al. proposed an SPGD algorithm and a scheme based on a helical-grating scanning algorithm to improve the spatial light-fiber coupling efficiency. The theoretical simulation results showed that the spatial light-fiber coupling efficiency was up to 81.0% [42].

In 2019, Baiqiu Zhao et al. combined two techniques of chapter-dynamic coupling algorithm and fast reflector of fiber optic photodetector together to obtain a maximum coupling efficiency of 510.6% under nondynamic conditions [43].

In 2019, Li et al. proposed an adaptive-coupling method for optical communication systems based on thick–fine laser nutation technology. The experimental results showed that, under simulated atmospheric turbulence, the average coupling efficiency of the system was improved to 62.4% [44].

In 2019, Qi et al. applied a pattern-search method to spatial optical-fiber coupling to achieve alignment coupling in X, Y, and Z degrees of freedom. This shortened the alignment time to within 25 s and achieved a success rate of over 90.0% [45].

Research on improving the spatial light-fiber coupling efficiency not only involves the receiving end, but also the light source. For example, the fiber-coupling output mode of a semiconductor laser can improve the asymmetry of the output beam and realize optical coupling between multiple semiconductor light sources, thus improving the output power and fiber-coupling efficiency.

In 2000, Shi et al. proposed a beam-shaping technology for high-power laser-array devices that achieved a coupling efficiency of 50.0% [46].

In 2001, Bo et al. used a cylindrical lens to collect and collimate the output beam of an array semiconductor laser and finally coupled the output beam to a multimode fiber. The coupling efficiency was as high as 75.0% [47].

In 2004, Zhou et al. calculated the surface-shape formula of two groups of orthogonal collimating microlens arrays and conducted coupling experiments between high-power semiconductor lasers and fibers. They obtained a coupling efficiency greater than 53.0% [48].

In 2010, Wang et al. developed a fiber-coupling module with excellent performance using a step-mirror group for beam shaping a semiconductor laser array, and the coupling efficiency reached 73.8% [49].

In 2014, Chen et al. coupled four 980-nm single-tube semiconductor lasers into a fiber after combining the beams and obtained a coupling efficiency of 51.7% [50].

In 2015, Xu et al. developed an efficient and high-power array of fiber-coupled semiconductor-laser modules using beam-shaping and spatial-beam combination methods. The experimental results showed that the optical output power of the fiber could reach 327 W, and the coupling efficiency was greater than 90.0% [51].

In 2015, Liu et al. designed a multibeam fiber-coupling system. After coupling beams into a fiber through a ZEMAX simulation, the coupling efficiency exceeded 98.0% [52].

In 2017, Liu et al. successfully developed a high-power semiconductor-laser fiber coupling module using polarization and space-coupling technology. The experimental results showed that the fiber-coupling efficiency was 60.0% [53].

An optical-fiber lens can change the size and shape of the optical-fiber mode field. Microlenses have the advantages of changing the spot size and adding a control algorithm; therefore, optical-fiber lenses or lens technology is also widely used in optical-fiber coupling to improve the coupling efficiency.

In 2002, Wang et al. used a multimode fiber with a small aperture to replace the microlens and coupled the output beam of a laser-diode line array into a multimode fiber array. The coupling efficiency measured in the experiment was 75.0% [54].

In 2002, Lu et al. studied a coupling method of placing fiber microlenses between semiconductor lasers and fibers, and experimentally measured coupling efficiencies up to 80.0% [55].

In 2003, Wei et al. proposed the use of a telescope collimator system to improve the fiber-coupling efficiency. The experimentally measured coupling efficiencies of a polarization-maintaining fiber and single-mode fiber were 68.0% and 70.0%, respectively [56].

In 2003, Zhao et al. established a theoretical model of the coupling between a cone-end spherical-lens fiber and a flat-end fiber. The results showed that the

maximum coupling efficiency was 79.3% when the spherical radius was 25.6 μm and cone angle was 110 ° [57].

In 2014, Liu et al. processed fiber end faces into wedge-shaped microlenses and found that the coupling between a semiconductor laser and fiber could satisfy phase and mode field matching, with a maximum coupling efficiency of 81.3% [58].

In 2016, Shi et al. designed cylindrical and aspherical lenses using geometric optics and verified the designed lens system using the ZEMAX simulation software. The simulation results showed that the coupling efficiency was improved by approximately 12.0% [59].

Optimizing the self-coupling system and fiber structure makes the system easier to process and design, and the anti-interference ability is stronger, which improves the fiber-coupling efficiency. In 1981, Li et al. coupled a light-emitting tube with a ball-end fiber, and obtained a maximum coupling efficiency of 14.0% in the final experiment [60].

In 2008, Feng et al. nutated the coupling of a Gaussian beam to a multimode fiber using a novel optical-antenna communication system. Theoretical calculation showed that when the laser wavelengths were 1310 nm and 1550 nm, the maximum coupling efficiencies were 81.5% and 82.5%, respectively [61].

In 2011, Wang et al. used a specially designed miniaturized optical antenna to reduce the impact of turbulent atmosphere on the communication quality. The results showed that the receiving sensitivity of this system was greater than −35 dBm [62] at a certain communication distance and rate.

In 2013, Hu et al. established a conical multimode fiber transmission model, which obtained a coupling efficiency of nearly 80.0% through theoretical calculation [63].

In 2014, Zhang et al. welded single-mode fibers with large and small cores, and then coupled a spatial beam from one side of the large core. Experiments showed that this method could achieve a fiber-coupling efficiency of 60.0% [64].

In 2019, Yan et al. proposed using conical fiber in a optical wireless communication coupling system, which improved the lateral-migration capacity difference and increased the coupling efficiency [65].

In 2021, Ren et al. designed a structure with a symmetrical front flange that was suitable for a high-temperature environment and had a high coupling efficiency. The simulation showed that when the temperature field was 40 °C, the coupling efficiency loss of the front-flange symmetric structure was reduced by approximately 61.0%, compared with the bottom-mounted structure [66].

In a spatial optical-fiber coupling system, in addition to external factors affecting the fiber-coupling efficiency, incident light waves and fiber end faces have many static errors and affect the space optical-fiber coupling efficiency.

In 2013, Zhang et al. found that the central axis of the coupling lens deviated from the single-mode fiber, and the incident light-wave mode was poorly matched with the single-mode fiber. This led to a decrease in the coupling efficiency of the single-

mode fiber. Through simulation, it was found that the coupling efficiency was influenced more by tilt and lateral deviations than by defocusing [67].

In 2013, Luo et al. found that the coupling efficiency was greater than 80.0% when the off-axis value between the multimode fiber and the outbound beam of a Cassegrain antenna was less than 4.64 μm and the antenna off-axis angle was less than 0.055 rad. When the off-axis angle or axial quantity increased, the coupling efficiency decreased [68].

The relevant research progress in China is presented in Table 13.2.

Research Progress on Spatial Optical-Fiber Coupling Technology

Since 2000, Professor Ke Xizheng's team from Xi'an University of Technology has conducted extensive research on the optical design of communication systems [69], coding-modulation technology for signal transmissions [70], optical wireless coherence detection technology [71, 72], adaptive-optics technology [73], etc. The team also successfully developed a differential phase-shift keying (DPSK)-modulated coherent detection system terminal and constructed communication links with 600-m, 1.3-km, 10-km, and 100-km distances for high-definition video transmissions.

To effectively improve the fiber-coupling efficiency and communication quality, Professor Ke's team has systematically investigated the field of space optical-fiber coupling technology in optical wireless communication. Chen [74] analyzed the multimode fiber coupling problem under the influence of weak turbulence. The results showed that the coupling efficiency of multimode fibers decreased less than that of single-mode fibers under the influence of random spot jitter.

Lei [75] proposed to use the off-axis Gaussian-beam emission of a Maksutov–Cassegrain (Maka) antenna array and spatial light coupling technology to integrate the antenna's transmitter and receiver. The experimental results showed that the transmission efficiency of the Maka antenna was significantly improved. Luo [2] designed an automatic-alignment closed-loop device system to complete the coupling. The system used piezoelectric ceramics to control the optical fibers. Experiments showed that the system improved the alignment, positioning time, and the coupling efficiency of the optical fiber.

Zhang [76] found that mode conversions greatly improved the fiber-coupling efficiency. Yang [77] studied the influence of wavefront distortion at different distances on the coupling efficiency. The experimental results showed that the lifting effect of long-distance correction was inferior to that of short-range correction and that the numerical fluctuation of long-distance coupling efficiency was greater than that of short-range coupling efficiency.

Yin [78, 79] designed a single-mode fiber-coupling device system based on piezoelectric ceramics. The experiment automatically aligned a space light and single-mode fiber through the control algorithm, and the coupling efficiency was increased to 53.2%. Wu [80] designed a fiber coupler with a five–degrees of freedom (5-DOF) coupling device. The experimental results showed that the 5-DOF fiber coupler corrected different alignment errors, and the single-mode fiber coupling efficiency of the system was significantly improved after the closed loop.

Space-Light–Single-Mode-Fiber Coupling in Atmospheric Turbulence

Lei et al. compared the single-mode fiber coupling efficiency of a lens array with that of a single lens under atmospheric turbulence conditions and analyzed the spatial optical-coupling performance of a Maka antenna as a receiving antenna.

Coupling Efficiency of a Lens Array in Atmospheric Turbulence

Figure 13.1 shows planar and physical drawings of a lens and lens array of equal area. Figure 13.1a shows a single lens with a diameter of D_A, and Fig. 13.1b shows a lens array with a total diameter of D_A, consisting of an unit lens array with a diameter of $d_A = D_A/3$. It can be seen from the figure that the total areas of the single lens and lens array have the same relative aperture.

Figure 13.2 shows the coupling efficiency curve of the equal-area lens and lens array under medium–strong turbulence, where a is the coupling parameter, C_n^2 is the structural constant of the atmospheric refractive index, l_0 is the internal turbulence

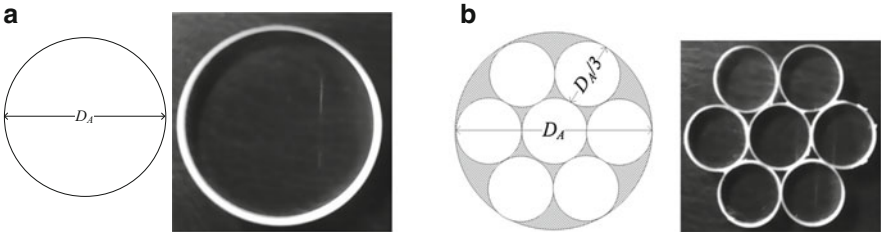

Fig. 13.1 Planar diagram of equal-area lens and lens array [76]. (**a**) Lens. (**b**) Lens array

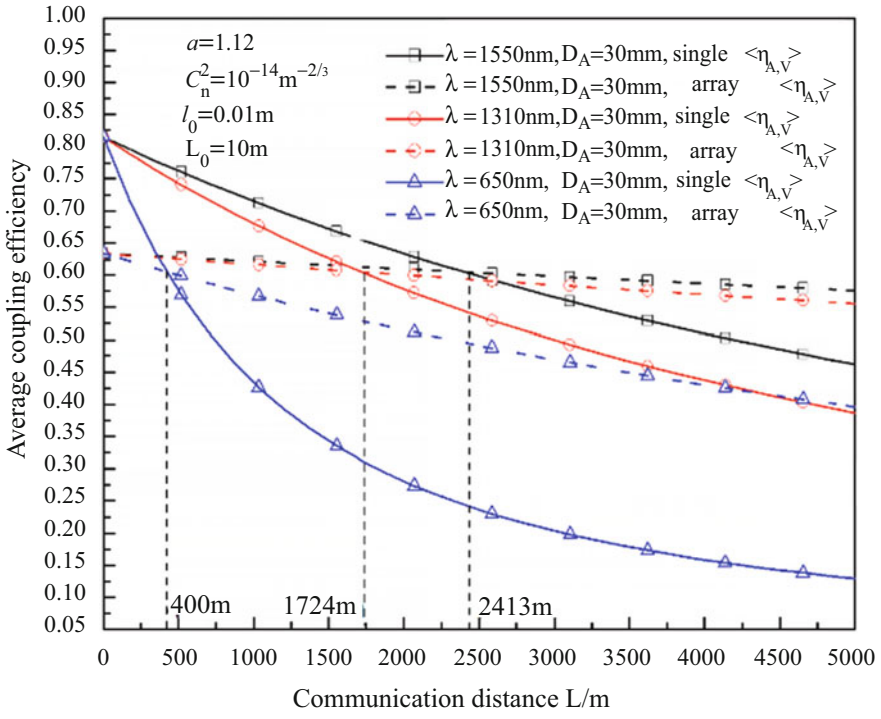

Fig. 13.2 Coupling efficiency curve of a lens and lens array under medium–strong turbulence [75]

scale, L_0 is the outer turbulence scale, and λ is the wavelength. It can be seen that the coupling efficiency of the single lens is higher than that of the lens array in short-distance communication. This is because the gaps between the lens units in the lens array are not fully utilized; hence, part of the beam cannot be fully coupled into the fiber through the gaps, resulting in a certain degree of coupling efficiency loss [81].

When the communication distance increased gradually, the coupling efficiency of the lens array decreased slowly with an increase in the communication distance, owing to the turbulence intensity. When the transmission distance exceeded a certain value, the coupling efficiency of the lens array was higher than that of a single lens with an equal area. This is because the diameter of an array element is smaller than that of the single lens; therefore, the number of speckles on the surface of the lens array is much smaller than that of the single lens, resulting in an increase in the coupling efficiency [82].

Figure 13.3 shows the variation of the power-lift coefficient K of the lens array relative to the single lens with the communication distance under medium–strong turbulence. When the communication wavelengths are 650, 1310, and 1550 nm and the communication distances are greater than 400, 1724, and 2413 m, respectively,

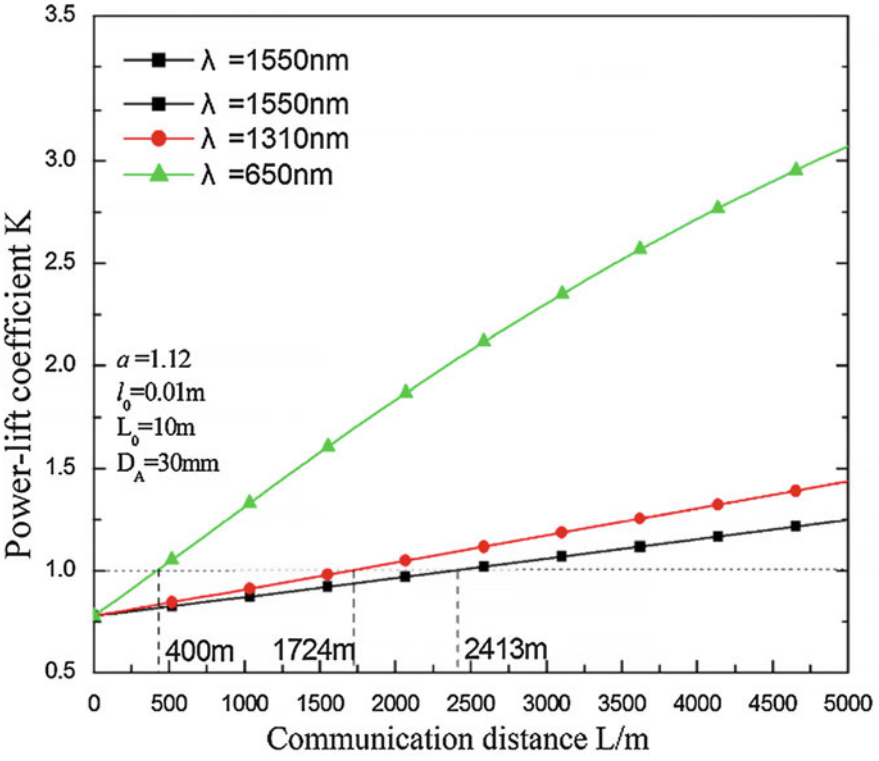

Fig. 13.3 Power-lift coefficient K of the array relative to the lens under medium–strong turbulence with varying communication distance [75]

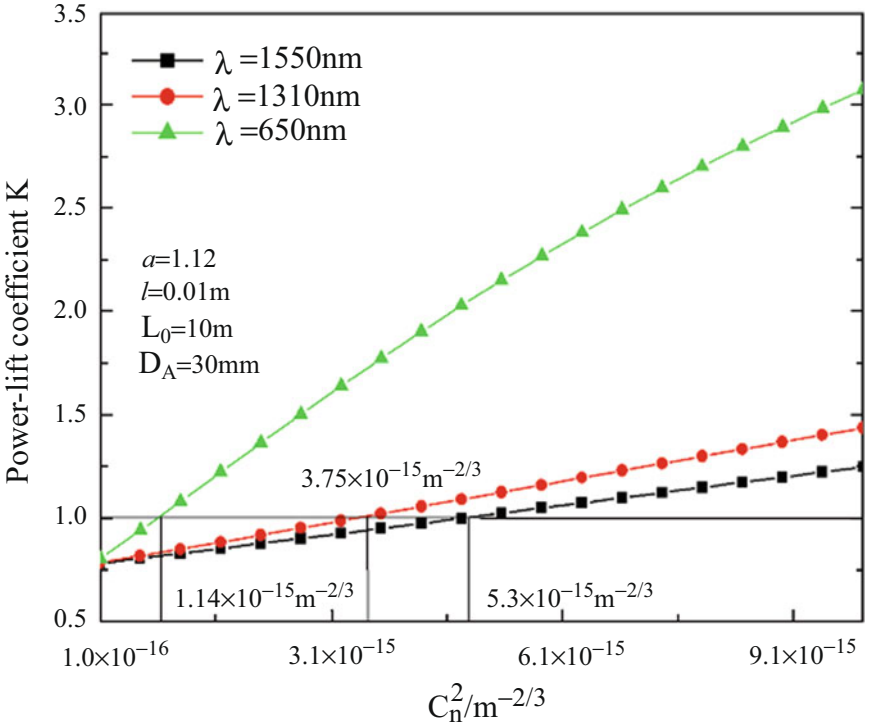

Fig. 13.4 Power-lift coefficient K of the array relative to the lens with a fixed communication distance (5 km) and varying turbulence intensity [75]

the optical power of the coupled lens array exceeds that of the coupled single lens, and a conclusion consistent with Fig. 13.1 is drawn.

Figure 13.4 shows that the power-lift coefficient K of the lens array relative to the single lens varies with the turbulence intensity when the communication distance is 5 km. When different wavelengths exceed a certain turbulence intensity, the optical power of the coupled lens array exceeds that of the coupled single lens.

Coupling Efficiency of a Maka Antenna Under Atmospheric Turbulence

Figure 13.5 shows a schematic diagram of the structure of a retractable Maka antenna. This structure makes the Maka antenna small, lightweight, and easy to fabricate. When it is used as a spatial optical-coupling system, it enables large-aperture coupling for the receiver and high-light power convergence technology.

Lei et al. studied the coupling efficiency of spatial fiber when a Maka antenna was considered equivalent to a lens system and used as a receiving antenna under the influence of atmospheric turbulence.

Figure 13.6 shows the curves of coupling parameter a and the coupling efficiency under different shielding ratios b with weak turbulence ($C_n^2 = 10^{-16} m^{-2/3}$) for a horizontal transmission. L is the communication distance, λ is the wavelength, D is

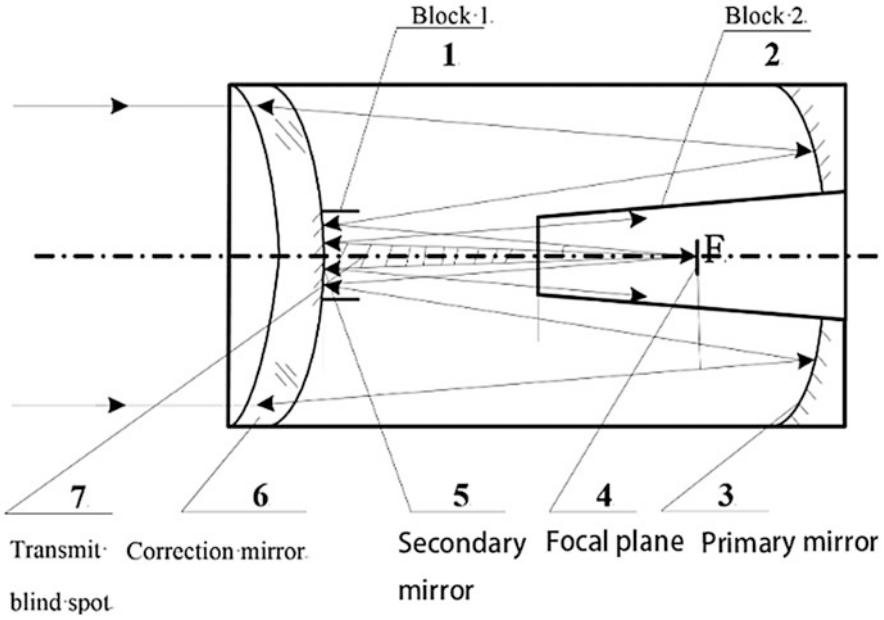

Fig. 13.5 Structural diagram of a retractable Maka antenna [75]

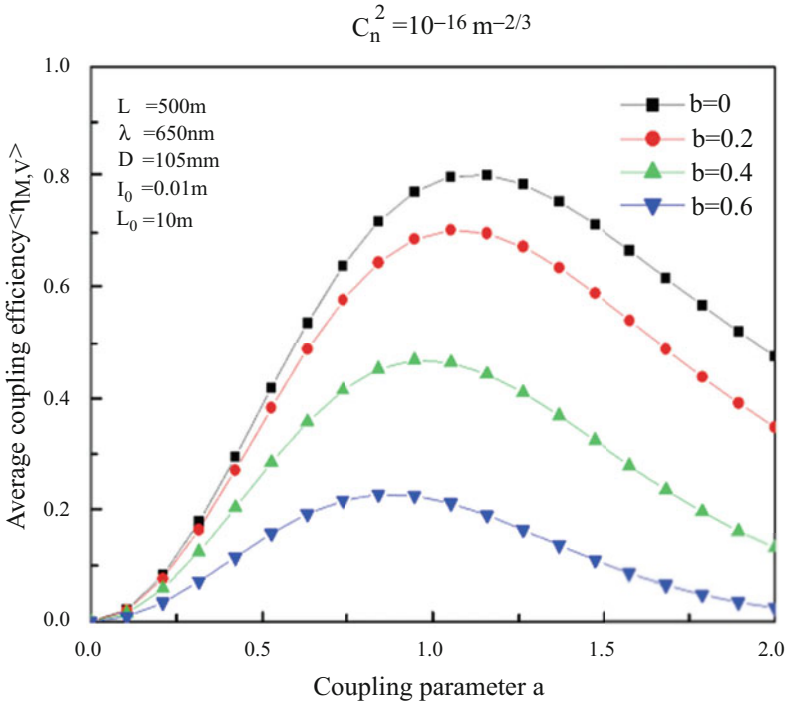

Fig. 13.6 Coupling parameters and coupling efficiency in weak turbulence [74]

the diameter of the Maka antenna, l_0 is the inner turbulence scale, and L_0 is the outer turbulence scale. It can be observed that when the shielding ratio is constant, the coupling efficiency first increases and then decreases with an increase in the coupling parameters. When the coupling parameters are fixed, the maximum coupling efficiency increases with an increase in the shielding ratio.

Figure 13.7 shows how the coupling efficiency varies with the communication distance for a horizontal transmission and weak turbulence ($C_n^2 = 10^{-16}m^{-2/3}$). With an increase in the communication distance, the coupling efficiency decreases slowly under different wavelength conditions. The coupling efficiency when the shielding ratio $b = 0$ is significantly greater than that when the shielding ratio $b = 2$. Therefore, in the case of weak turbulence, the most important factor affecting the change in coupling efficiency is the shielding ratio of the Maka antenna.

Figure 13.8 shows the curve of the coupling efficiency changing with the coupling parameters under different shielding ratios b for a horizontal transmission with medium–strong turbulence ($C_n^2 = 10^{-14}m^{-2/3}$). It can be observed that when the shielding ratio is constant, the coupling efficiency first increases and then decreases with an increase in the coupling parameters. The smaller the shielding ratio, the larger the maximum coupling efficiency. When the coupling parameters are fixed, the maximum coupling efficiency decreases rapidly with the increase of the shielding ratio.

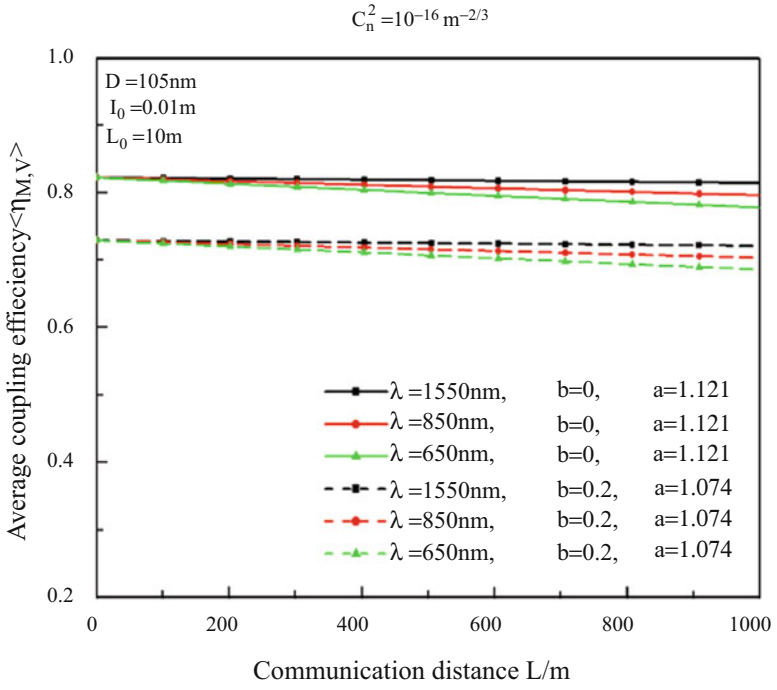

Fig. 13.7 Communication distance and coupling efficiency curve in weak turbulence [75]

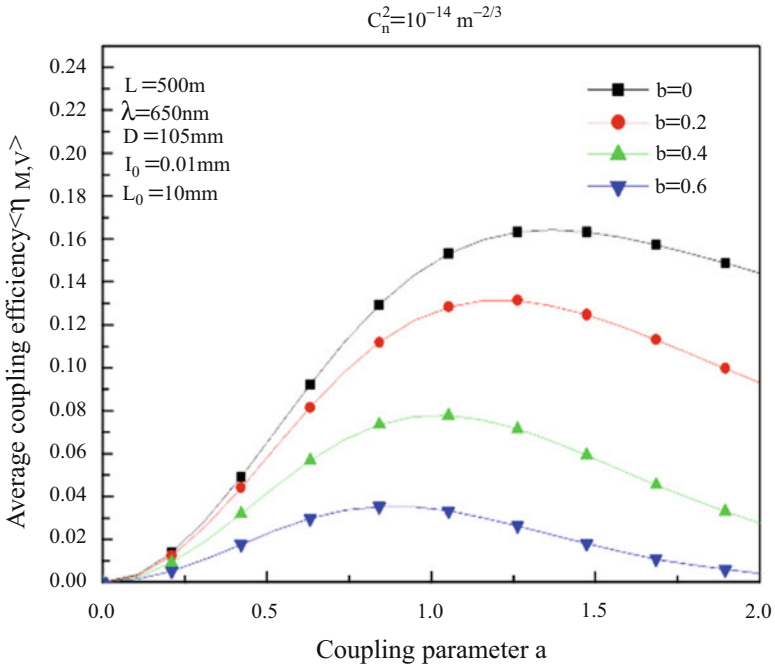

Fig. 13.8 Coupling parameters and coupling efficiency in medium–strong turbulence [75]

Figure 13.9 shows the curve of the coupling efficiency changing with the communication distance for a horizontal transmission with medium–strong turbulence ($C_n^2 = 10^{-14}m^{-2/3}$). It can be seen that with an increase in the communication distance, the longer the wavelength, the smaller the decrease in coupling efficiency. In the case of medium–strong turbulence, the most important factor affecting the coupling efficiency is the transmission distance.

Comparison of the Coupling System with a Lens Array and a Maka Antenna Under Atmospheric Turbulence

Table 13.3 shows the advantages and disadvantages of the coupling system with a single lens, lens array, and Maka antenna under atmospheric turbulence, as well as the research results of coupling efficiency changes under various influencing factors.

Integrated Maka Antenna Transmitting and Receiving Technology

Figure 13.10 shows a schematic diagram of the Maka antenna integrated transceiver experiment. The effective receiving area of this structure is the blind transmitting area of the cassette antenna. From the perspective of the transmitting terminal, the

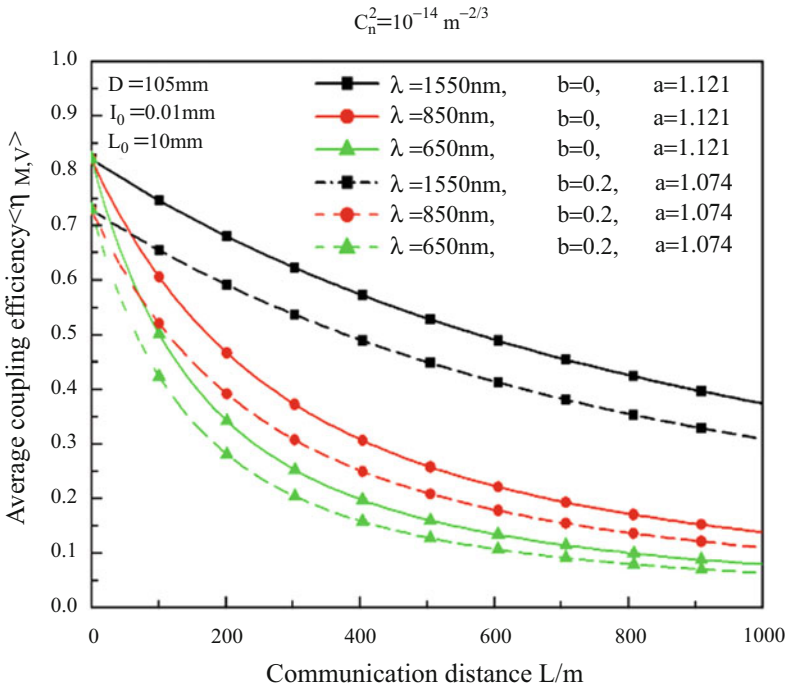

Fig. 13.9 Communication distance and coupling efficiency curve in medium–strong turbulence [75]

effective transmitting area can be maximized by changing the beam-waist size and divergence angle.

The experimental results show that the output light power of the collimator is 16.8 mW, and that of Maka antenna A is 14.9 mW. The calculated transmission efficiency is approximately 94.0%. Compared to the previously used axial-transmission method, the transmission efficiency of this method is increased by 85.0%, and the optical-power loss caused by secondary-mirror occlusion was successfully solved. The experimental results are listed in Table 13.4.

As can be seen from Table 13.4, when the distance between Maka antennas A and B was 5 m or 15 m, the received optical power fluctuated at approximately 3 mW. This is because the distance between the two antennas is relatively small, so the received light spots are generally located in the effective receiving area of the antenna. Hence, there is no significant difference in the received optical power. When the distance between the two antennas is 30 m, the transmitted beam diverges, and only part of the light spot is located in the effective receiving area, resulting in a partial power loss.

Table 13.3 Comparison of coupling systems of a single lens, lens array, and Maka antenna under atmospheric turbulence

Lens	Advantages	Shortcomings	Coupling efficiency variation
Equal-area lens (compared to array)	Relatively large effective area and all beams incident in the aperture plane can be coupled into the optical fiber	Weak ability to inhibit turbulence	Coupling efficiency of an equal-area lens is higher than that of a lens array for shorter communication distances
Lens array	Better ability to restrain turbulence in turbulent flow	The effective area is 0.778, and all the beams incident in the aperture plane cannot be coupled into the fiber	Coupling efficiency of a lens array is higher than that of an equal-area lens when the communication distance and turbulence intensity increase
Maka antenna	Large-aperture coupling receiving technology and strong convergent optical-power capability	Secondary-mirror occlusion causes energy loss	In weak turbulence, the blocking ratio of the Macca antenna is the main factor that reduces the coupling efficiency; in strong turbulence, the coupling efficiency of short wavelengths decreases to less than 20% when the transmission distance exceeds the order of km

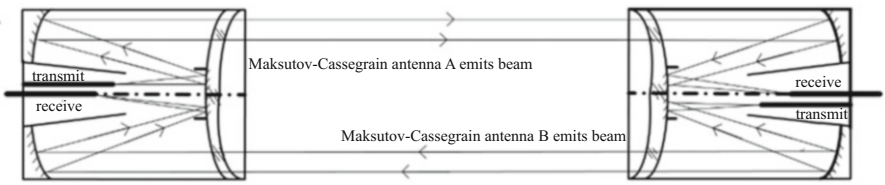

Fig. 13.10 Schematic diagram of the integrated transceiver experiment [74]

Table 13.4 Maka antenna integrated transceiver experimental data [75]

Distance/m	Antenna B emits optical power/mW	Antenna A receives optical power/mW	Coupling efficiency of Antenna A (%)	Antenna A emits optical power/mW	Antenna B receives optical power/mW	Coupling efficiency of Antenna B (%)
5		3.1	21.6		2.8	20.2
15	14.3	3.0	20.9	14.8	2.9	20.9
30		2.3	16.1		2.2	15.8

Automatic Spatial Optical-Coupling Alignment

Automatic spatial optical-coupling alignment has a direct influence on the coupling efficiency. Luo et al. studied the simulated-annealing algorithm [2] and stochastic parallel gradient-descent (SPGD) algorithm to control the voltage on piezoelectric ceramics, drive the fiber to generate a displacement, adjust the fiber position in real time, align the optical axis, and improve the coupling efficiency.

Application of a Simulated-Annealing Algorithm to Automatic Spatial Optical-Coupling Alignment

To improve the efficiency of coupling spatial light to an optical fiber, the voltage-signal output by the photodetector is used as a feedback signal. The voltage on the two-dimensional piezoelectric ceramics is adjusted by a simulated-annealing algorithm to dynamically adjust the optical-axis alignment. Figure 13.11 shows the automatic space optical-coupling alignment system using two-dimensional piezoelectric ceramics.

Figure 13.12a shows the voltage of the X-axis output after the simulated-annealing algorithm was adopted. As the number of iterations increases in the initial

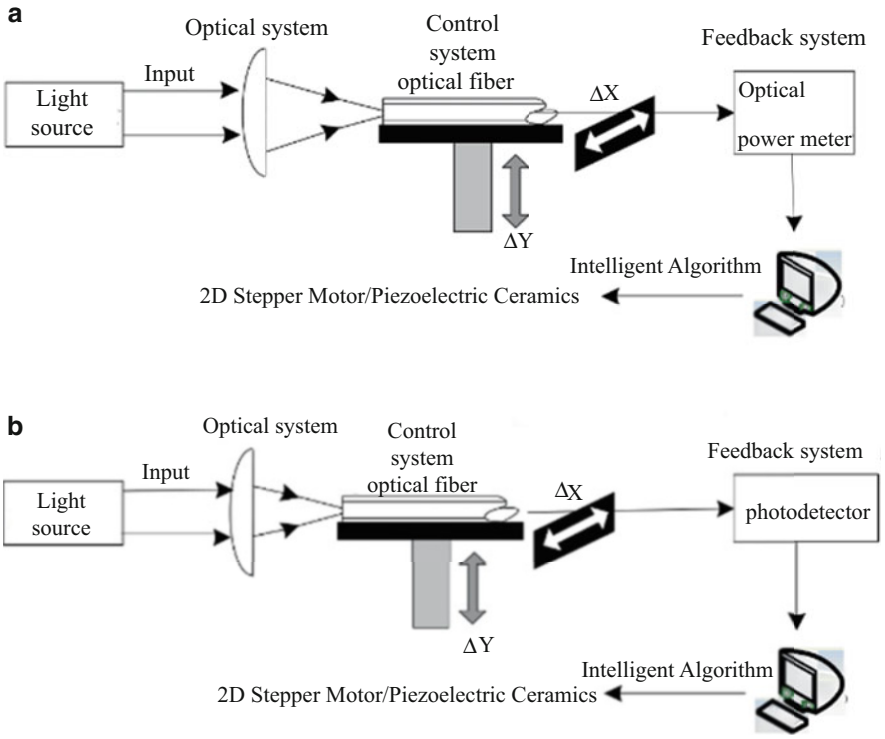

Fig. 13.11 Automatic space optical-fiber coupling alignment system [83]. (**a**) Optical signal acquisition system. (**b**) Electrical signal acquisition system

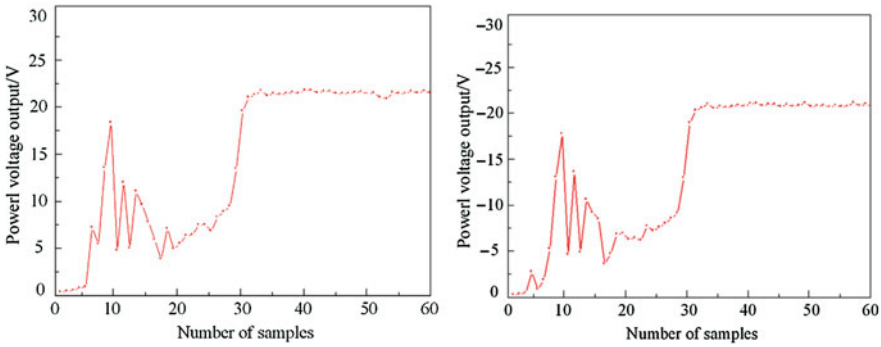

Fig. 13.12 Voltage variation when the simulated-annealing algorithm is added [2]. (**a**) *X* axis. (**b**) *Y* axis

stage, the curve fluctuates significantly. The curve fluctuation reflects the process of the system searching for the optimal coupling position. When the number of iterations is greater than 30, the curve stabilizes because the system initially searches for the optimal voltage. The voltage fluctuates slightly around 20.68 V and stabilizes, indicating that the optimal coupling position has been determined by the system.

Figure 13.12b shows the Y-axis output voltage after the simulated-annealing algorithm is used. It can be seen that the curve fluctuates with an increase in the number of iterations in the initial stage. After the fluctuation, the voltage value fluctuates slightly around −20.323 V and stabilizes; that is, the optimal coupling position has been determined. The voltage graph reflects the entire search process.

The simulated-annealing algorithm can be used to determine the optimal position in a short time, and the coupling efficiency was as high as 51.4%. The self-designed alignment system has the advantages of a reliable fixed mode and high-precision driving circuit. This is a highly efficient method for improving the precision alignment of optical fibers.

Application of the SPGD Algorithm to Automatic Spatial Optical-Coupling Alignment

To achieve higher-precision regulation of the fiber end face, Yin et al. designed a constant-voltage DC power supply and voltage-amplifying circuit corresponding to the three working conditions of piezoelectric ceramics by using three different displacement modes. Using the SPGD algorithm, the optical power in the coupled single-mode fiber is taken as real-time feedback to automatically align the coupling of the spatial optical and single-mode fibers, so that the end face of the fiber is in the best coupling position. Figure 13.13 shows the automatic-alignment block diagram of the five-dimensional piezoelectric ceramics in the space optical coupling.

Figure 13.14 shows the curve of the coupling optical power changing with the number of iterations under the influence of axial deviation. It can be observed that the coupling power of the single-mode optical fiber increases with an increase in the

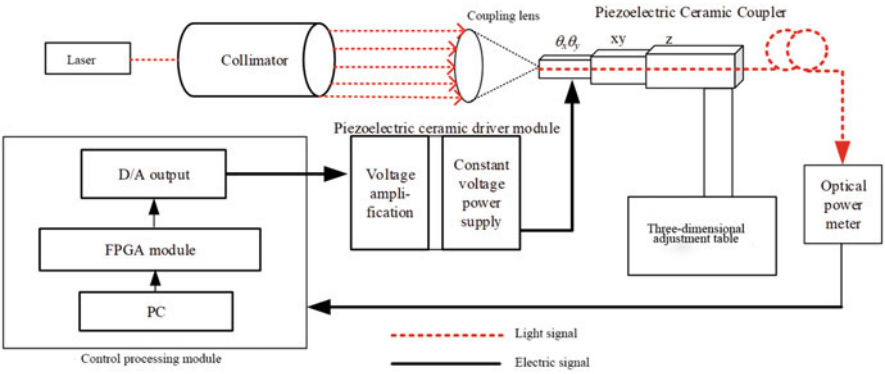

Fig. 13.13 Schematic diagram of the automatic spatial optical-coupling alignment experiment [78]

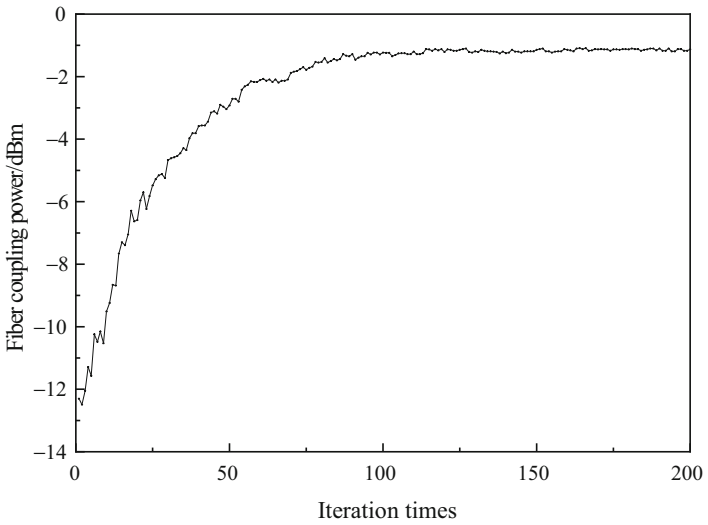

Fig. 13.14 Coupling optical-power variation with axial deviation with a varying number of iterations [78]

number of algorithm iterations, which means that the axial deviation is effectively compensated.

Figure 13.15 shows the curve of the coupling optical-power changing with the number of iterations under the influence of radial deviation. It can be observed that the coupling power of the single-mode optical fiber increases with an increase in the number of iterations, which means that the radial deviation is effectively compensated.

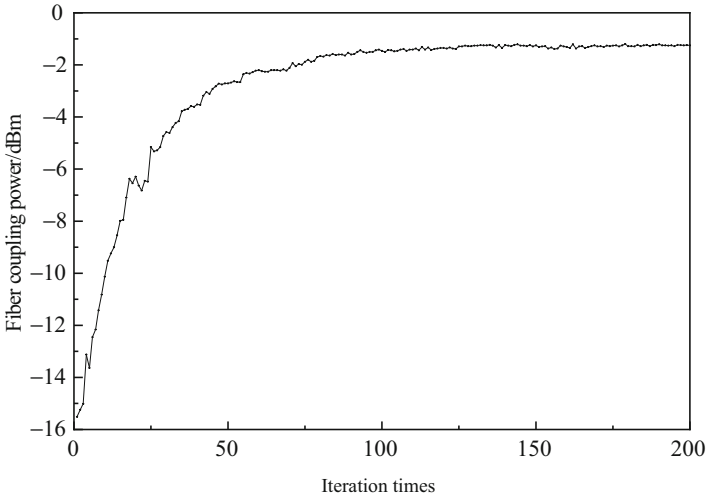

Fig. 13.15 Coupling optical-power variation with radial deviation with a varying number of iterations [78]

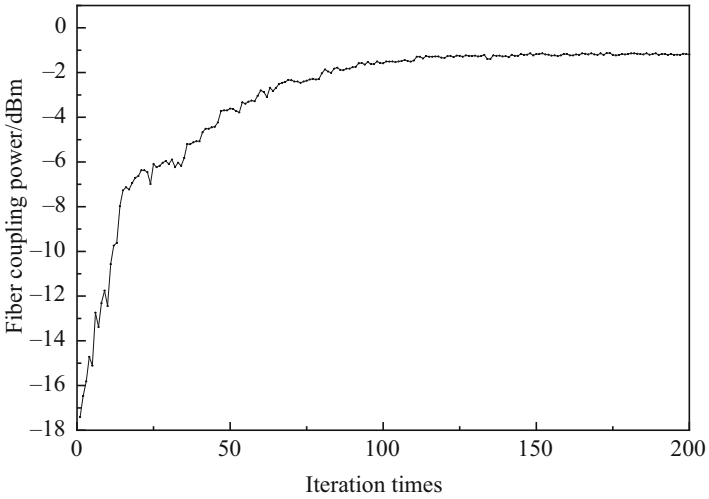

Fig. 13.16 Coupled optical-power variation with the angular deviation with the number of iterations [78]

Figure 13.16 shows the curve of the coupling optical-power changing with the number of iterations under the influence of angular deviation. It can be observed that the coupling power of the single-mode optical fiber increases with an increase in the number of algorithm iterations, which means that the angular deviation is effectively compensated.

The SPGD algorithm can automatically align and position the fiber in a relatively short time, and the coupling efficiency reaches 53.2% [78]. Moreover, the coupling device has the advantage of a small and compact structure.

Mode-Conversion Method

Under the influence of atmospheric turbulence, some beam modes in optical wireless communication systems degenerate from a low-order mode to a high-order mode during transmission. This leads to a reduction in the fundamental mode energy, and thus, reduces the coupling efficiency of the single-mode fiber. Using a mode-conversion method, Zhang et al. overcame the above problems through mode-matching conversion and improved the efficiency of coupling spatial light to single-mode fibers [76, 84]. Figure 13.17 shows the optical path constructed using a liquid-crystal-spatial light modulator (LC-SLM) for mode conversion.

The mode-conversion results collected by the beam analyzer are shown in Fig. 13.18. In the figure, part of the mode of the second behavior spot degenerates into a higher-order mode after passing through atmospheric turbulence, and changes to LP01 mode after a mode conversion. It can be seen that, compared with the ideal light intensity distribution, the energy distribution of the LP02-mode light field in the first column is uniform and symmetrical; however, high-order diffraction components are still present.

The degraded higher-order mode is processed by LC-SLM2, and the obtained mode light field conforms to the mode field distribution under the ideal state. When the mode order is converted to a low order, the light field distribution is concentrated,

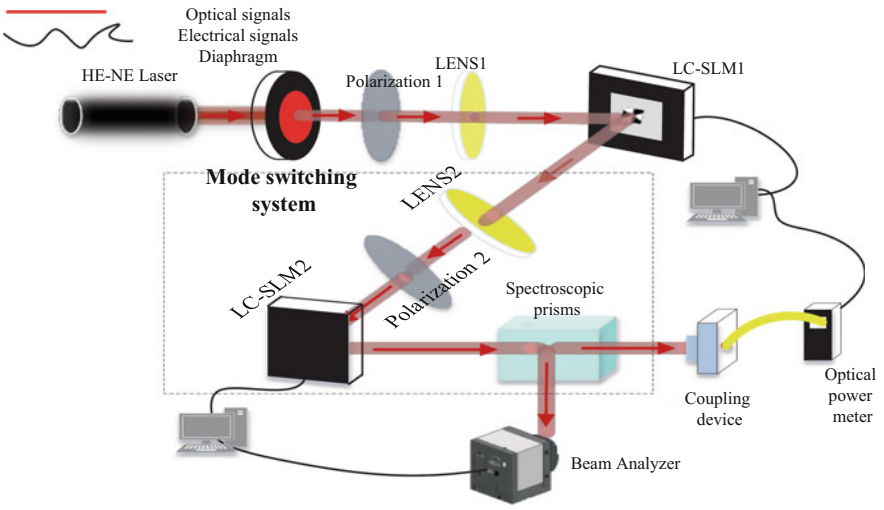

Fig. 13.17 Optical path diagram of a spatial-optical mode conversion based on LC-SLM [76]

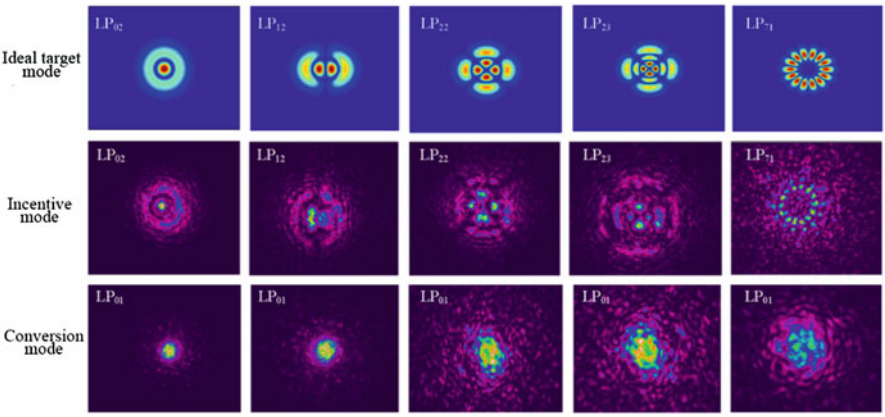

Fig. 13.18 Results of the schema transformation [85]

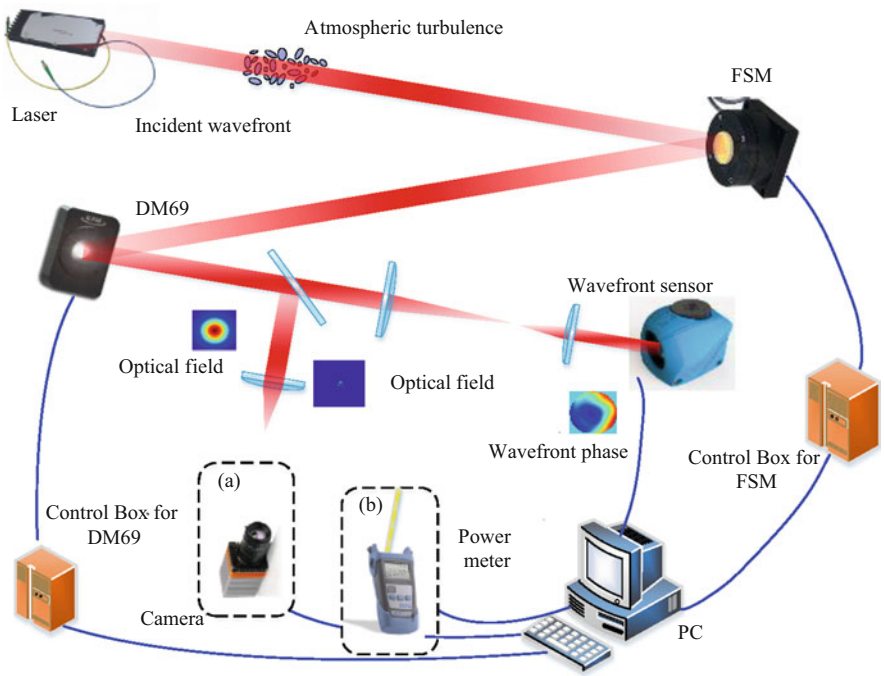

Fig. 13.19 Schematic diagram of an adaptive-optical wavefront correction fiber-coupled control system [77]

and the energy is located in the center of the light field, so the mode-conversion method plays an obvious role.

After pretreatment, the mode degenerates to LP22 when the coupling power is −18.53 dBm, and the coupling efficiency can be further increased from 55.9–66.2%

by using the simulated-annealing algorithm. It can be seen that the mode-conversion method plays an important role in improving the coupling efficiency. The coupling efficiency can be increased to 69.2% after converting the minimum low-order mode LP02. The coupling efficiency of the maximum high-order mode LP71 can be increased to 60.3%.

Adaptive-Optical Wavefront Correction

Because the efficiency of coupling a spatial light and fiber is reduced by the wavefront distortion caused by atmospheric turbulence, Yang et al. effectively improved the coupling efficiency of free-space coherent-optical communication by adopting adaptive-optics (AO) technology.

The adaptive-optical wavefront correction fiber-coupled control system is shown in Fig. 13.19. The adaptive-optical system consists of a wavefront sensor (WFS), deformable mirror (DM), bias fast-steering mirror (FSM), and personal computer (PC). The optical-fiber coupling system is composed of a coupling lens, beam splitter, optical-power meter, single-mode fiber, and infrared camera. The optical-fiber coupling power is controlled by the wavefront closed-loop control of the adaptive-optics system.

In an actual adaptive-optical system, owing to the static aberration of each lens, the wavefront phase located on the optical-fiber end face differs from that collected by the wavefront sensor. Therefore, the non-common optical-path aberration is usually corrected using the SPGD optimization algorithm without a wavefront mode. A closed loop consisting of a deformable mirror, optical-power meter, and computer was constructed.

Figure 13.20 shows the coupled optical-power curve and wave-front phase peak-to-valley (PV) curve before and after error elimination using the SPGD algorithm. It can be seen that before the error is eliminated, the power of the adaptive-optical closed loop decreases with an increase in the number of samples, while the coupling power increases with an increase in the number of samples after the error is eliminated, and finally stabilizes at −28.5 dBm.

Figure 13.21 shows the coupled power and PV curves after correcting the wavefront distortion. It can be seen that the coupled optical power increases from −35 to −27 dBm when the wavefront distortion is corrected, and the PV value of the wavefront is reduced from 5 to 1 μm. Figure 13.22 shows the coupling-power curves of the closed and open adaptive-optics loops. It can be seen from the figure that the coupling power increases from −33.75 to −30 dBm after correction, and the coupling capacity is significantly improved.

Figure 13.23 shows the coupling efficiency variation-trend curve with the increase of iteration times at various distances, according to the measured wavefront Zernike coefficient. As can be seen from the figure, after the wavefront correction, light waves are transmitted successively through distances of 500 m, 1 km, 5 km, 10 km, 100 km, and indoors.

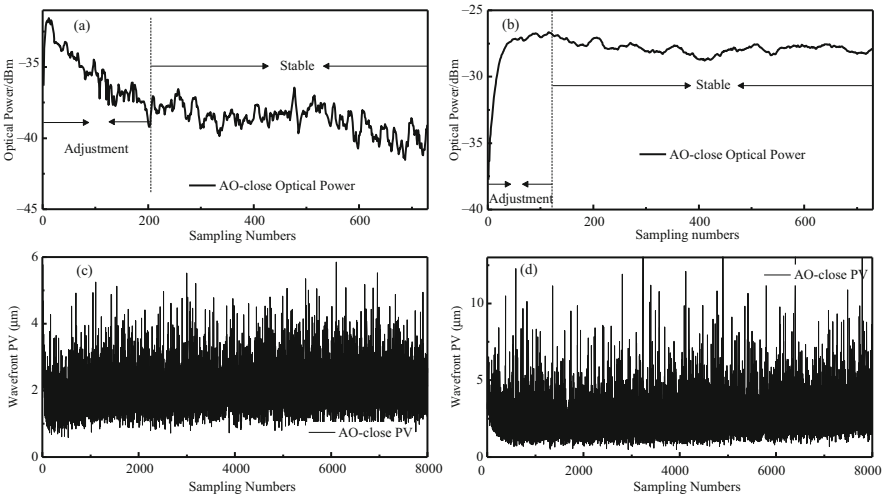

Fig. 13.20 Influence of non-common optical-path aberrations on AO closed-loop coupling power and wavefront phase [77]

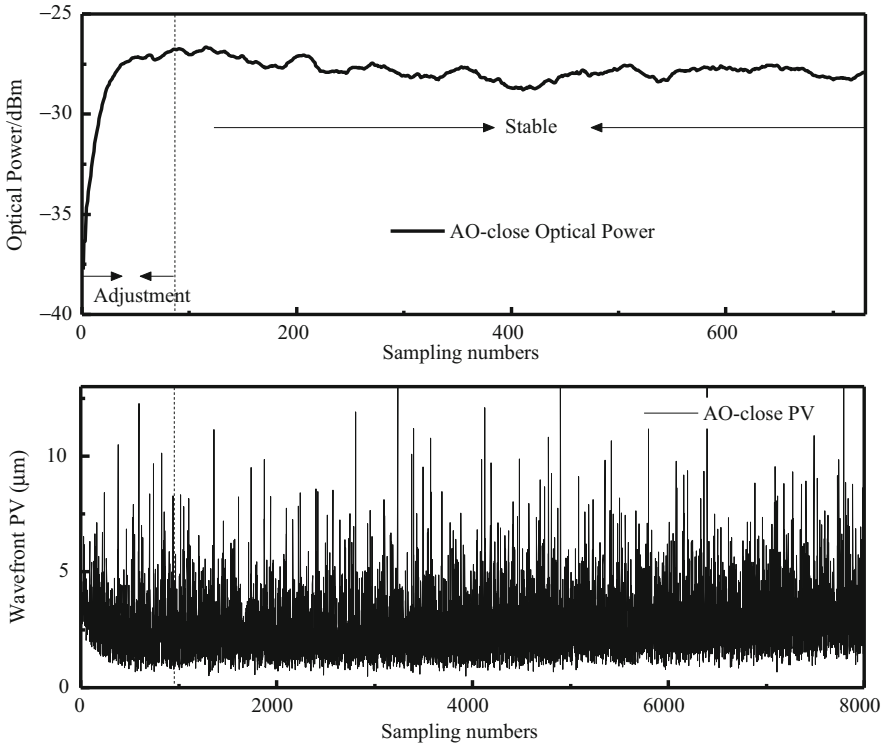

Fig. 13.21 Change curve and PV curve of fiber-coupling power before and after wavefront correction [77]

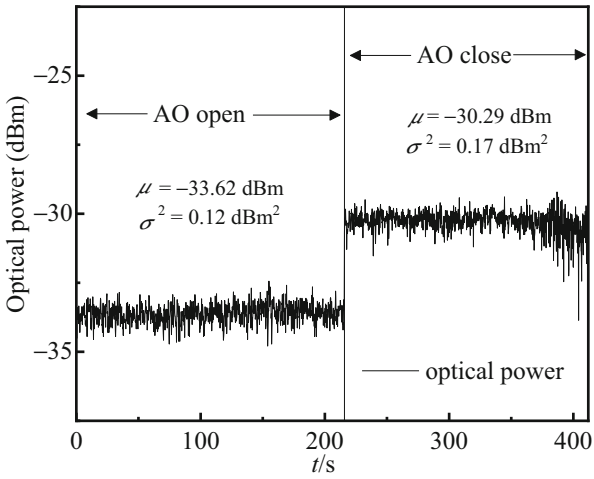

Fig. 13.22 Change curve of fiber-coupling power before and after wavefront correction [77]

In addition, it can be seen that with an increase in the communication distance, the fluctuation of the correction curve intensifies. The lifting effect of the long-distance correction is inferior to that of the short-distance correction, and the value fluctuation of the long-distance coupling efficiency is greater than that of the short-distance coupling efficiency. Therefore, under the influence of various factors, improving the efficiency of coupling long-distance spatial light to fiber is a complicated process, which is related to the beam alignment, beam mode, fiber-alignment error, wavefront measurement accuracy, detection speed, closed-loop correction bandwidth, and atmospheric-measurement environment.

Correction of Non-common Path Aberrations by Reverse-Transmission Calibration

Reverse-Transmission Calibration of a Non-common Optical-Path Aberration

Assuming that the beam-transmission direction is that shown in Fig. 13.19, and the phase introduced by atmospheric turbulence is $\varphi_{turbulence}$, the Zernike polynomial can be used to describe it in polar coordinates.

$$\varphi_{\text{turbulence}}(r,\theta) = \sum_{i=1}^{30} a_i \cdot z_i(r,\theta) \tag{13.1}$$

In Eq. (13.1), a_i is the Zernike coefficient and z_i is a Zernike series. *Noll* gives the relationship of the covariance $E(a_i, a_{i'})$ between Zernike coefficients a_i and $a_{i'}$ and the atmospheric coherence length r_0 [86].

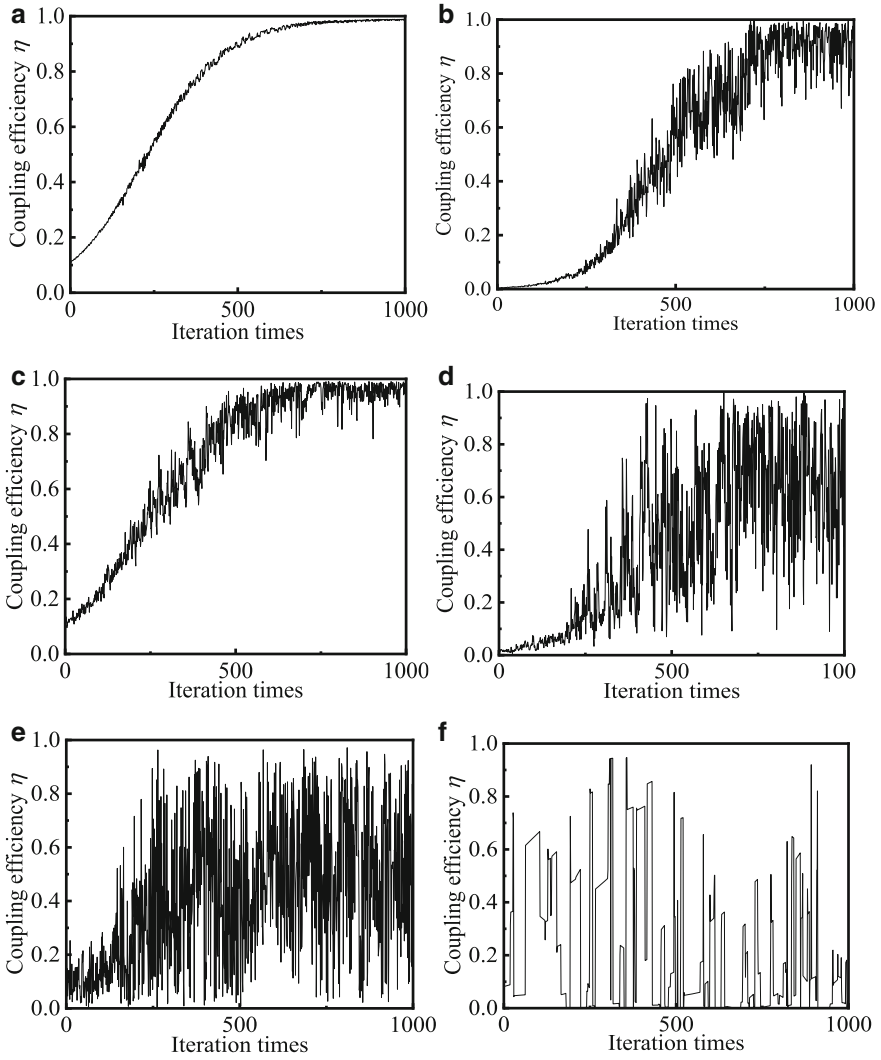

Fig. 13.23 Influence of the wavefront correction on the coupling efficiency at different distances. (**a**) indoor. (**b**) 500 m. (**c**) 1 km. (**d**) 5 km. (**e**) 10 km. (**f**) 100 km

$$E(a_i, a_{i'}) = \frac{2.2698(-1)^{(n+n'-2m)/2}\sqrt{(n+1)(n'+1)}\cdot\delta_Z\cdot\Gamma\left[\left(n+n'-\frac{5}{3}\right)/2\right]\cdot(D/r_0)^{5/3}}{\Gamma\left[\left(n-n'+\frac{17}{3}\right)/2\right]\cdot\Gamma\left[\left(n'-n+\frac{17}{3}\right)/2\right]\cdot\Gamma\left[\left(n+n'+\frac{23}{3}\right)/2\right]} \tag{13.2}$$

In Eq. (13.2), n and n' are the radial order of coefficients a_i and $a_{i'}$, respectively; m is the angular order of coefficient a_i; z is the Kronecker function, and D is the

aperture of the receiving antenna. The aberrations existing in lenses 3, 4, and 5 are φ_3, φ_4, and φ_5, respectively, and the aberrations generated by the transmission and reflection of the spectroscope are φ_T and φ_R. The phase information φ_{mea} collected by the branch of the wavefront sensor can be expressed as

$$\varphi_{\text{mea}} = \varphi_{\text{IWF}} + \varphi_{\text{turbulence}} + v \cdot IF_{\text{cmd2phase}} + \varphi_{\text{DM-error}} + \varphi_T + \varphi_3 + \varphi_4. \quad (13.3)$$

In Eq. (13.3), φ_{IWF} is the phase of the outgoing laser wavefront after collimation, v is the voltage signal applied by the deformable mirror, $IF_{\text{cmd2phase}}$ is the influence function of the surface shape of the deformable mirror, and $\varphi_{\text{DM-error}}$ is the plane-fitting error of the deformable mirror, which can be fitted by a Gaussian function.

$$\varphi_{\text{DM-error}}(x, y) = \exp\left(\ln(\omega)\left(\frac{\sqrt{(x - x_i)^2 + (y - y_i)^2}}{d}\right)^{\alpha}\right), i = 1, 2, \cdots n \quad (13.4)$$

In Eq. (13.4), α stands for the Gaussian index, d is the distance between the individual drives, (x_i, y_i) is the coordinate value of the ith drive, n is the total number of drives, and ω represents a cross-link value. At this time, the wavefront aberration generated by the φ_{focal} plane of the communication branch coupled lens (i.e., the coupling fiber end face) can be expressed as

$$\varphi_{\text{focal}} = \varphi_{\text{IWF}} + \varphi_{\text{turbulence}} + v \cdot IF_{\text{cmd2phase}} + \varphi_{\text{DM-error}} + \varphi_R + \varphi_5. \quad (13.5)$$

Equations (13.5) and (13.3), and the difference of $(\varphi_T + \varphi_3 + \varphi_4) - (\varphi_R + \varphi_5)$ are known as the common optical-path aberration.

To measure and correct non-common optical-path aberrations, the traditional method is to adopt an optimization algorithm represented by the SPGD algorithm. The loop in Fig. 13.19, consisting of a deformable mirror, optical-power meter, and computer, is taken as a wavefront-free sensing system and passed through the iteration meter [87].

$$v(k + 1) = v(k) + \gamma \cdot \Delta v(k) \cdot \Delta P(k) \quad (13.6)$$

In Eq. (13.6), $v(k)$ is the voltage applied to the deformed mirror in the kth iteration, ΔP is the change in the objective-function value of the system (coupled optical power) in the kth iteration, γ is the disturbance amplitude, and $\Delta v(k)$ is the control quantity of the random disturbance applied to each driver of the deformed mirror in the kth iteration, which follows both the independent and Bernoulli distributions. When the coupling optical power reaches convergence stability, the wavefront phase acquired by the wavefront sensor at this moment is denoted as $\varphi_{\text{mea-S}}$.

Reverse transmission means that an identical beam is sent from the receiving end to the sending end. We assume multiple emission light sources into the laser-coupling optical-fiber access, as shown in Fig. 13.24. The position of the deformable

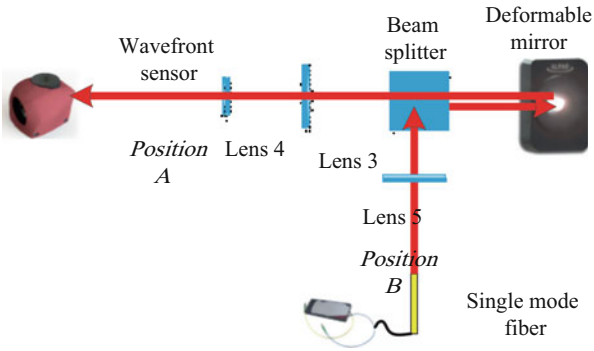

Fig. 13.24 Measurement of a non-common path aberration using the reverse-transmission calibration method

mirror is 10° counterclockwise. The deformable mirror is instructed to simultaneously clear the conditions and the reflection is in a fully planar deformation state. After the light output by the coupled fiber is reflected by the spectroscope, it is reflected by the deformable mirror directly into the wavefront sensor, to measure the wavefront information at the current moment.

As shown in Fig. 13.24, in the reverse-transmission state, the wavefront phase output by the fiber-coupling port is denoted as $\varphi_{\text{fiber-I}}$. According to the optical-path reversibility principle, the optical field carrying the phase information $\varphi_{\text{fiber-I}}$ can produce the highest coupling efficiency. At this time, the wavefront phase collected by the wavefront sensor can be expressed as

$$\varphi_{\text{mea-I}} = \varphi_{\text{fiber-I}} - \varphi_5 - \varphi_R + \varphi_{\text{DM-error}} + \varphi_T + \varphi_3 + \varphi_4. \tag{13.7}$$

Because $\varphi_{\text{mea-I}}$ contains both, it maximizes the coupling efficiency of the wavefront phase $\varphi_{\text{fiber-I}}$ and also includes the common optical path as the differential phase $(\varphi_T + \varphi_3 + \varphi_4) - (\varphi_R + \varphi_5)$.

Adaptive-Optical System

A block diagram of the adaptive-optical closed-loop control with wavefront sensing shown in Fig. 13.19 is shown in Fig. 13.25. The nth closed-loop iteration can be expressed as

$$v(k+1) = v(k) + k_i \cdot [\varphi_{\text{tar}} - \varphi_{\text{mea}}(k)] \cdot CM_{\text{phase2cmd}}, \tag{13.8}$$

where φ_{tar} controls the target wavefront phase, φ_{mea} is the phase collected by the wavefront sensor, $CM_{\text{phase2cmd}}$ is the command matrix for transforming the wavefront phase to the voltage of the deformable mirror, and k_i represents the integral gain. Considering the algorithm complexity and calculation speed of a real-time control system, the wavefront can be controlled by a single integral operation.

According to the mode field matching principle and Fresnel diffraction formula, the discretization expression of the fiber-coupling efficiency can be expressed as

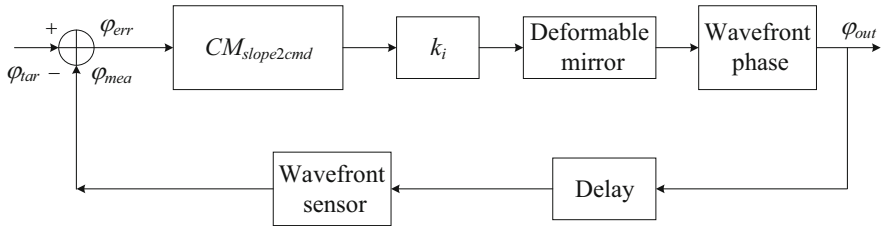

Fig. 13.25 Block diagram of an adaptive-optical closed-loop control

$$\eta = \frac{\left|\sum_{u=0}^{M-1}\sum_{v=0}^{N-1}\frac{W_m}{M}\cdot\frac{2\pi}{N}\cdot U_f(u,v)\cdot U_i^*(u,v)\cdot\frac{u}{M}W_m\right|^2}{\left(\sum_{u=0}^{M-1}\sum_{v=0}^{N-1}\frac{W_m}{M}\cdot\frac{2\pi}{N}\cdot U_f(u,v)\cdot U_f^*(u,v)\cdot\frac{u}{M}W_m\right)\left(\sum_{u=0}^{M-1}\sum_{v=0}^{N-1}\frac{W_m}{M}\cdot\frac{2\pi}{N}\cdot U_i(u,v)\cdot U_i^*(u,v)\cdot\frac{u}{M}W_m\right)}, \tag{13.9}$$

where M and N are the discrete points of the radial and angular coordinates, respectively; and W_m is the mode field radius of the single-mode fiber. U_f is the mode field distribution of the single-mode fiber [88]:

$$U_f(u,v) = \sqrt{\frac{2}{\pi}}\frac{1}{W_m}\cdot\exp\left[-\left(\frac{u}{M}\right)^2\right]. \tag{13.10}$$

U_i is the optical-field distribution located at focal plane 5 of the lens (i.e., the end face of the coupled fiber), which can be expressed as [88]

$$U_i(u,v) = \frac{\exp(ikf)}{ikf}\cdot\exp\left(\frac{ik\left(\frac{u}{M}W_m\right)^2}{2f}\right)\cdot\left(\frac{D_a}{2}\right)^2\cdot\phi(u,v), \tag{13.11}$$

where f_5 is the focal length of lens 5, D_a is the diameter of lens 5, $k = 2\pi/\lambda$ is the wave vector, and (u, v) is the discrete two-dimensional Fourier transform of φ_{focal} [93]:

$$\phi(u,v) = \sum_{x=0}^{M-1}\sum_{y=0}^{N-1}\varphi_{\text{focal}}(x,y)\cdot\frac{2}{MN}\cdot\frac{x}{M}\cdot\exp\left[-j2\pi\left(\frac{x}{M}W_m\right)\cdot\left(\frac{u}{M}\frac{D_a}{2\lambda f}\right)\cdot\cos\left(\frac{y}{N}2\pi-\frac{v}{N}2\pi\right)\right].$$
$$u = 0,1,\cdots,M-1$$
$$v = 0,1,\cdots,N-1 \tag{13.12}$$

Simulation Analysis

Numerical simulations were performed according to Eqs. (13.1–13.12). The integral coefficient $k_i = 0.3$, $\varphi_{\text{IWF}} = 0$, M and N were both 50, $W_m = 5.25$ m, $D_a = 25.4$ mm,

$\lambda = 1550$ nm, and $CM_{\text{slope2cmd}}$ and $IF_{\text{cmd2phase}}$ adopted the surface matrix provided by ALPAO, an adaptive-optics product manufacturer. The Gaussian index of the deformable mirror was $\alpha = 2$, the cross-linking value was $\omega = 0.08$, and the variance was 10^{-4}. The drive spacing $d = 1.5$ mm. Lenses 3, 4, and 5 are flat convex lenses with focal lengths of 175, 75, and 125 mm, respectively.

According to the integral-conversion relationship between geometric and wave aberrations, the differences in the wave phase after the beam passes through the optical device are calculated as φ_3, φ_4, and φ_5. The aberrations of the transmitted and reflected waves of the spectroscope are denoted as φ_T and φ_R, respectively. $\varphi_{\text{turbulence}}$ follows the Karhunen–Loeve function. $D/r_0 = 1$ is used to calculate the phase of the Zernike coefficient.

When $\varphi_{\text{tar}} = 0$, that is, the phase of the wavefront collected by the wavefront sensor is controlled as a plane wave, the peak–valley (PV) value and root-mean-square (RMS) value of the wavefront in the uncorrected and closed-loop states, as well as the coupling efficiency, can be obtained according to Eq. (13.8).

With a non-common optical-path aberration, after 1000 frames of closed-loop control iteration, the PV values of the wavefront decrease from an uncorrected 18.59 m to a closed loop 1.78 m, and the RMS value of the wavefront decreases from an uncorrected 1.51 m to a closed loop 0.24 m. The three-dimensional figures in Fig. 13.26a represent the wavefront phase collected by the wavefront sensor in the initial state (left) and after the closed-loop control of 1000 frames (right), according to the arrow direction. The wavefront flatness after the closed loop was obviously better than that in the uncorrected state. As shown in Fig. 13.26b, the coupling efficiency decreased from 36.52% to 18.79%. This is because $\varphi_T + \varphi_3 + \varphi_4$ in Eq. (13.3) is not equal to $\varphi_R + \varphi_5$ in Eq. (13.5).

$\varphi_{\text{tar}} = \varphi_{\text{mea-S}}$ and $\varphi_{\text{tar}} = \varphi_{\text{mea-I}}$. The SPGD algorithm and reverse-transmission calibration method were adopted to measure and correct the non-common optical-path aberrations. The disturbance amplitude $\gamma = 0.6$, the random disturbance control quantity $\Delta v = 0.01$ from the Bernoulli distribution, and φ_{tar} were used to reconstruct

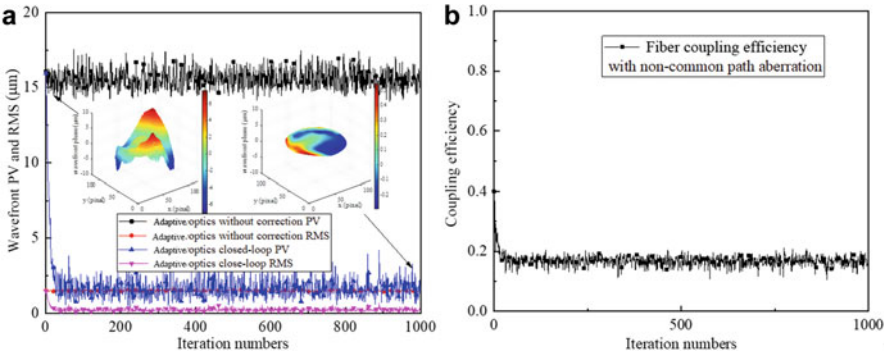

Fig. 13.26 Adaptive-optical system with non-common path aberrations. (**a**) Uncorrected and closed-loop PV values and RMS values of the wavefront. (**b**) Closed-loop coupling efficiency

the wavefront. The PV and RMS values of the wavefront and coupling efficiency in the uncorrected and closed-loop states were obtained, as shown in Fig. 13.28.

The SPGD algorithm was used to measure and correct the non-common optical-path aberration. After the closed loop, the PV value of the wavefront decreased from 18.55 to 1.75 μm, the RMS value of the wavefront decreased from 1.51 to 0.24 μm, and the coupling efficiency increased from 36.79–48.41%. This is because the SPGD algorithm is affected by turbulence, as shown in Fig. 13.27a, so it easily falls into local extrema; thus, it fails to fully calculate the wavefront phase information of the non-common optical-path aberration when the iteration is stopped. The maximum objective function determines the coupling efficiency in the closed-loop state. The PV value of the wavefront decreased from 18.64 to 3.28 μm, and the RMS value decreased from 2.76 to 0.68 μm.

As shown in the inset figures in Fig. 13.24a, c, there is no significant difference between the uncorrected and corrected wavefront phases, and the convergence degree is the same. The corresponding conversion was performed in the reconstruction process after closed-loop control, and the coupling efficiency of the reverse-

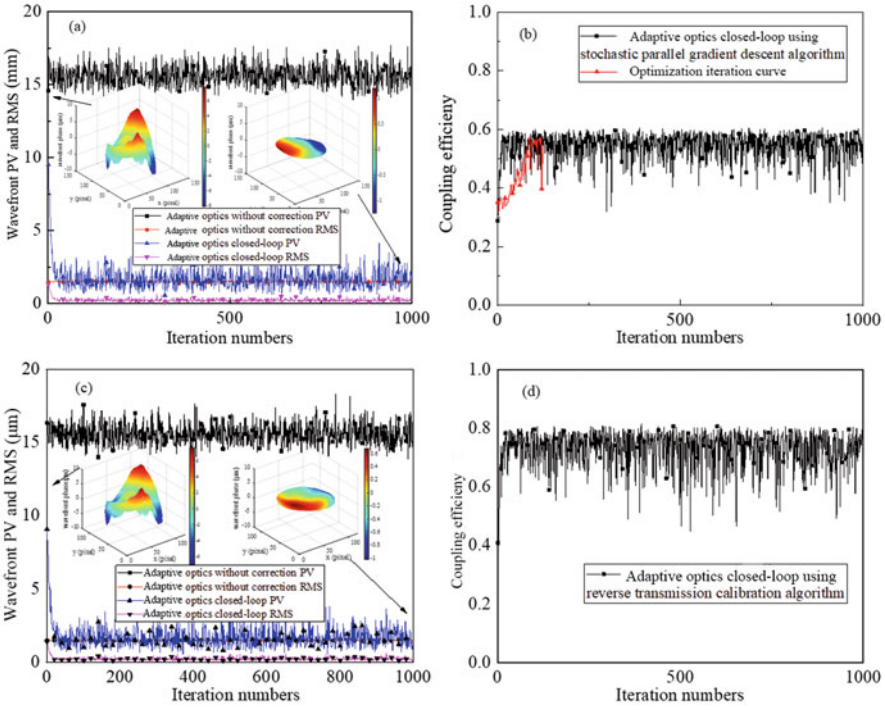

Fig. 13.27 Adaptive-optical system for correcting non-common path aberrations. (**a**) Uncorrected and wavefront RMS and PV values of the SPGD method. (**b**) Coupling efficiency of SPGD method. (**c**) Coupling efficiency of uncorrected and wavefront RMS and PV values of the reverse-transmission calibration method. (**d**) Coupling efficiency of reverse-transmission calibration method

transmission calibration method improved from 28.31–69.14%. This is because the beam-transmission direction in Fig. 13.27c is not affected by the turbulent environment, and the non-common optical-path aberration can be measured completely and steadily. In the closed-loop state, the coupling efficiency is better improved than that of the SPGD algorithm.

Experimental Results and Analysis

(a) **Measurement and correction of non-common path aberrations in a static environment**

The local oscillator light in a optical wireless coherent communication system was connected to a single-mode fiber using the reverse-transmission calibration method. Figure 13.28 shows the wavefront slope and corresponding wavefront phase of the non-common optical-path aberration measured by the wavefront sensor. The PV value is 3.71 μm and the RMS value of the wavefront is 1.34 μm, which are sufficient to significantly affect the coupling efficiency.

Figure 13.29 shows the coupling efficiency of the adaptive-optical system without correcting the non-common optical-path aberration, using the SPGD and reverse-transmission calibration methods, and the PV and RMS values of the wavefront before and after conversion.

The sampling rate of the wavefront sensor after reconstructing the wavefront (approximately 50 Hz) was approximately ten times than that of the serial-port sampling rate of the optical-fiber power meter (approximately 5 Hz). The coupling efficiency decreased from 12.83% to 6.79% after the closed loop without correction. Using the SPGD method, the coupling efficiency increased from the initial 12.88–25.28%. The coupling efficiency of the reverse-transmission calibration method increased from 10.04–45.21%.

The PV values of the wavefront without conversion reconstruction tend to first decrease and then increase. This is because the wavefront phase of the fiber branch

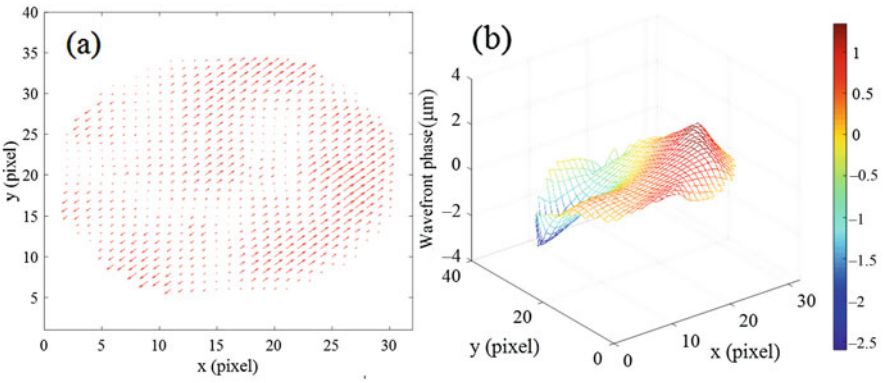

Fig. 13.28 Non-common optical-path aberration. (**a**) Wavefront slope; (**b**) wavefront phase in the actual system

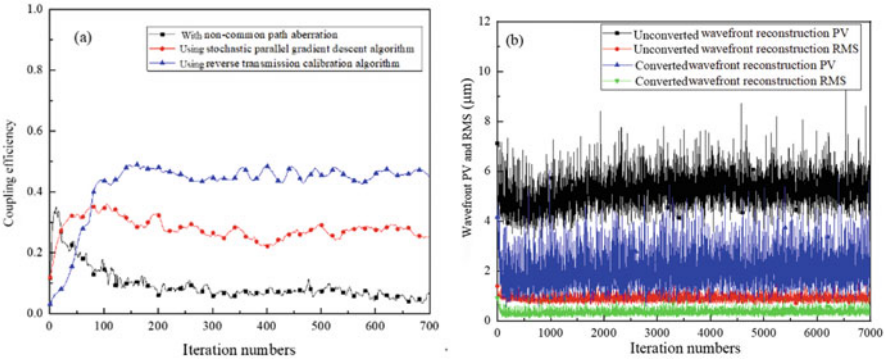

Fig. 13.29 1550-nm band adaptive-optical system closed-loop measurement. (**a**) Coupling efficiency of the uncorrected non-common optical-path aberration and the SPGD and reverse-transmission calibration methods; (**b**) unconverted and converted wavefront PV values and RMS values

reaches the optimal coupling efficiency after correction from the initial state. The wavefront-sensing branch corresponding to the same time period does not show the same numerical trend, owing to the aberration conversion of the non-common optical path and the positive and negative characteristics of the wavefront phase value. In addition, the internal noise of the wavefront sensor leads to some synaptic data in the wavefront slope measurement and wavefront phase calculation, but does not significantly affect the fluctuation of the coupling efficiency.

(b) **Field experiment in a turbulent environment**

An outfield experiment for the coherent detection of optical wireless coherent communication was conducted. The two ends of the communication were located at the South Second Ring Road of Xi'an City and the sixth floor of Xi'an University of Technology, respectively. The communication distance was 1.3 km, and the measurement date was April 16, 2021; the weather was clear with a level-2 southwest wind.

The structure of the optical wireless coherent communication system using adaptive optics is shown in Fig. 13.30. The transmitter uses external modulation to load the signal source onto the modulator. After amplification by the fiber amplifier, the optical antenna collimates the output. The output power of the fiber amplifier is 16.77 dBm.

After the beam is converged by the receiving antenna, adaptive-optics technology is used for wavefront correction, and the spatial light is directly coupled into the single-mode fiber. After frequency mixing and balance-detection processing, the intermediate-frequency (IF) signal is output and demodulated. The mixer model is Kylia COH24, the balancing detector model is General Photonics BPD-002, and the signal laser and local oscillator are both Koheras BASIK E15 narrow-width fiber lasers.

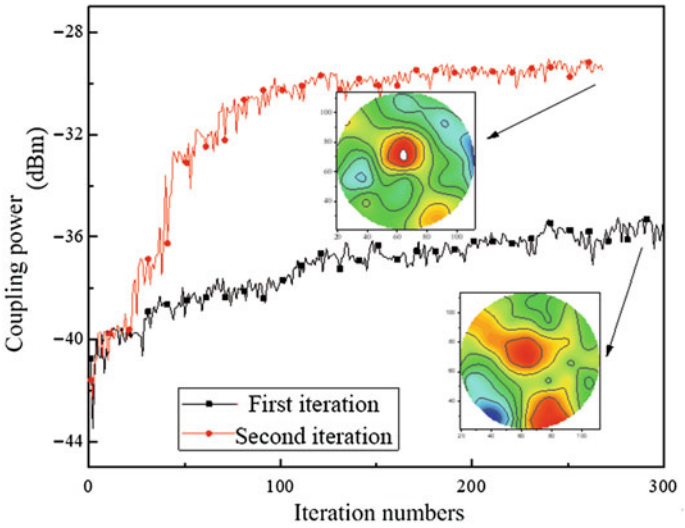

Fig. 13.30 Coupling-power variation and corresponding deformed-mirror profiles under different iterations using the SPGD method

The coupled light power was taken as the evaluation index, and the SPGD algorithm was adopted to obtain the coupled power at different times. The deformation mirror shape was fitted according to the voltage applied by the deformation mirror when the iteration was stopped, as shown in Fig. 13.30.

As shown in Fig. 13.30, the maximum power values obtained by the different iterations differ. The inset figures in Fig. 13.30 show obvious defocusing terms in the surface shapes fitted by the deforming mirror when the iteration is stopped; however, some differences still exist. The accuracy of the aberration measurement in a non-common optical path is bound to be affected by the local optimization of the different SPGD profile errors.

Figure 13.31 shows the non-common optical-path aberrations measured by the SPGD algorithm at different times. The wavefront phase presents a ring structure because the secondary mirror of the receiving antenna blocks the received light spots, and the measurement values of the non-common optical-path aberration in Fig. 13.31a are different from those in Fig. 13.31b. The measurement results at different times are also affected by atmospheric turbulence and thus differ.

Figure 13.32 shows the coupling efficiency curve and IF-signal waveform in the uncorrected and closed-loop adaptive-optics states after measuring and correcting non-common optical-path aberrations using the reverse-transmission calibration method. The adaptive-optics coupling efficiency in the uncorrected and closed-loop states increased from 19.72% to 36.93%. The peaking value of the IF signal increased from 400 mV to 1.4 V, while the maximum output peaking value of BPD-002 is 3.1 V. The mixing efficiency of the system increased from 1.66% in the uncorrected state to 20.40% in the closed-loop state.

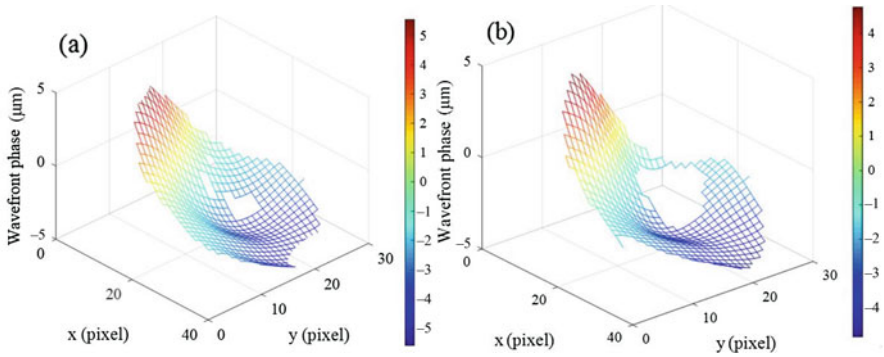

Fig. 13.31 1.3-km experimental link using the SPGD algorithm to measure a non-common optical-path aberration. (**a**) First measurement; (**b**) second measurement

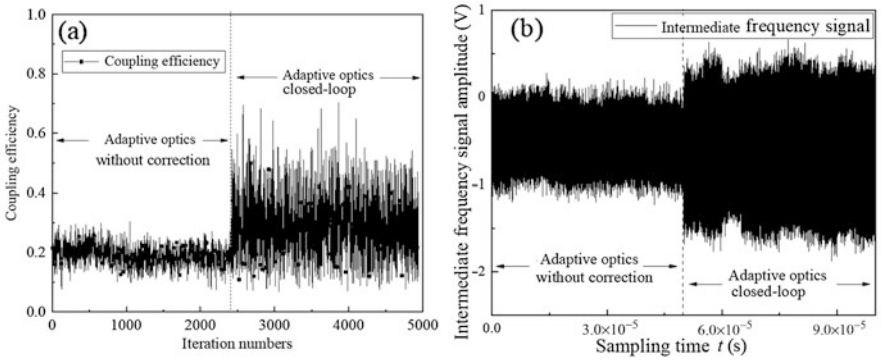

Fig. 13.32 Uncorrected and closed-loop states of 1.3-km adaptive optics in a field experiment. (**a**) Coupling efficiency; (**b**) IF signal waveform

(c) **Field experiment in a complex environment**

Based on the above experiments, the transmitting end is located in Xiaozhai Village, Bailuyuan, Xi'an City, and the receiving end is located on the sixth floor of Xi'an University of Technology. At the receiving end, a piezoelectric deformable mirror is used to randomly generate wavefront distortions of different frequencies and amplitudes; then, the wavefront is corrected and the fiber is coupled through the adaptive-optical system. The experiment took place on November 6, 2021, when the weather was cloudy with light rain. The experiment-link distance was 10.2 km.

The transmitter output power of the fiber amplifier is 23.01 dBm. Before correction, the power of the receiver coupled into the single-mode fiber fluctuated from −44 to −27 dBm. The coupling power does not increase significantly with the transmission-power increase; thus, it is necessary to use adaptive-optics technology to improve and stabilize the coupling efficiency.

Figure 13.33 shows the coupled-power iteration curve obtained using the SPGD algorithm for the 10.2-km link and the wavefront phase collected by the wavefront

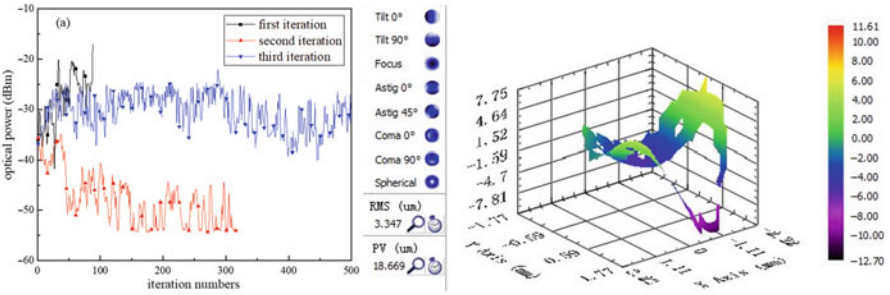

Fig. 13.33 10.2-km link adaptive-optical initialization using the SPGD algorithm. (**a**) Coupled optical-power iteration curve; (**b**) wavefront phase

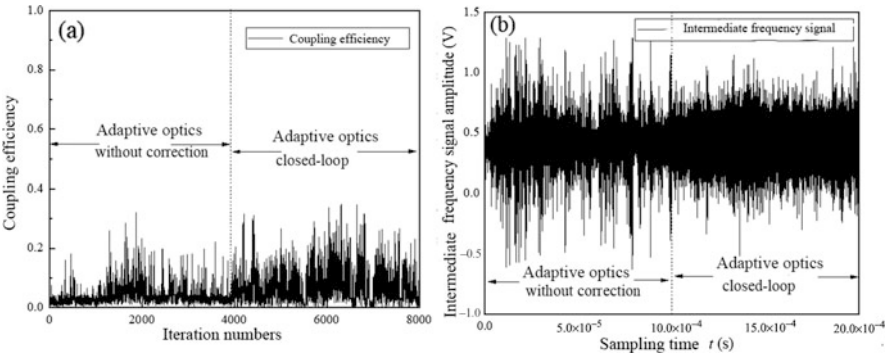

Fig. 13.34 Uncorrected and closed-loop states in a 10.2-km adaptive-optics field experiment. (**a**) Coupling efficiency; (**b**) IF signal waveform

sensor when the iteration stopped. The coupling power does not obviously increase with the increase of the number of iterations, and some of it even declines. The wavefront phase is difficult to detect, owing to the light intensity flicker caused by atmospheric turbulence. Thus, the non-common path aberration-information acquisition is incomplete. This indicates that the SPGD algorithm is not universal for adaptive-optical initialization calibration over long-distance transmissions.

Figure 13.34 shows the coupling efficiency and IF-signal waveform in the closed-loop state after adaptive-optics initialization with uncorrected adaptive optics and the reverse-transmission calibration method on a 10.2-km link. The average coupling efficiency increased from 3.91% in the uncorrected state to 10.13% in the closed-loop state, while the variance of the peak-to-peak value of the IF signal increased from 33 mV in the uncorrected state to 123 mV in the closed-loop state. The average mixing efficiency of the system increased from 3.87% in the uncorrected state to 8.52% in the closed-loop state. This indicates that with the increase in communication distance, atmospheric turbulence has a more significant effect on the adaptive-optical correction effect than the non-common optical-path aberration.

According to the reversible optical-path principle, a calibration method using a reverse transmission is proposed to measure and correct the aberration of a non-common optical path. The closed-loop control of the non-common optical-path aberration improves the coupling efficiency while correcting the wavefront. Compared with the traditional SPGD algorithm, this scheme does not fall into local optima, is not affected by the external environment, and can assist in the alignment and debugging of the optical path. It is simple and feasible, easy to implement in engineering, and has reference significance and practical value for the fiber-coupling technology of optical wireless coherent communication systems.

Comparison of Several Different Methods to Improve the Spatial Optical-Fiber Coupling Efficiency

Comparison of Different Methods to Improve Fiber Coupling

Table 13.5 compares the research on three methods, namely automatic alignment, mode conversion, and adaptive-optical wavefront correction. They improve the

Table 13.5 Comparison of different methods to improve the spatial optical-fiber coupling efficiency

Method classification		Applicable background	Method	Coupling efficiency
Automatic-alignment method	Simulated-annealing algorithm	The single-mode optical-fiber core is small, the manual alignment is time consuming and laborious, and the precision is low	The voltage on the two-dimensional piezoelectric ceramic is controlled to drive the optical-fiber displacement, and the optical-fiber position is adjusted in real time	Reached 51.4%
	SPGD algorithm		The optical-fiber position is adjusted in real time by controlling the voltage on the 5-DOF piezoelectric ceramic	Reached 53.2%
Mode-conversion method		Owing to the influence of atmospheric turbulence, the beam mode degrades and the energy of the fundamental mode decreases	The coupling efficiency of the spatial-optical single-mode fiber is improved by mode conversion	Maximum was 69.2%
Adaptive-optical wavefront correction method		The wavefront distortion caused by atmospheric turbulence reduces the efficiency of coupling the space light and fiber	Adaptive-optics technology is used to effectively improve the coupling efficiency of the space-optical single-mode fiber	Maximum increase was 80.0% at different distances

coupling efficiency of spatial optical fiber from different aspects, such as method classification, application background, specific methods, and coupling efficiency.

Comparison of Domestic and Foreign Research on the Automatic-Alignment Method

Table 13.6 compares the automatic-alignment research results of Xi'an University of Technology to those of Adept Company [89] and Zhejiang University [90], in terms of the alignment platform, control method, automatic-alignment algorithm, and coupling efficiency.

Comparison of Domestic and Foreign Research on Adaptive-Optical Wavefront Correction

Table 13.7 compares the research results of the adaptive-optical wavefront correction method of Xi'an University of Technology to those of Lawrence Livermore Laboratory, Jilin University and Changchun University of Science and Technology, in terms of the correction algorithm, transmission distance, and coupling efficiency. It provides some theoretical basis and reference value for the future research and development in this field.

Table 13.6 Comparison of domestic and foreign automatic-alignment methods

Researcher	Alignment platform	Control method	Automatic-alignment algorithm
Adept Company (U.S.)	Three degrees of freedom x, y, z	Optical-power feedback	Rough alignment: Image processing Fine alignment: Mountain-climbing method
Zhejiang University	3D micro-workbench: x, y, z	Optical-power feedback	Sweep sampling method
Xi'an University of Technology	Five degrees of freedom x, y, z, θx, θy	Optical-power feedback	SPGD algorithm

Table 13.7 Comparison of domestic and foreign achievements in adaptive-optical wavefront correction methods

Researcher	Correction algorithm	Transmission distance (km)	Coupling efficiency
Lawrence Livermore Laboratory, USA	SPGD algorithm	28.2	33.0% increase
Jilin University	SPGD algorithm, no wavefront detection control algorithm	20.0	69.0% increase
Xi'an University of Technology	SPGD algorithm	11.0	35.2% increase
Changchun University of Science and Technology	Zernike mode-correction method	1.0	20.0% increase

Summary

This chapter systematically summarized the domestic and foreign research in the field of space optical-fiber coupling, and introduced the work in related fields by Xi'an University of Technology.

The first part of the chapter discussed overcoming the influence of atmospheric turbulence on the space optical-fiber coupling efficiency, such as improving the beam quality from the source, and optimizing and improving the coupling-system scheme. In the second part, the automatic-alignment, mode-conversion, and adaptive-optical wavefront correction methods were introduced to improve the coupling efficiency.

In simulations and experimental measurements, different technologies improved the coupling efficiency of spatial optical fiber to different degrees. This lays a foundation for development in this field, but also has many shortcomings.

1. Automatic alignment: The algorithm operating bandwidth is low and the piezoelectric-ceramic modules influence each other.
2. Mode conversion: The conversion can only be carried out between single modes, not multiple modes.
3. Adaptive-optical wavefront correction: The correction effect is not obvious for long distances.

In the future, it is necessary to develop more intelligent, convenient, efficient, and simpler spatial optical-coupling technologies, to send more effective optical-signal transmissions and improve the communication quality. To promote the development of spatial light-fiber coupling technology in optical wireless communication, the following areas have been investigated:

1. In the mode-conversion method, an excellent feedback optimization algorithm was studied to realize free-space light mode conversion and improve the fiber-coupling efficiency [75].
2. In the mode-conversion method, based on single-mode conversion, the simultaneous conversion of multiple modes was studied to achieve a better coupling effect [77].
3. In the automatic-alignment method, a more stable and compact optical-fiber structure based on piezoelectric ceramics was developed, which further improved the stability and accuracy of the optical-fiber position [78].
4. To optimize the coupling structure, a more convenient and accurate tuning structure was developed to realize an integrated-transceiver Maka antenna with higher coupling efficiency [82].
5. Automatic spatial light-fiber coupling alignment technology was investigated under different turbulence intensities and transmission models to improve the fiber-coupling efficiency under atmospheric turbulence [83].

Introduction

In optical wireless communication links, atmospheric turbulence affects the optical signal at the receiving end, resulting in amplitude flicker, coherent attenuation, beam spread, and drift, which greatly limit the practical application of optical wireless communication. Therefore, a reasonable description of the refractive-index fluctuation of atmospheric turbulence has become key to the study of atmospheric-turbulence effects.

Atmospheric turbulence is a type of random motion. The turbulence-field parameters change irregularly with time and space. Random fluctuations of the atmospheric refractive index produce various atmospheric-turbulence effects, which seriously restrict the performance of optical wireless communication systems. To suppress the effects of atmospheric turbulence on the performance of optical wireless communication systems, it is necessary to establish a turbulence-spectrum model that can accurately describe atmospheric refractive-index fluctuations.

This chapter summarizes the research progress of atmospheric-turbulence spectral models by scholars at home and abroad in recent years, analyzes the theoretical establishment of different atmospheric-turbulence spectral models (Kolmogorov, Tatarskii, von Kármán, non-Kolmogorov, etc.), and compares their application ranges. In addition, it introduces the turbulence channel models established by experimental measurements in actual atmospheric turbulence, and finally forecasts the development trends of atmospheric-turbulence models.

Atmospheric Refractive-Index Power Spectra

Turbulence Formation

Following theoretical analyses, scholars have successively proposed a variety of atmospheric-turbulence spectral functions [1]. At present, most research on atmospheric-turbulence spectral models is based on the local homogeneous isotropy

of atmospheric turbulence (i.e., Kolmogorov statistical theory of turbulence). However, a large number of observational experiments in recent years have shown that most actual atmospheric turbulence tends to be anisotropic [2]. Therefore, establishing a more accurate atmospheric-turbulence spectral model is key for future research on statistical turbulence characteristics.

As shown in Fig. 14.1, turbulence was initially defined as irregular movement in a fluid, which is reflected in the formation of clouds in the atmosphere and movement of water in rivers. Daily life contains many turbulent flows, such as the blood flow in our own veins and arteries, and the flow of natural gas, oil, and water from their sources to the city interior.

Although turbulence is irregular, it has the following three characteristics [3]:

1. Irregularity and unpredictability: Turbulence is irregular in space and time, with unpredictable random patterns.
2. Statistical characteristics: Some statistical order appears in the irregularity of turbulent motion. The average and correlation are regular and predictable.
3. Mixing and enhanced diffusion: The fluid passes through complex and circuitous paths, resulting in a large amount of mixing of different parts of the fluid. This mixing significantly enhances the diffusion and increases the transfer of momentum, energy, heat, and other advections.

As shown in Fig. 14.2, Reynolds carefully observed the transition from laminar to turbulent flow in a series of experiments at the end of the nineteenth century [3]. First, still water in a water tank was slowly dropped into glass tubes of different diameters, the flow rate of the fluid in different tubes was changed, and the flow was observed in different tubes.

Reynolds believed that a dimensionless critical value could exist. Once the critical value was exceeded, the laminar flow would produce "bending" movement. The above experiments confirmed the existence of a critical value. Reynolds used the similarity theory to define this dimensionless quantity, called the Reynolds number [4]:

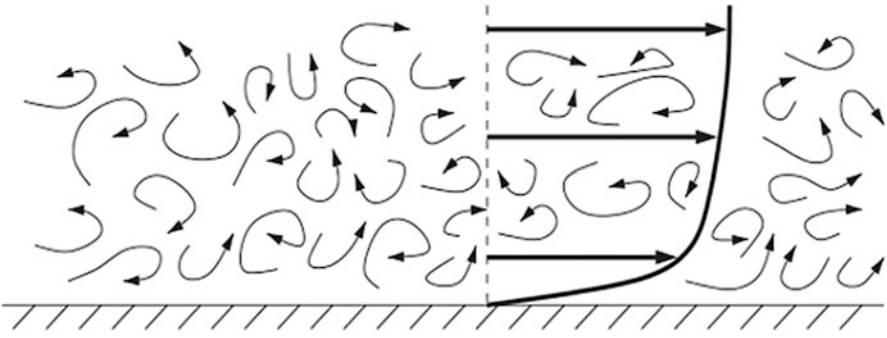

Fig. 14.1 Schematic diagram of irregular turbulent motion [3]

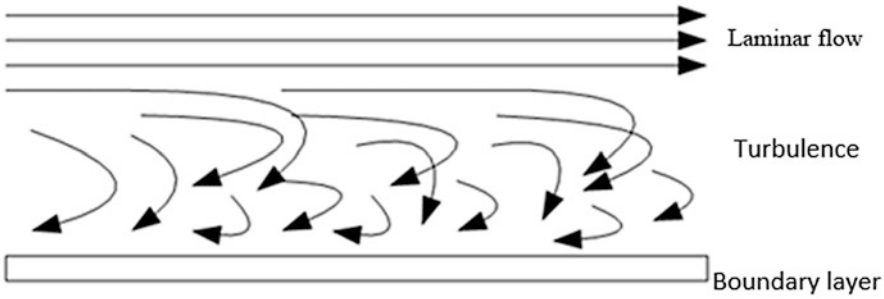

Fig. 14.2 Schematic diagram of laminar-flow and turbulent-flow transformation [3]

$$\mathrm{Re} = \frac{\rho \upsilon L}{\mu} = \frac{\upsilon L}{\nu}, \tag{14.1}$$

where L represents the fluid size (unit: m); υ represents the characteristic velocity (unit: m/s); and ρ indicates the fluid density. μ is the fluid's viscosity coefficient with dimension $MT^{-1}L^{-1}$ and $\nu = \frac{\mu}{\rho}$ is the kinematic viscosity coefficient with dimension M^2T^{-1}.

For smaller Re values, the viscosity dominates and the flow is laminar. For larger Re values, the inertial term dominates and the flow becomes more complex, eventually forming turbulence. In practical applications, different types of Reynolds numbers can be used according to the selection of the characteristic velocity and fluid size. In any case, the larger the Reynolds number, the more complex the flow.

Atmospheric Refractive-Index Fluctuation

The atmospheric refractive index is a random field that fluctuates slowly over time [2]. The random field of the atmospheric refractive index can be represented by $n(R, t)$, where t represents the time position, and $R = (x, y, z)$ represents the space position. The change in the atmospheric refractive index with time t is relatively slow, and the function $n(R)$ of the spatial position R is typically used to represent the sample function of the random field.

$\langle n(\mathrm{R})\rangle$ is the mean value of the sample function $n(R, t)$. When $\langle n(R)\rangle$ is independent of the spatial position R, it means that the statistics are uniform at this time. $B_n(R)$ is the covariance function of the random process, which is independent of the specific spatial location and is related only to the location interval $R = R_1 - R_2$. The expression for $B_n(R)$ is as follows [1]:

$$B_n(R) = \langle [n(R_1) - \langle n(R_1)\rangle][n^*(R_2) - \langle n^*(R_2)\rangle]\rangle, \tag{14.2}$$

where $\langle\rangle$ represents the statistical average, R_1 and R_2 are the positions of any two points in space, $n(R)$ is the function of the spatial position R, and $n^*(R)$ is the

conjugate complex function of $n(R)$. Generally, $n(R)$ is locally statistically uniform. The structure function $D_n(R)$ is typically used to describe the statistical characteristics of locally statistically uniform random fields [3] and is expressed as follows:

$$D_n(R) = \left\langle n(R_1 + R) - n(R_1)^2 \right\rangle, \tag{14.3}$$

where $D_n(R)$ is a structural function. Its relationship with the covariance function $B_n(R)$ is as follows:

$$D_n(R) = 2[B_n(0) - B_n(R)]. \tag{14.4}$$

Because $R = R_1 - R_2$, when $R_1 = R_2$, $B_n(R)$ becomes $B_n(0)$.

The power-spectral density $\Phi_n(K)$ and covariance function $B_n(R)$ form a Fourier transform pair; thus, they contain the same information but in different forms. The relationships are expressed as follows:

$$B_n(R) = \int e^{-iKR} \Phi_n(K) dK \tag{14.5}$$

$$\Phi_n(K) = \left(\frac{1}{2\pi}\right)^3 \iiint_{-\infty}^{\infty} e^{-iKR} B_n(R) d^3R, \tag{14.6}$$

where $K = (\kappa_x, \kappa_y, \kappa_z)$ represents the vector wavenumber, unit: *rad/m*; the module $\kappa = |K|$ represents the vector wavenumber, unit: *rad/m*. κ is also called the spatial wavenumber; it is the reciprocal of the spatial scale l; that is, $\kappa \sim 1/l$. e^{-iKR} is a complex variable function. Because the vector distance of $B_n(R)$ and $D_n(R)$ can be simplified into the scalar distance $R = |R_1 - R_2|$, the result can be expressed as

$$\Phi_n(\kappa) = \frac{1}{2\pi^2 \kappa} \int_0^{\infty} B_n(R) \sin(\kappa R) R dR. \tag{14.7}$$

The relationship $\Phi_n(\kappa)$ with $D_n(R)$ is derived:

$$\Phi_n(\kappa) = \frac{1}{4\pi^2 \kappa^2} \int_0^{\infty} \frac{\sin(\kappa R)}{\kappa R} \frac{d}{dR} \left[R^2 \frac{d}{dR} D_n(R) \right] dR. \tag{14.8}$$

Atmospheric Structure Constants

Atmospheric turbulence is anisotropic; however, it can be approximately regarded as a local homogeneous isotropy in a sufficiently small area. On this premise, the atmospheric refractive-index distribution meets the "two-thirds law" of the atmospheric refractive-index structure function $D_n(r)$ proposed by Kolmogorov [6]:

$$D_n(r) = C_n^2 r^{\frac{2}{3}} \quad (l_0 << r << L_0), \tag{14.9}$$

where r is the distance between two points of statistical turbulence characteristics, and l_0 and L_0 are the internal and external turbulence scales, respectively.

When the studied spatial scale is smaller than the inner turbulent scale l_0, viscous dissipation plays a major role in the influence of atmospheric fluctuation and inhibits the further development of turbulence. When the spatial scale is larger than the outer turbulent scale L_0, the inertial force of the air flow plays a major role in the atmospheric-fluctuation characteristics.

The atmospheric refractive-index structure constant C_n^2 is one of the basic parameters in atmospheric optics. Because the atmospheric structure constant on a slanted path is uneven, its size changes with the height. For a horizontal transmission, a typical value of the atmospheric structure constant is generally used. Therefore, to study the propagation characteristics of light beams in atmospheric turbulence, the atmospheric structure constant must be found.

Atmospheric turbulence can be divided into two categories: boundary layer and free atmosphere. The "boundary-layer" turbulence state is greatly affected by ground conditions; its thickness is about tens to hundreds of meters. The other is "free atmosphere" turbulence, which is basically unaffected by the ground. The boundary between the two layers is affected by the geographical environment, macrometeorological conditions, ground conditions, and other factors.

Boundary-layer turbulence is mainly affected by the surface temperature, humidity, and pressure. Wyngaard et al. proved that the relationship between the atmospheric structure constant in the boundary layer and the height is $-3/4$ power, which is a semi-empirical theory; however, the $-3/4$ power relationship well describes the change rule of the atmospheric structure constant over 100 m above the ground [7].

Later, Neff et al. also verified the $-3/4$ power relationship in Wyngaard's theory through an experiment of the change in C_n^2 with height measured by acoustic radar [8]. Kukharets and Tsvang later proposed an exponential model to describe the atmospheric refractive-index structure constant [9].

The atmospheric refractive-index structure constant C_n^2 fluctuates significantly over the course of 1 day, in addition to its variation with height. Figure 14.3 shows an example of the 24-h C_n^2 characteristics of the Rocky Mountains near Boulder, Colorado, at a distance of 2 m from the ground.

Ochs measured the change in the atmospheric structure constant with height h below a 3.2-km altitude. Hufnagel et al. provided a C_n^2 empirical formula applicable in the range of 3–24 km, based on measured data [11]:

$$C_n^2(h) = \left[2.2 \times 10^{-53} h^{10} (W/27)^2 \mathrm{e}^{-h/1000} + 10^{-16} \mathrm{e}^{-h/1500}\right] \cdot \mathrm{e}^{J(h,t)}. \tag{14.10}$$

In Eq. (14.10), J is a uniform Gaussian random variable with a zero mean value, and its correlation function is [12]

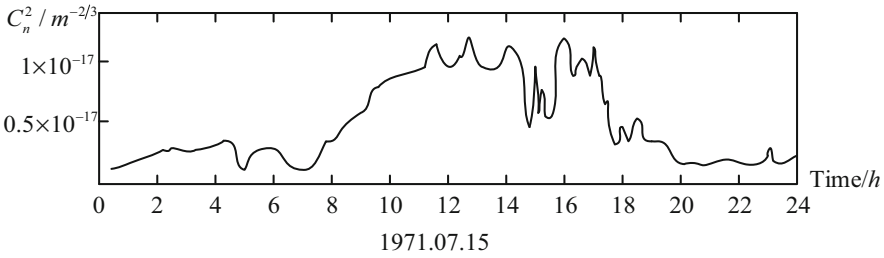

Fig. 14.3 24-h characteristics of C_n^2 on sunny days [10]

$$\langle J(h+h_1, t+\tau)\rangle = A\left(\frac{h_1}{100}\right)\mathrm{e}^{-\tau/5} + A\left(\frac{h_1}{100}\right)\mathrm{e}^{\tau/80}, \tag{14.11}$$

where

$$A\left(\frac{h_1}{100}\right) = \begin{cases} 1 - h/100 & h < 100 \\ 0 & h \geq 100 \end{cases}. \tag{14.12}$$

In Eqs. (14.11) and (14.12), h represents the height and τ is the time interval. The function W represents the root-mean-square velocity of the altitude between 5 and 20 km, expressed as

$$W = \left[\frac{1}{15}\int_5^{20} v^2(h)\mathrm{d}h\right]^{1/2}, \tag{14.13}$$

where (h) is the wind speed at the given altitude.

The typical data for W proposed by Hufnagel [13] is that the mean value is 27 m/s, and the standard deviation is 9 m/s. In 2001, the International Telecommunication Union-Radiocommunication Sector (ITU-R) issued a new atmospheric-structure model. This model makes it possible to theoretically analyze the oblique transmission of light waves [14]. Figure 14.4 shows the change in atmospheric structure constant with height issued by the ITU-R in 2001.

It can be observed that the atmospheric structure constant C_n^2 decreases with an increase in height. At 1–4 km, the atmospheric structure constant is unaffected by the wind speed with $C_n^2(0)$ at the surface. Above 10 km, it is affected by the wind speed [15]:

$$\begin{aligned} C_n^2(h) = {} & 8.148 \times 10^{-56} v_{RMS}^2 h^{10} \mathrm{e}^{-h/1000} \\ & + 2.7 \times 10^{-16} \mathrm{e}^{-h/1500} + C_0 \mathrm{e}^{-h/100}. \end{aligned} \tag{14.14}$$

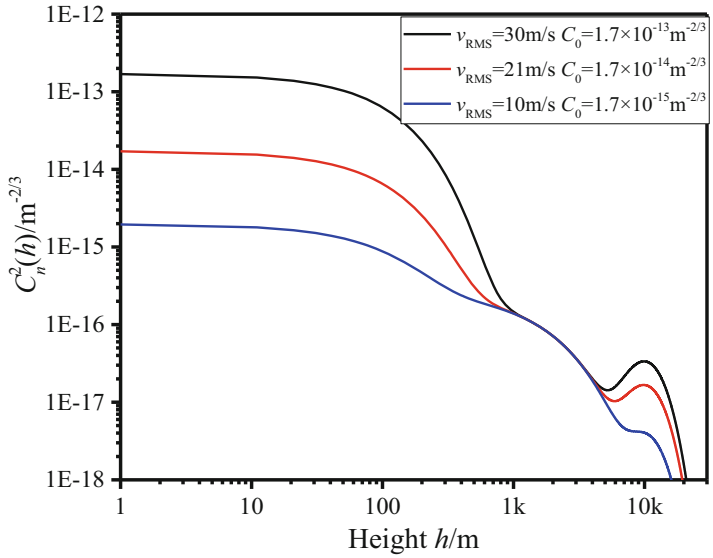

Fig. 14.4 Variation of the atmospheric structure constant with height h

Atmospheric Turbulence Effects

Beam Divergence

As shown in Fig. 14.5, F_0 is the curvature radius of the wavefront of the transmission plane. $F_0 = \infty$, $F_0 > 0$, and $F_0 < 0$ correspond to collimated, focused, and divergent beams, respectively. In the experiment, the beam is typically collimated or focused.

As shown in Fig. 14.6, in an optical wireless communication system, when the laser beam is transmitted in an ideal state, it is focused on the surface of the photodetector through a coupling lens, and then photoelectrically converted to obtain an electrical signal. The ideal facula obtained in the ideal state is denoted as Facula 1 in the figure (Fig. 14.7).

When propagating in atmospheric turbulence, because of the fluctuation of the atmospheric refractive index, the beam expands, and the energy of the beam cross section is reduced. This results in part of the beam not reaching the surface of the photoelectric detector through the coupling lens, such as the beam represented by the dotted line. The light spot obtained on the receiving surface is shown in Fig. 14.8. Atmospheric turbulence increases the light-spot radius and lowers the beam energy [16].

Beam Drift

As shown in Fig. 14.8, a wireless laser-communication system is composed of a transmitting antenna and a receiving antenna. Transmitting and receiving antennas

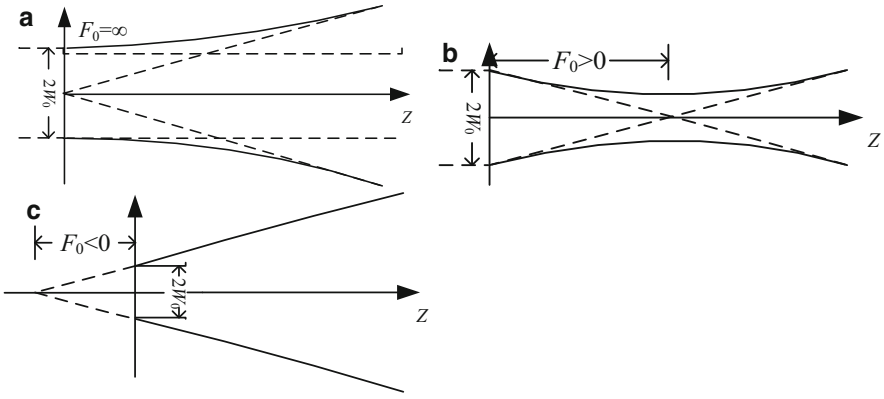

Fig. 14.5 Schematic diagram of different beams. (**a**) Collimated beam; (**b**) focused beam; (**c**) divergent beam

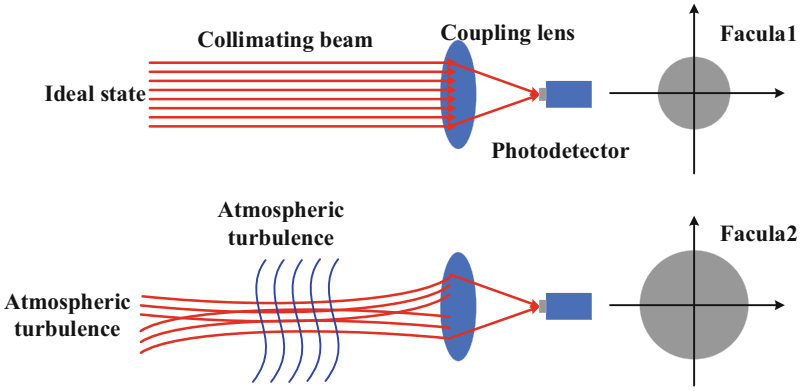

Fig. 14.6 Impact of beam spreading on atmospheric laser-communication system

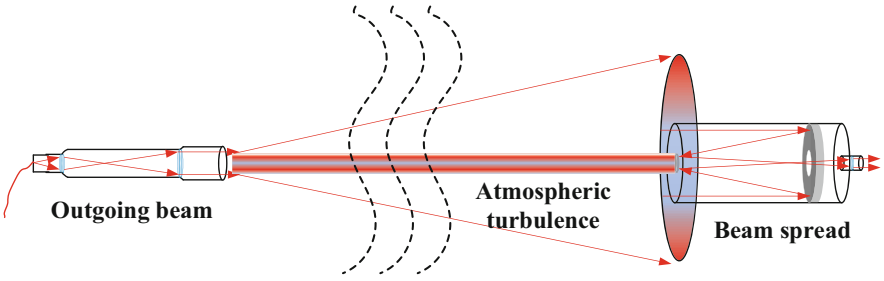

Fig. 14.7 Schematic diagram of beam spread

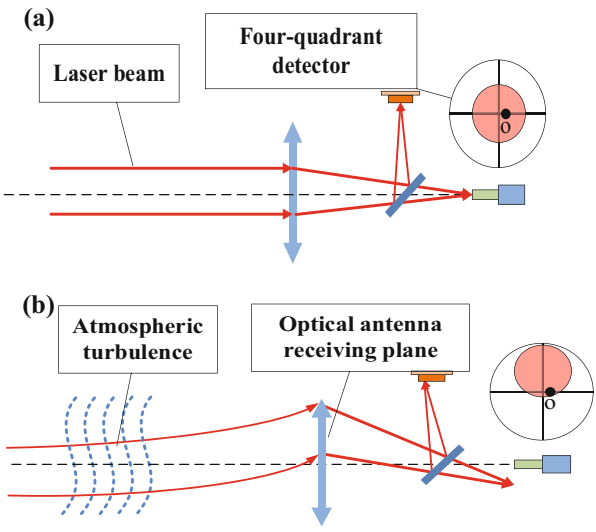

Fig. 14.8 Effect of spot drift on optical wireless communication system. (**a**) Ignoring atmospheric turbulence; (**b**) considering atmospheric turbulence

usually use a Cassegrain telescope; its optical structure can be simplified as a single-lens system. The following can be seen from Fig. 14.8:

1. When atmospheric turbulence is ignored, the transmitting beam is transmitted to the receiving surface of the receiving optical antenna, and its main optical axis coincides with the viewing axis of the receiving antenna. The beam focus is concentrated on the receiving end of the communication detector through the receiving optical system.

A beam-splitter prism is placed on the optical path inside the optical system to divide the receiving optical path into two parts: one for communication detection and the other for spot-position detection. A four-quadrant detector is used as the detection sensor. Using the spot position on the receiving surface of the four-quadrant detector, the center position of the spot can be obtained, and the spot center coincides with the center of the four-quadrant detector [17].

2. When atmospheric turbulence is considered, the beam drifts, owing to the influence of atmospheric turbulence during transmission. The beam moves randomly perpendicular to the optical axis and deviates from the receiving surface. At this time, the optical axis of the transmitted beam no longer coincides with the visual axis of the receiving antenna and includes an angle, which causes the focus of the beam converging through the optical antenna to shift. The shifted focus is no longer incident on the receiving surface of the communication detector.

At this time, the beam power received by the communication detector is significantly reduced, which adversely affects the signal detection of the communication system. The offset of the spot centroid, relative to the central position of the four-quadrant detector, can be detected through four-quadrant detection. With further turbulence development, the transmitting beam may drift completely out of the receiving surface of the receiving antenna. At this time, the receiving antenna cannot converge the transmitting beam, which interrupts the communication link [18].

Beam Spreading

As shown in Fig. 14.9, if we briefly observe the receiving plane, we can see that the distance from the widened spot with radius r_1 to the origin r_2 is the beam-drift amount. If the observation is sufficiently long, we can see that the random walk of the spot will produce a large spot with a mean-square radius of r_3. The former is called short-term beam spreading and the latter is called long-term beam spreading [19, 20].

Beam spreading refers to a change in the spot radius or area on the receiving plane caused by the turbulence vortex. When light passes through a small-scale vortex, it produces a diffraction effect, leading to beam expansion; in contrast, when it passes through a large-scale vortex, it is refracted, causing the beam to drift [21–23].

Light-Intensity Flicker

As shown in Fig. 14.10, when the beam diameter is much larger than the turbulence scale, the beam section contains multiple turbulence vortices, each of which will independently scatter and diffract the beam, causing the optical density on the detector plane to change continuously in time and space.

If the light intensity is measured at a certain distance from the light source in the turbulent atmosphere, the light intensity I will change with time and fluctuate randomly around the average value $<I>$, which is called light-intensity flicker. The magnitude of the flicker is directly related to the strength of the turbulence, and the flicker effect will increase the bit-error rate of the communication system [24–27].

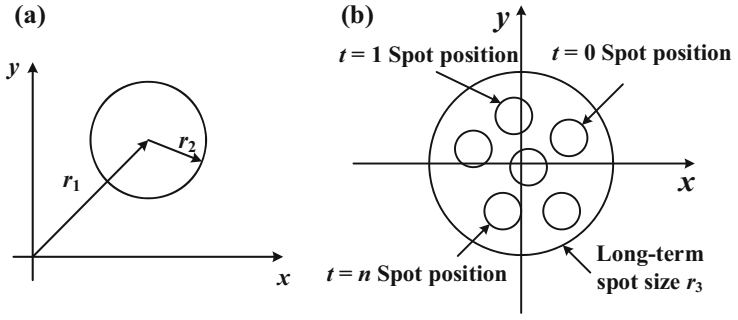

Fig. 14.9 Schematic diagram of a light spot observed on the receiving plane. (**a**) Short-term images; (**b**) long-term images

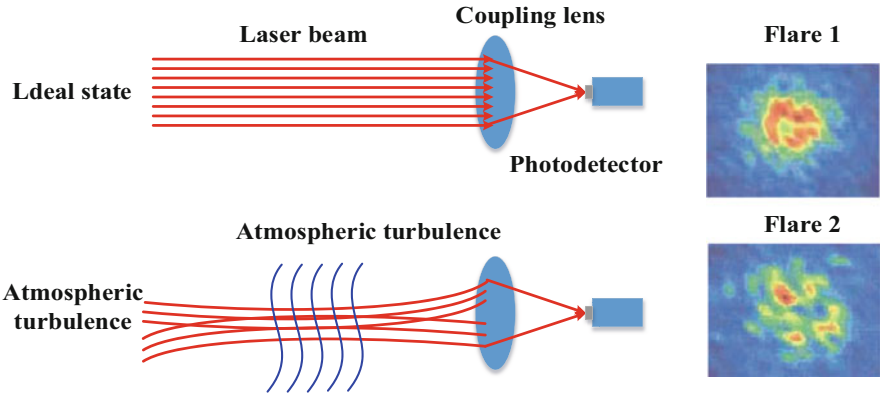

Fig. 14.10 Effect of light-intensity flicker on atmospheric laser-communication system

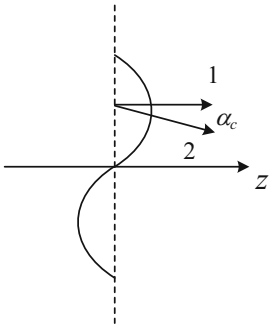

Fig. 14.11 Schematic diagram of the local arrival angle. (1) Uniform phase front normal; (2) equal phase normal

Angle-of-Arrival Fluctuation

As shown in Fig. 14.11, the laser has a uniform wavefront when propagating in a uniform medium. When propagating in a turbulent atmosphere, owing to the fluctuation of the atmospheric refractive index in different parts of the beam cross section, different parts of the beam wavefront undergo different phase changes [28, 29].

As shown in Fig. 14.12, atmospheric turbulence may cause laser-power attenuation, pulse broadening, intensity fluctuation, beam drift, angle-of-arrival fluctuation, and beam spreading. These decrease the signal-to-noise ratio of the communication system, increase the fluctuation variance, and increase the bit-error rate. Compared with fully coherent light, partially coherent light can suppress spot drift, intensity flicker, and angle-of-arrival fluctuation.

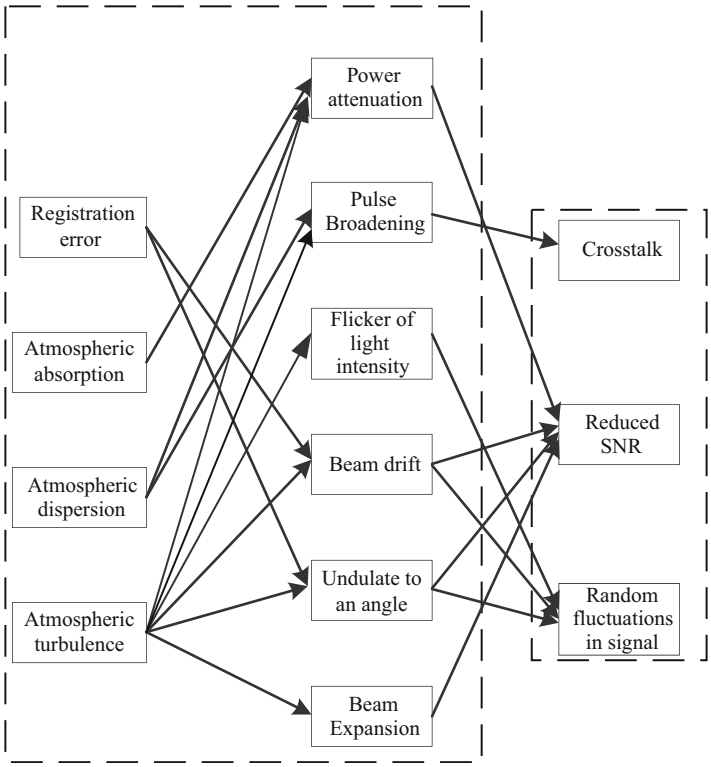

Fig. 14.12 Impact of atmospheric channels on optical communications

Spectral Models of Atmospheric Turbulence

Foreign Research Progress

In his famous turbulence theory [5] published in 1941, Kolmogorov formally proposed the concept of an atmospheric-turbulence power-spectrum model and established the Kolmogorov spectrum model. Subsequently, researchers worldwide began to investigate the atmospheric-turbulence power spectrum and successively established different atmospheric-turbulence spectrum models. The most commonly used models include the Kolmogorov [30], von Kármán [31], Hill [38], and non-Kolmogorov spectra [53].

In 1941, Kolmogorov et al. established the theory of locally isotropic turbulence and proposed that turbulence should be approximated as a locally isotropic Kolmogorov spectrum. In the inertial subregion, the relationship between the atmospheric refractive-index structure function and turbulence structure constant followed the well-known two-thirds law, and the power index of the power spectrum was $-5/3$ [30].

In 1948, von Kármán et al. proposed the von Kármán spectrum to describe the turbulence generated in a circular tube. This spectrum included the influence of both internal and external scales, and avoided the singularity of the power spectrum at the origin. This is applicable to the full wavenumber region [31].

In 1961, Tatarskii et al. established the Tatarskii spectrum by introducing an internal-scale influence factor as the truncation function and extended the application area of the spectrum to the dissipation area (i.e., the area where the energy dissipation exceeds the kinetic energy) [32].

In 1963, von Kármán et al. considered the influence of internal and external turbulence scales, based on the Kolmogorov spectrum, and established a modified von Kármán spectrum, which solved the problem that the Kolmogorov and Tatarskii spectra could not integrate singular points [33].

In 1968, Busch et al. experimentally measured the atmospheric turbulence in different regions. The results showed that the measured one-dimensional velocity spectrum usually followed the $-5/3$ power law, and the wavenumber was far less than that expected within the spectral-inertia subrange [34].

In 1972, Kaimal et al. conducted a study on the turbulence spectrum in a near-ground environment. The results showed that the turbulence power spectrum in the inertial subinterval satisfied Kolmogorov's $-5/3$ law and conformed to the isotropic property [35].

In 1974, Greenwood et al. experimentally measured the turbulence power spectrum on a rough underlying surface and proposed the Greenwood–Tarazano spectrum, based on experimental data [36].

In 1977, Champagne et al. conducted an experimental study on the turbulence spectrum in Minnesota, U.S. The study found that all power-spectral densities showed a bulge at high wavenumbers. When the wavenumbers gradually approached the high-wavenumber area, the spectrum deviated from the $-11/3$ rule and declined rapidly [37].

In 1978, Hill considered the influence of sudden changes in the power spectrum in the region close to a high wavenumber, and proposed a numerical model for accurately describing the spectrum in the inertial and dissipation regions (Hill spectrum) [38].

In 1986, Manning et al. proposed a model to describe the anisotropy of refractive-index fluctuations near the Earth's surface and derived the parameters of the model based on experimental data. The results showed that the anisotropy of the atmospheric-turbulence field could be verified by the difference in the transverse mutual-interference function of the propagating plane wave [39].

In 1990, Kraichnan et al. studied the Kolmogorov spectrum in the inertial range when Fourier mode, homogeneity, and local isotropy were not natural assumptions, gave effective scaling parameters, and generalized the $-5/3$ law for the eigenvalue spectrum of the two-point velocity correlation matrix [40].

In 1992, Andrews et al. proposed the Andrews spectral model based on the Hill spectral model, which reasonably described the protrusion of the power spectrum in the high-wavenumber region [41].

In 1995, based on the Kolmogorov turbulence spectrum, Beland expressed the structure function and turbulence spectrum describing non-Kolmogorov turbulence, and the formulas for the logarithmic-amplitude fluctuation variance and coherent length under weak fluctuation conditions [42].

In 1995, Emaleev et al. investigated the anisotropy of the turbulence spectrum of the ground atmosphere. The results showed that the anisotropy of the low-frequency characteristics of the turbulence spectrum depended largely on the height above the underlying surface [43].

In 1998, Stribling et al. experimentally observed that the exponential value of the measured power function was significantly different from the eigenvalue of the Kolmogorov theoretical spectrum. Based on the assumption of turbulence isotropy, they studied the basic relationship between the exponential structural function and exponential power spectrum [44].

In 1999, Mikhail et al. studied the anisotropy of the horizontal and vertical tilt components caused by the anisotropy of turbulence near an optical antenna. The results showed that, owing to the turbulence anisotropy, the power spectrum of the horizontal tilt exceeded that of the vertical tilt [45].

In 2004, Lipatack et al. defined the generalized Tatarskii spectrum, which expanded the structure function to a smaller power-law value, had singularity when $K = 0$, and was effective for all beams [46].

In 2007, Phillips et al. compared the von Kármán spectrum with the Hill spectrum and obtained a method to estimate the external atmospheric-turbulence scale, based on the correlation function of the transverse displacement of a horizontal transmission beam [47].

In 2008, Zilberman et al. studied the turbulence characteristics of a communication link under a change of the logarithmic amplitude, based on the three-layer model of the refractive-index fluctuation spectrum in a free atmosphere. They proposed a turbulence-spectrum model that varied with altitude, according to the experimental and theoretical data of the troposphere and the lower-stratosphere turbulence profile [48].

In 2008, Toselli et al. proposed a non-Kolmogorov turbulence power-spectrum model that explained the heterogeneity and anisotropy of atmospheric turbulence [49].

In 2010, Zilberman et al. analyzed the impact of Kolmogorov and non-Kolmogorov turbulence statistics on the laser-communication link for different transmission scenarios [50].

In 2014, Toselli et al. proposed an anisotropic atmospheric-turbulence spectrum and described in detail the asymmetry of atmospheric-turbulence vortices in the vertical and horizontal directions [51].

In 2018, Helin et al. observed the problem of joint estimation of a turbulence profile and unknown power-spectral density on the ground. They proposed three numerical-reconstruction methods that could accurately locate local disturbances under the non-Kolmogorov power-spectral density [52].

In 2021, Santos et al. studied nearly isotropic turbulence through experiments, determined the flow-field characteristics that affected the dissipation frequency, and modified the von Kármán spectrum to simulate the dissipation range [53].

In 2021, Goldman et al. used an analytical model of steady turbulence to obtain the inertial-range power spectrum of compressible turbulence. The results showed that the rate of controlling the energy transferred to all relatively large quantities through turbulent viscosity decreased, and the inertial range was a power law with exponent −2 [54].

In 2021, Hosoi et al. adopted the inertial-dissipation method of the Kolmogorov turbulence theory and von Kármán spectral model. The analysis results showed that the average value of the logarithm of the turbulent dissipation rate increased with decreasing height [55].

Domestic Research Progress

With the continuous investigation of the optical characteristics of atmospheric turbulence, domestic scholars have conducted a large number of experimental measurements and theoretical analyses on the atmospheric-turbulence power spectrum from different regions, meteorological conditions, and underlying surfaces. They further improved the theory of atmospheric-turbulence spectrum models and laid a solid foundation for subsequent research on atmospheric turbulence.

In 1975, Zhou et al. defined a vortex Reynolds number R_a, established the relationship between the vortex scale and vortex Rayleigh number, and derived the turbulent energy-spectrum exchange function related to the binary velocity [56].

In 1978, Liu et al. proposed a dimensionless quantity R_i to describe the characteristics of the atmospheric-turbulence power spectrum, based on the distribution of an inversed turbulence spectrum obtained from a large amount of measured atmospheric-turbulence power-spectrum data, and used this dimensionless quantity to divide the spectral area [57].

In 1984, An et al. proposed a formula for calculating the energy-spectrum density of homogeneous isotropic turbulence. The results showed that the turbulence-energy spectrum in the wavenumber range of the dissipation zone was consistent with the actual measurement results [58].

In 1986, Song et al. studied the influence of the von Kármán turbulence spectrum and exponential spectrum on beam drift in weak and strong fluctuation regions, respectively. The results showed that the theoretical values obtained with the different turbulence spectra were consistent with the experimental results [59].

In 1986, based on the frozen-fluctuation hypothesis, Wu et al. used the path-integral method of the parabolic-wave equation to define the relevant scale of the generalized refractive-index fluctuation power spectrum, in the case of a strong fluctuation limit with diffraction parameter λ. The results showed that when the propagation distance was far greater than the transverse scale of the refractive-index fluctuation, the refractive-index correlation scale had little influence on the optical-wave fluctuation characteristics [60].

In 1992, Wang et al. conducted turbulence-observation experiments in Lanzhou City, China, and analyzed the wind-speed component spectrum, temperature spectrum, and momentum co-spectrum. The results showed that the terrain features had little influence on the turbulence-spectrum features [61].

In 1993, Xu et al. studied the intensity, correlation coefficient, scale, and velocity spectrum of atmospheric-surface turbulence in Guangzhou, China. The results showed that in the urban near-surface layer, the turbulence behavior was consistent with the local isotropy law of the inertial subregion, which conformed to the Kolmogorov spectrum theory [62].

In 1998, Hu et al. used discrete orthogonal wavelets to conduct a multiscale decomposition of the boundary-layer turbulence fluctuation signals. The results showed that the energy spectral density was a power-exponential function of the frequency, and the turbulence spectral scale index met the $-5/3$ of the Kolmogorov spectrum [63].

In 1998, Zeng et al. analyzed the near-ground temperature power spectrum of a complex terrain in an actual atmosphere. The results showed that the power rate of the temperature spectrum was steep for complex terrain, and was between $-5/3$ and -3, which did not conform to the Kolmogorov turbulence-spectrum theory [64].

In 1999, Rao analyzed the turbulence intermittency and its model and established an intermittency model of the turbulent temperature field according to experimental data [65].

In 2000, Rao et al. proposed a theoretical method to analyze the temporal and spatial characteristics of non-Kolmogorov turbulent phase fluctuations and obtained their time-structure function and power spectrum [66]. In the same year, they proposed a new method to measure the power-spectrum exponential-decline factor for non-Kolmogorov turbulence [67].

In 2005, Zhu et al. proposed a method for simultaneously inverting the turbulence internal scale and refractive-index structure constant using the Andrews spectral model [68].

In 2005, Zhang et al. summarized the research status of the atmospheric-turbulence power spectrum and established a simplified turbulence power-spectrum model, based on the modified von Kármán spectrum [69].

In 2005, Liu et al. performed experimental measurements of the local turbulence isotropy. The results showed that in the inertial subregion, the turbulence spectrum conformed to the $-2/3$ exponential law of Kolmogorov turbulence; however, in the low-frequency region, it was in a decentralized state [70].

In 2006, Ma et al. measured the atmospheric-scintillation spectrum by building an 800-m laser-transmission experimental platform. The results showed that the high-frequency power index in the actual atmospheric-turbulence spectrum exhibited an unstable random fluctuation, in which the decline rate of the high-frequency spectrum was closely related to the distribution of the dissipation area of the turbulence spectrum [71].

In 2007, Gong et al. simulated the turbulence power-spectrum characteristics based on a numerical-prediction model. The slope of the power spectrum obtained

from the experimental simulation was nearly twice that of the turbulence power spectrum in the actual atmosphere [72].

In 2008, Wu et al. established a near-surface atmospheric estimation and prediction model and verified its validity using field measurement data [73].

In 2008, Wu et al. tested the hypothesis of local homogeneity on the surface of snow and fitted the spectral power rate to the normalized spectrum. The fitting result was 85%, which was consistent with −5/3 [74].

In 2010, Zhao et al. experimentally measured atmospheric-turbulence characteristics using microwave rangefinders and established a preliminary framework for a prediction model for sea-surface atmospheric refractive-index fluctuations [75].

In 2010, Ma et al. modified the non-Kolmogorov power spectrum based on the consistency between the refractive-index structure function and the power-spectral density and estimated the impact of non-Kolmogorov turbulence on the angle-of-arrival fluctuation [76].

In 2011, Jin et al. simulated multichannel radiant-brightness temperatures by using the atmospheric data measured during typhoon Phoenix. They proposed an improved atmospheric-absorption model and built a statistical matrix for retrieving atmospheric temperature profiles [77].

In 2011, Xue et al. deduced a generalized modified atmospheric-spectral model containing limited internal and external turbulence scales. The power-law value of this spectrum was between 3 and 5, instead of the standard power-law value of 3/12. When the internal and external scales were set to zero and infinity, respectively, the spectral model was simplified to a classic non-Kolmogorov spectrum [78].

In 2014, Li studied the change in the working frequency of the atmospheric-noise spectral density in the range of 10 Hz–1 kHz. The results showed that the atmospheric-noise level in autumn was significantly higher than that in spring, and the atmospheric-noise spectral density was close to a log-normal distribution [79].

In 2014, Ai et al. started with Kolmogorov's atmospheric-turbulence theory, elaborated on Kolmogorov's turbulence spectrum, and compared the similarities and differences between the Kolmogorov, Tatarskii, and other models [80].

In 2016, Li et al. obtained the anisotropic power spectrum of hypersonic-turbulence refractive-index fluctuation by transforming the generalized anisotropic von Kármán spectrum [81].

In 2018, Wang et al. conducted an experimental study on laser transmissions with a 610-m link length in Lanzhou. They measured the atmospheric refractive-index structure constant in sunny, overcast, dusty, sleet, and rainy weather conditions using the scintillation method. The results showed that atmospheric turbulence was medium intensity in all weather types [82].

In 2018, Zhang et al. built an indoor simulation device for non-Kolmogorov turbulence. They found that the power-law change in the time spectrum was primarily affected by the atmospheric-turbulence model [83].

In 2019, Changqiong Hu et al. introduced the calculation methods for various types of atmospheric-turbulence characteristic parameters and conducted experimental measurements of the atmospheric-turbulence power spectrum near the

ground level at the bridge location. The results showed that the power spectrum density increased by 1 to 2 orders of magnitude at high wind speeds compared to low wind speeds [84].

In 2021, Zhao et al. established a non-Kolmogorov turbulence spectrum with an anisotropic tilt angle on horizontal and satellite links, and derived the analytical expression of the scintillation index of the anisotropic non-Kolmogorov horizontal and satellite links [85].

In 2022, Yang et al. conducted an experimental study on the spectral characteristics and similarity laws of turbulence in the Qinghai, Tibet region. The results showed that the slope of the inertial subzone of the wind speed and temperature spectra in all directions followed the $-2/3$ rule, and both met the isotropic conditions [86].

Power-Spectrum Models of Atmospheric Turbulence

Because the turbulent-flow field is a random function of time and space variables, statistics are required to describe it. To fully understand and describe the statistical characteristics of a turbulent-flow field, it is necessary to understand the atmospheric refractive-index power spectrum. However, because it is difficult to accurately obtain the statistical properties of high-order moments theoretically and experimentally, turbulence statistical theory usually focuses on the statistical properties of low-order moments, especially the second-order statistical properties.

The power-spectrum model of atmospheric refractive-index fluctuation differs in different turbulent environments. To further study the optical-transmission characteristics in atmospheric turbulence, scholars have successively proposed a variety of atmospheric refractive-index power-spectrum models suitable for different conditions, as shown in Tables 14.1 and 14.2.

The atmospheric refractive-index power spectrum model was developed from the original Kolmogorov spectrum, with an assumed external scale $L_0 \to \infty$ and internal scale $l_0 = 0$, to the von Kármán spectrum, which reflects the characteristics of internal and external scales, to the more accurate universal Hill spectrum model, as well as the non-Kolmogorov spectrum, which is most consistent with the actual atmospheric characteristics at present [87]. The development of these models also marks the continuous improvement of current theoretical turbulence research.

Kolmogorov Spectrum

In 1941, Kolmogorov proposed three assumptions about the equilibrium state in uniform turbulence at a sufficiently high Reynolds number and sufficiently small scale, and thus established the basis of classic turbulence theory [30]:

Table 14.1 Power-spectrum models of the atmospheric-turbulence refractive index

Power-spectrum name	Function
Kolmogorov	$\Phi_n(\kappa) = 0.033 C_n^2 \kappa^{-11/3}$
Tatarskii	$\Phi_n(\kappa) = 0.33 C_n^2 \kappa^{-11/3} \exp\left(\frac{\kappa^2}{\kappa_m^2}\right)$
Von Kármán	$\Phi_n(\kappa) = 0.33 C_n^2 \kappa^{-11/3} \exp\left(\frac{\kappa^2}{\kappa_m^2}\right)$
Modified von Kármán	$\Phi_n(\kappa) = 0.33 C_n^2 \frac{\exp\left(-\kappa^2/\kappa_m^2\right)}{\left(\kappa^2+\kappa_0^2\right)^{11/6}}$
Greenwood–Tarazano	$\Phi_n(\kappa) = 0.33 C_n^2 \left(\kappa^2 + \kappa\kappa_0\right)^{-11/6}$
Hill	$\Phi_n(\kappa) = 0.033 C_n^2 \kappa^{-11/3} \times \left\{ \exp\left(-1.2\kappa^2 l_0^2\right) + 1.45 \exp\left[-0.97(\ln \kappa l_0 - 0.452)^2\right] \right\}$
Andrews	$\Phi_n(\kappa) = 0.033 C_n^2 \left[1 + a_1(\kappa/\kappa_l) - a_2(\kappa/\kappa_l)^{7/6}\right] \frac{\exp\left(-\kappa^2/\kappa_l^2\right)}{\left(\kappa_0^2+\kappa^2\right)^{11/6}}$
Non-Kolmogorov	$\Phi_n(\kappa, \alpha) = \Gamma(\alpha - 1)\cos(\alpha\pi/2)/(4\pi^2)\widetilde{C}^2{}_n \kappa^{-\infty}$
Generalized modified non-Kolmogorov	$\Phi_n(\kappa, \alpha) = \frac{A(\alpha)\widetilde{C}_n^2}{\left(\kappa^2+\kappa_0^2\right)^{\alpha/2}} \exp\left(-\kappa^2/\kappa_m^2\right)$

Table 14.2 Classification diagram of atmospheric-turbulence refractive-index power-spectrum models

Turbulence type	Power-spectrum type	Power spectrum	Internal-scale influence	External-scale influence
Kolmogorov turbulence (power-law value is 11/3)	Basic	Kolmogorov	Not considered	Not considered
	Mathematical derivation	Tatarskii	Considered	Not considered
		Von Kármán	Considered	Considered
	Physical analysis	Greenwood–Tarazano	Considered	Considered
		Hill	Considered	Considered
		Andrews	Considered	Considered
Non-Kolmogorov turbulence (power-law value is between 3 and 5)	Basic	Non-Kolmogorov	Not considered	Not considered
	Mathematical derivation	Generalized modified non-Kolmogorov	Considered	Considered

1. Small-scale turbulent motion is statistically isotropic.
2. The statistics of small-scale turbulent motion have the energy-dissipation rate ε and kinematic viscosity v, which is the only general form to be determined. This scale range is also called the universal equilibrium range.
3. Large-scale turbulent-motion statistics have a unique ε, whose general form can be determined and is independent of v.

Turbulence satisfying these three assumptions is called Kolmogorov turbulence [30]. The Kolmogorov theory of local isotropic turbulence allows for nonuniformity and anisotropy on a large scale. It is assumed that with the cascade transfer of energy to a small scale, the directional effect generated on a large scale becomes increasingly smaller and weaker, until the vortex motion becomes statistically uniform, isotropic, and independent of the specific energy-generation mechanism.

Based on the research results of Kolmogorov's turbulence theory, turbulence can be divided into input, inertia, and dissipation areas, according to the size of the spatial wavenumber κ (see Fig. 14.13). In the figure, r represents the turbulence scale, and l_0 and L_0 are the internal and external turbulence scales, respectively.

The region of $\kappa < 2\pi/L_0$ is the input region, in which $\Phi_n(\kappa)$ is usually anisotropic. The area of $2\pi/l_0 > \kappa > 2\pi/L_0$ is the inertial area; at this time, the shape of $\Phi_n(\kappa)$ is determined by the physical laws that restrict the breaking of large turbulent vortices into small ones. When κ continues to increase until $\kappa > 2\pi/l_0$, the turbulence area enters the dissipation area. The turbulent energy in the dissipation area dissipates much more than the generated kinetic energy, so $\Phi_n(\kappa)$ declines significantly more rapidly.

Kolmogorov proposed that when R is less than L_0, the turbulence is locally statistically homogeneous and isotropic [6]. In the inertial subregion, the

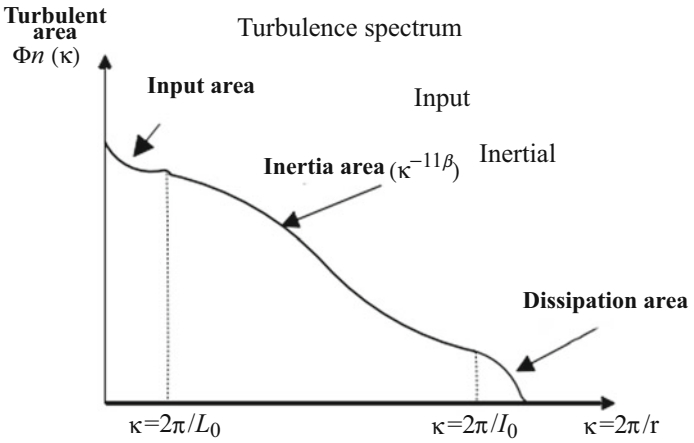

Fig. 14.13 Kolmogorov turbulence-spectrum model [4]

refractive-index structure function $D_n(R)$ is proportional to the two-thirds power of the scalar distance R:

$$D_n(R) = C_n^2 R^{2/3}, \tag{14.15}$$

where C_n^2 is the atmospheric refractive-index structure constant, and the unit is $m^{-2/3}$. The Kolmogorov spectrum can be obtained by substituting Eq. (14.15) into Eq. (14.16):

$$\begin{aligned} \Phi_n(\kappa) &= \frac{\Gamma(a+1)}{4\pi^2} \sin[(a-1)\pi/2] C_n^2 \kappa^{-a-2} \\ &= 0.033 C_n^2 \kappa^{-11/3}, 1/L_0 \le \kappa \le 1/l_0, \end{aligned} \tag{14.16}$$

where $a = 5/3$ and $\Gamma(a)$ represents the gamma function.

Tatarskii Spectrum

In the atmospheric-boundary layer, the characteristic-length scale of turbulent motion is the turbulence scale, defined as follows [5]:

$$L = \frac{1}{\sigma^2} \int_0^\infty R(r) dr, \tag{14.17}$$

where σ^2 is the variance of the velocity component or temperature, r is the spatial displacement, and $R(r)$ is the sum of the autocorrelation functions of the velocity component or temperature. L is the turbulence scale.

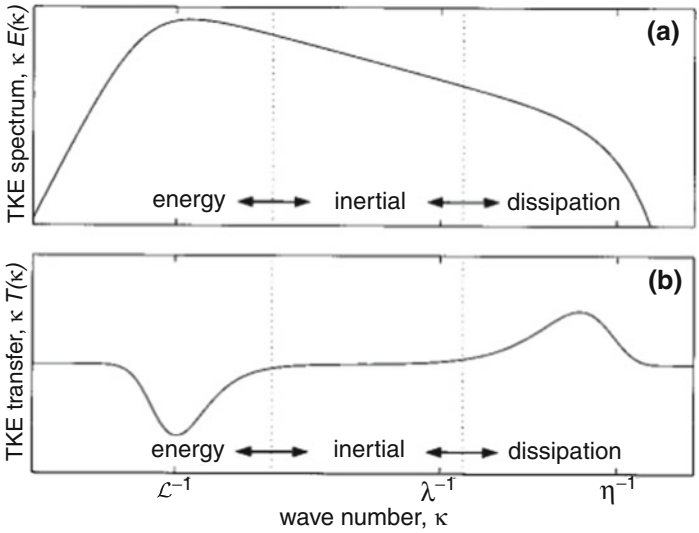

Fig. 14.14 Spectral map of the corresponding turbulence scale [5]

Figure 14.14a shows the spectrum of turbulent kinetic energy (TKE), where $E(k)$ is the TKE per unit mass. Figure 14.14b shows the TKE spectral conversion, where $T(k)$ is the amount of energy transferred from the wavenumber to all other wavenumbers.

Kolmogorov's inertial subrange scale is only applicable to the smaller turbulent scale. However, in actual atmospheric turbulence, there is no universal value for the turbulence scale, owing to the influence of atmospheric conditions, height above the ground, and terrain structure.

Tatarskii obtained a spectrum function by introducing a turbulence internal-scale parameter ($\kappa_m = 5.92/l_0$), which has the form of a Gaussian function, $\exp\left(\frac{\kappa^2}{\kappa_m^2}\right)$. For mathematical-description convenience, Tatarskii improved the power spectrum [15] used by Novikov in the study of turbulent wind-speed fluctuation, applied it to the study of atmospheric refractive-index fluctuation, and established the Tatarskii spectrum [33]:

$$\Phi_n(\kappa) = 0.33C_n^2\kappa^{-11/3}\exp\left(\frac{\kappa^2}{\kappa_m^2}\right), \kappa > 1/L_0, \kappa_m = 5.92/l_0. \tag{14.18}$$

The Tatarskii spectrum can only be applied to the dissipation area, and the definition domain of the Eqs. (14.16) and (14.18) spectral model has a singular point ($L_0 \to \infty$). This means that the structure function $D_n(R)$ in Eq. (14.15) can be calculated; however, the covariance function $B_n(R)$ in Eq. (14.14) cannot be calculated. Therefore, the Tatarskii spectrum is isotropic only when it is in the inertial region or outside the dissipative region.

Von Kármán Spectrum

The Kolmogorov and Tatarskii spectra are homogeneous and isotropic only outside the inertial region or dissipation region (i.e., $\kappa = 1/L_0$); when $\kappa < 1/L_0$, it is generally considered to be nonuniform, and its form is unknown [35]. The von Kármán spectrum improves the Kolmogorov and Tatarskii spectrum models and expands the range of κ to 0–∞; thus, it is also uniform and isotropic in the range of $\kappa < 1/L_0$. Therefore, the spectrum can contain all the beam ranges.

When the spatial wavenumbers, $D_n(R)$ and $B_n(R)$ of the von Kármán spectrum also exist simultaneously, which solves the problem that the Kolmogorov and Tatarskii spectra cannot integrate singular points. The von Kármán spectral expression is [7]

$$\Phi_n(\kappa) = 0.33C_n^2\left(\kappa^2 + \kappa_0^2\right)^{-11/6}, 0 \le \kappa \le \infty, \kappa_0 = 2\pi/L_0. \tag{14.19}$$

When the inertial region is $\kappa_0 \le \kappa \le \kappa_m$, Eq. (14.19) can be transformed into the Kolmogorov spectrum in Eq. (14.16).

To fully consider the influence of the inner and outer turbulence scales, the inner turbulence-scale parameter κ_m is also introduced into the von Kármán model, and a modified von Kármán spectrum is proposed. The spectrum expression is as follows [31]:

$$\Phi_n(\kappa) = 0.33C_n^2 \frac{\exp\left(-\kappa^2/\kappa_m^2\right)}{\left(\kappa^2 + \kappa_0^2\right)^{11/6}}, 0 \le \kappa \le \infty; \kappa_m = 5.92/l_0, \kappa_0 = 2\pi/L_0, \tag{14.20}$$

where $0 \le \kappa \le \infty$, $\kappa_0 = 2\pi/L_0$, and $\kappa_m = 5.92/l_0$. When the inertial region is $\kappa_0 \le \kappa \le \kappa_m$, Eq. (14.20) can be transformed into the Kolmogorov spectrum. However, outside the inertial region, Eq. (14.20) does not reflect the influence of mutation factors in the high-wavenumber region, so it cannot accurately describe the actual physical phenomena [40]. In view of their convenience in theoretical calculations, the Tatarskii and von Kármán spectra have become widely used models for subsequent research on refractive-index power-spectrum theory.

Greenwood–Tarazano Spectrum

The von Kármán spectrum describes the fluid in a pipe, which has only one characteristic dimension, namely, the pipe diameter. However, actual atmospheric turbulence has many characteristic scales because of the height, boundary-layer thickness, and nonuniform ground scales in the atmospheric boundary layer; therefore, the von Kármán spectrum cannot fully describe the actual atmospheric turbulence [39].

Because the temperature spatial-structure function is related to the spatial power spectrum and does not depend on the Taylor freezing hypothesis, Greenwood et al.

reconstructed the refractive-index spectrum by using a spatial structure function measured experimentally and compared it with the von Kármán spectrum. The results showed that the von Kármán spectrum is not the best model, according to the data. Hence, Greenwood et al. proposed the Greenwood–Tarazano spectrum [35], based on experimental data:

$$\Phi_n(\kappa) = 0.33C_n^2\left(\kappa^2 + \kappa\kappa_0\right)^{-11/6}, 0 \le \kappa \le \infty, \kappa_0 = 2\pi/L_0. \tag{14.21}$$

Equation (14.21) combines experimental-measurement data based on Eq. (14.18) and replaces the internal-scale parameter κ with external-scale parameter κ_0. Therefore, compared with the von Kármán spectrum, the Greenwood–Tarazano spectrum decreases faster in the inertial subrange [39].

Hill Spectrum

Strictly speaking, the spectral models represented by Eqs. (14.16, 14.17, 14.18, 14.19, 14.20, and 14.21) are correct only in the inertial subrange because their application scope in the noninertial turbulence subrange is only in the mathematical sense. They cannot be reasonably explained in the physical sense. Champagne et al. [54] proved, according to experimental measurements, that the power-spectrum density has a small protrusion feature when it is close to $1/l_0$ of the high wavenumber (see Fig. 14.15); however, the power spectrum described in Eqs. (14.18, 14.19, 14.20, and 14.21) does not have this feature.

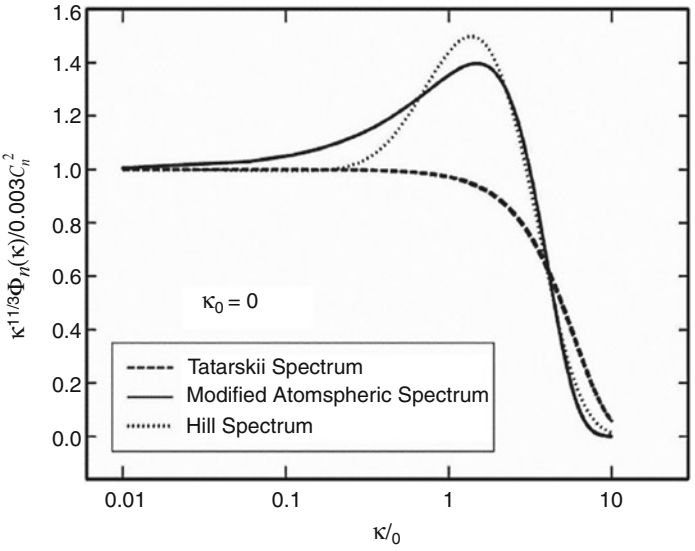

Fig. 14.15 Power-spectral density curves [63]

Figure 14.15 shows the Tatarskii, Andrews, and Hill spectral-density curves. Unlike the continuous decline of the Tatarskii spectrum, in the Hill and Andrews spectra, $\kappa = -1/l_0$; hence, the curve protrudes at $1/l_0$, and then drops rapidly.

Based on experiments, Hill considered the influence of mutation factors in the high-wavenumber region of the power spectrum; that is, the power spectrum changes from the inertial-convection range to the viscous-convection range in the relatively high-wavenumber region, and combines the κ –11/3 power law with the κ –3 power law. He then proposed the Hill spectrum, a numerical model that accurately described the inertial and dissipation regions [33]:

$$\begin{aligned}&\Phi_n(\kappa) = 0.033C_n^2\kappa^{-11/3}\\&\times\left\{\exp\left(-1.2\kappa^2 l_0^2\right) + 1.45\exp\left[-0.97(\ln\kappa l_0 - 0.452)^2\right]\right\}, 1/L_0 \le \kappa \le 1/l_0,\end{aligned} \tag{14.22}$$

where exp represents the exponential function with a constant e as the base, and ln represents the logarithm with a constant e as the base. The Hill spectrum is the solution to the following second-order linear variance:

$$\begin{aligned}&\frac{d}{dK}\left\{K^{14/3}\left[13.9K(0.135l_0)^{3.8} + 1\right]^{-0.175}\frac{d}{dK}\Phi_n(K)\right\}\\&\quad = 1.41K^4(0.135l_0)^{4/3}\Phi_n(K).\end{aligned} \tag{14.23}$$

Equation (14.23) is the second-order linear variance obtained by Hill in analyzing the experimental data, and the Hill spectrum is the numerical solution of Eq. (14.23). Because of the effect of the internal-turbulence scale, l_0, this spectrum differs from the Kolmogorov spectrum. Before entering the fast exponential decline, there is no rapid decline, but a small peak in the rise.

Andrews Spectrum

Owing to the complex form of the Hill spectral model, it is inconvenient for theoretical calculations [14]. Andrews interpolated the Hill spectrum model to provide the same theoretical model as the von Kármán turbulence spectrum. It describes the protrusion at high wavenumbers and has a mathematical form that is easy to handle, as shown in Eq. (14.24) [40]:

$$\Phi_n(\kappa) = 0.033C_n^2\left[1 + a_1(\kappa/\kappa_l) - a_2(\kappa/\kappa_l)^{7/6}\right]\frac{\exp\left(-\kappa^2/\kappa_l^2\right)}{\left(\kappa_0^2 + \kappa^2\right)^{11/6}}, \tag{14.24}$$

where $a_1 = 1.802$, $a_2 = 0.254$ and $\kappa_l = 3.3/l_0$. From Eq. (14.24), it can be seen that the Andrews spectral model can be simplified to the von Kármán spectral model

when $\alpha_1 = \alpha_2 = 0$. Moreover, the Andrews and von Kármán spectral models can be changed to the Kolmogorov spectral model when $\kappa_0 = l_0 = 0$.

The von Kármán spectrum is essentially the same as the Kolmogorov spectrum in the inertial subrange. With an increase in the wavenumber, the von Kármán spectrum decreases sharply and monotonically. The Hill and Andrews spectra differ significantly from the Kolmogorov spectrum in the high-wavenumber region of the inertial subregion, reflecting the impact of high-wavenumber mutations on optical transmissions.

Figure 14.16 shows the variation of the atmospheric refractive-index power spectrum with the spatial wavenumber. In Fig. 14.16, the outer scale $L_0 = 10$ m, inner scale $l_0 = 1$ cm, and the Kolmogorov, von Kármán, and Andrews spectra decrease with an increase in the spatial wavenumber. In the inertial-turbulence subregion, the three types of turbulence spectra exhibit the same trend, following the "−11/3" rule. When the spatial wavenumber increases to reach the dissipation region, the fluctuation of the Andrews spectrum in the dissipation region is well suppressed. However, the Kolmogorov and von Kármán spectra are unstable in the high-frequency turbulent dissipation region.

Non-Kolmogorov Spectrum

The classic Kolmogorov theory, based on the Richardson energy cascade, indicates that all turbulent vortices are isotropic in the inertial subscale range. However, in a free atmosphere, especially in a stable stratified stratosphere, turbulence may become

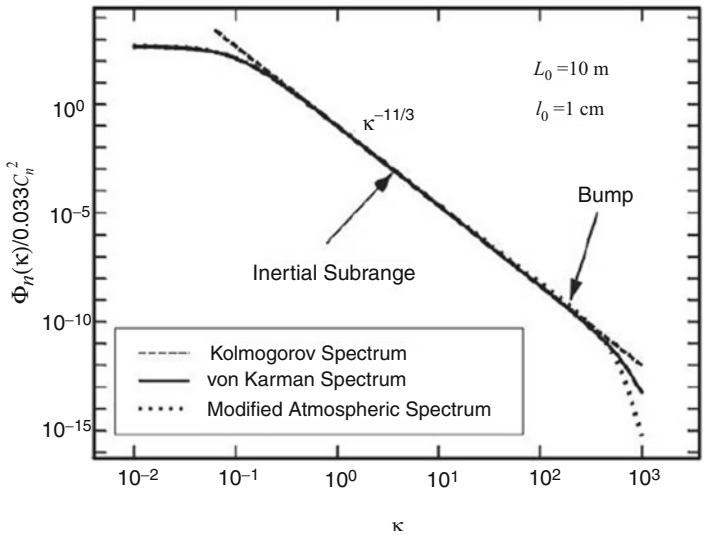

Fig. 14.16 Variation of the atmospheric refractive-index power spectrum with the spatial wavenumber [63]

anisotropic on a large scale, and most anisotropic cases occur in the boundary layer, namely, the ground, buildings, aircraft, etc.

Turbulence does not always follow the Kolmogorov power-spectrum model [5], even within the inertial range. This is due to the extraction of turbulent energy by buoyancy, resulting in a sharp decline in the energy-transfer rate. Therefore, kinetic energy is transmitted in the entire spectrum at a nonuniform rate and decreases with increasing wavenumber.

In 1962, Obukhov et al. found through experimental observations that large-scale turbulence had obvious anisotropy [76]; however, it was limited to the scope of large-scale turbulence. Later, Toselli et al. found that energy could be directly transferred between large-scale and small-scale turbulence [57]. Today, an increasing amount of experimental data shows that in actual atmospheric turbulence, most turbulence is in an anisotropic state, namely, non-Kolmogorov turbulence [88].

To study the influence of atmospheric turbulence on light-wave propagation in the non-Kolmogorov spectrum, Andrews et al. established a non-Kolmogorov spectral model [38]:

$$\Phi_n(\kappa,\alpha) = A(\alpha)\widetilde{C}_n^2\kappa^{-\infty}, 3 < \alpha < 4, \tag{14.25}$$

where κ is the spatial wavenumber, α is the power index of the power-spectral density of the refractive-index fluctuation, $\widetilde{C}_n^2$ is the refractive-index structure constant of non-Kolmogorov turbulence, in $m^{3-\alpha}$. $A(\alpha)$ maintains the consistency between the refractive-index structure function and its power spectrum: $A(\alpha) = \Gamma(\alpha - 1)\cos(\alpha\pi/2)/(4\pi^2)$.

At this time, $\alpha = 11/3$ h, $\widetilde{C}_n^2$, and $A(\alpha) = 0.033$, and Eq. (14.20) becomes the power-spectral density model of the refractive-index fluctuation of Kolmogorov turbulence.

To understand the influence of internal and external scales on the non-Kolmogorov atmospheric-turbulence effect, Andrews et al. developed a generalized modified non-Kolmogorov spectral model [32]:

$$\Phi_n(\kappa,\alpha) = \frac{A(\alpha)\widetilde{C}_n^2}{\left(\kappa^2+\kappa_0^2\right)^{\alpha/2}}\exp\left(-\kappa^2/\kappa_m^2\right), \quad 0 < \kappa < \infty, 3 < \alpha < 4, \tag{14.26}$$

where $\kappa_0 = 2\pi/L_0$, $\kappa_m = c(\alpha)/l_0$, and $c(\alpha)$ are the functions for the power of the refractive-index fluctuation power-spectral density α, which have the following forms:

$$A(\alpha) = \frac{1}{4\pi^2}\Gamma(\alpha-1)\cos\left(\frac{\pi}{2}\alpha\right) \tag{14.27}$$

$$c(\alpha) = \left[\frac{2\pi}{3}\Gamma\left(5-\frac{\alpha}{2}\right)A(\alpha)\right]^{1/(\alpha-5)}. \tag{14.28}$$

It can be seen from Eq. (14.27) that when $\alpha = 11/3$ h and $A(\alpha) = 0.033$, the non-Kolmogorov spectrum is equivalent to the modified von Kármán spectrum. When $\alpha = 11/3$, $A(\alpha) = 0.033$, $L_0 \to \infty$ and $l_0 \to 0$, the non-Kolmogorov spectrum is equivalent to the Kolmogorov spectrum.

As shown in Fig. 14.17, when $\alpha = 11/3$, $\tilde{C}_n^2 = C_n^2$, and $A(\alpha) = 0.033$, then, $\Phi_n(\kappa) = 0.033 C_n^2 \kappa^{-11/3}$ and the non-Kolmogorov spectrum becomes the Kolmogorov spectrum. When $\alpha = 3.1$, $\alpha = 10/3$ and $\alpha = 4.8$, the non-Kolmogorov spectrum obviously deviates from the Kolmogorov spectrum, and the greater the deviation, the greater the degree of deviation. However, in the inertial region (i.e., $\kappa < 1.1 \times 10^3$), the non-Kolmogorov and Kolmogorov spectra deviate slightly at different values. From the above analysis, we can see that the Kolmogorov spectrum is a special case of the non-Kolmogorov spectrum.

Figure 14.18 shows the curve of parameter M varying with the generalized exponential factor α when the beam propagates horizontally in the atmospheric-turbulent non-Kolmogorov spectrum at different propagation distances z.

Figure 14.18 shows the influence of the generalized exponential factor α on parameter M at different transmission distances. It also shows that the size of α directly affects the beam-transmission characteristics in atmospheric turbulence; that is, parameter M directly reflects the atmospheric-turbulence intensity, and the larger parameter M, the stronger the atmospheric turbulence [89]. As can be seen from

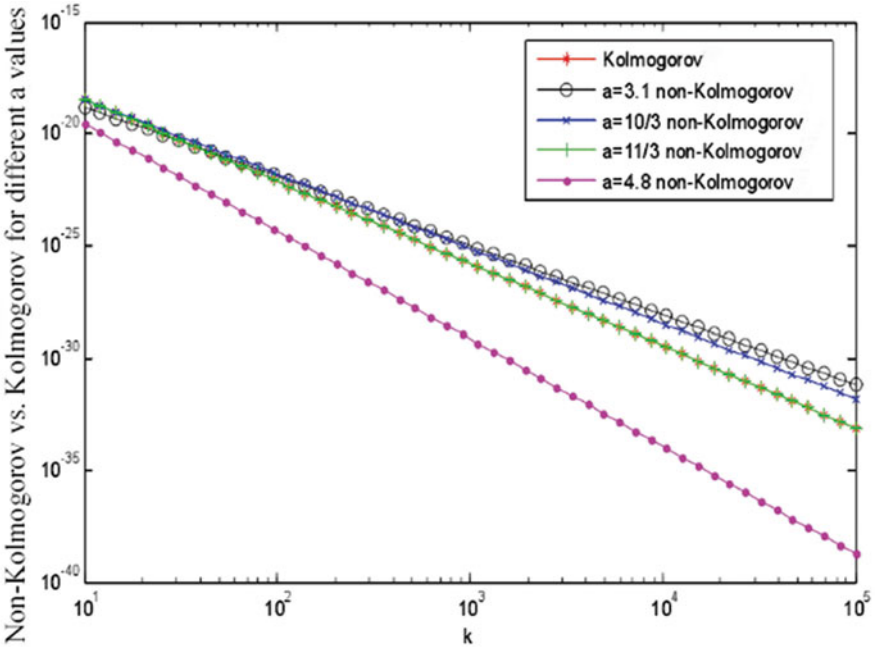

Fig. 14.17 Comparison of non-Kolmogorov and Kolmogorov spectra under different α values [89]

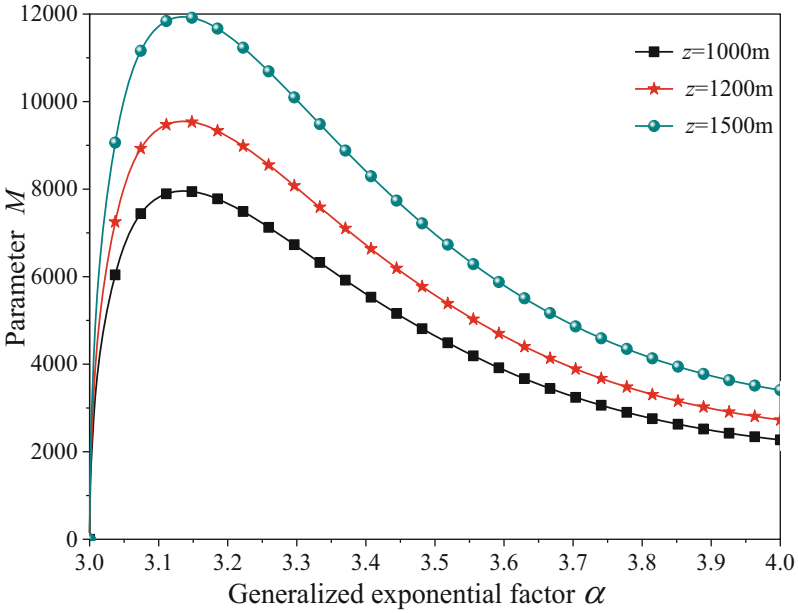

Fig. 14.18 Curve of M versus α at different transmission distances z [89]

Fig. 14.18, when z is 1000 m, 1200 m, and 1500 m, the α corresponding to the maximum M value increases correspondingly; however, it remains at approximately $\alpha = 3.1$. When $\alpha > 3.8$, parameter M tends to flatten with α.

Turbulence Spectra Varying with Altitude

There are two models of atmospheric-turbulence structure:

1. A two-layer model; that is, the turbulence in the Earth's atmosphere is composed of Kolmogorov turbulence in the troposphere and non-Kolmogorov turbulence in the stratosphere.
2. A three-layer model; that is, the turbulence in the Earth's atmosphere is composed of Kolmogorov turbulence in the boundary layer, non-Kolmogorov turbulence in the free atmosphere, and non-Kolmogorov turbulence in the stratosphere.

They have the following forms, respectively:

$$\Phi_{nB}(\kappa, z) = 0.033 C_n^2(z) \kappa^{-11/3} \tag{14.29}$$

$$\Phi_{nF}(\kappa, z) = 0.015\widetilde{C}_{nF}^{2}(z)\kappa^{-10/3} \tag{14.30}$$

$$\Phi_{nS}(\kappa, z) = 0.0024\widetilde{C}_{nS}^{2}(z)\kappa^{-5}, \tag{14.31}$$

where z is the propagation distance, $C_n^2(z)$ is the normal Kolmogorov turbulent refractive-index structural parameter in the boundary layer, with the unit of $\mathrm{m}^{-2/3}$, $\widetilde{C}_{nF}^{2}(z)$ is the non-Kolmogorov refractive-index structural parameter in the free troposphere, with the unit of $\mathrm{m}^{-1/3}$, and $\widetilde{C}_{nS}^{2}(z)$ is the non-Kolmogorov refractive-index structural parameter in the stratosphere, with the unit of m^{-2}. The above three parameters depend on the altitude.

The three-dimensional power spectrum of any power-law refractive-index fluctuation can be defined as

$$\Phi_n(\kappa, a) = A(\alpha) \cdot C_n^2 \cdot K^{-\alpha}, \tag{14.32}$$

where C_n^2 is the general refractive-index structure constant, and the unit is $m^{3-\alpha}$; $A(\alpha)$ is a constant that maintains the consistency between the structure function and its power spectrum.

According to the experiment, Arkadi found that the power spectrum of turbulence in the free troposphere and stratosphere might exhibit non-Kolmogorov characteristics [52]. The spectral behavior of the refractive-index fluctuation changes with altitude, which makes general models, such as those in Eqs. (14.21, 14.22, 14.23, 14.24, 14.25, 14.26, 14.27, 14.28, and 14.29), inapplicable.

Based on the three-layer model of the refractive-index fluctuation spectrum in the free atmosphere (boundary layer (2–3 km), free troposphere (8–10 km), and stratosphere above them), and on the experimental and theoretical data of the turbulence profile in the troposphere and lower stratosphere, Arkadi proposed a turbulence-spectrum model that varied with height [28]:

$$\alpha(z) = \frac{\alpha_1}{1 + (z/H_1)^{b_1}} + \frac{\alpha_2 (z/H_1)^{b_1}}{1 + (z/H_1)^{b_1}} \cdot \frac{1}{1 + (z/H_2)^{b_2}} + \frac{\alpha_3 (z/H_2)^{b_2}}{1 + (z/H_2)^{b_2}}, \tag{14.33}$$

where $\alpha_1 = 11/3$, $\alpha_2 = -10/3$, $\alpha_3 = -5$, z is the height from the ground, H_1 and H_2 are the characteristic heights, and b_1 and b_2 are fitting coefficients.

The experimental results showed that the turbulence characteristics do not change smoothly with height, and the height dependence of α is expressed by a three-layer height model, wherein the first layer corresponds to the boundary layer with Kolmogorov turbulence ($\alpha = 11/3$), the second corresponds to the free troposphere with non-Kolmogorov turbulence ($\alpha = -10/3$), and the third corresponds to the stratosphere with non-Kolmogorov turbulence ($\alpha = -5$).

Figure 14.19 shows the power-profile distribution of the turbulent power spectrum when $H_1 = 2$ km, $H_2 = 8$ km, $b_1 = 8$, $b_2 = 10$ (solid line), $b_1 = 15$, and $b_2 = 20$ (dotted line).

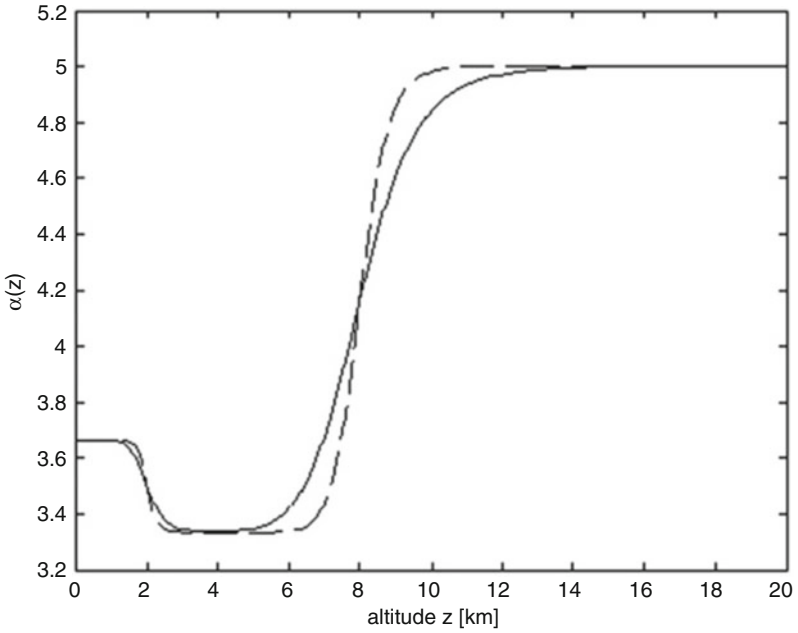

Fig. 14.19 Turbulence power-spectrum power-exponential profile distribution [52]

Atmospheric-Turbulence Channel Models

Owing to the effect of atmospheric turbulence, when a laser beam is transmitted in the atmosphere, the light intensity at the receiving end fluctuates randomly; that is, it produces the light-intensity flicker effect, which leads to signal fading at the receiver and deteriorating received-signal quality. Therefore, to improve the performance of a free-space optical (FSO) system, it is necessary to establish channel models that describe different atmospheric-turbulence conditions. Table 14.3 shows the classification of various atmospheric-turbulence channel models.

Log-Normal Distribution

The log-normal distribution probability-density function describes the flicker and fading statistics in the weakly turbulent region. Considering the log-normal model, the probability-density function of the received optical signal is given by the following formula [3]:

$$P(I) = \frac{1}{\sqrt{2\pi\sigma_l^2 I}} \exp\left\{-\frac{(\ln(I/I_0) - E[I])^2}{2\sigma_l^2}\right\}, \tag{14.34}$$

Table 14.3 Classification diagram of atmospheric-turbulence channel models

Channel-model distribution	Probability-distribution function	Applicable turbulence range
Log-normal	$P(I) = \frac{1}{\sqrt{2\pi\sigma_l^2} I} \exp\left\{ - \frac{(\ln(I/I_0) - E[I])^2}{2\sigma_l^2} \right\}$	Weak
Gamma–gamma	$p(I) = \int_0^{+\infty} p_y(I\|x) p_x(x) dx = \frac{2(\alpha\beta)^{(\alpha+\beta)/2}}{\Gamma(\alpha)\Gamma(\beta)} I^{(\alpha+\beta)/2-1} K_{\alpha_\beta}\left[2(\alpha\beta I)^{1/2}\right]$	Medium and strong
Negative exponential	$p(I) = \frac{1}{I_0} \exp\left(-\frac{I}{I_0}\right)$	Strong
K	$P(I) = \frac{2a^{(a+1)/2}}{\Gamma(a)} I^{(a-1)/2} K_{a-1}\left(2\sqrt{aI}\right)$	Medium and strong
Malaga	$P(I) = A \sum_{k=1}^{\infty} a_k I^{\frac{\alpha+k}{2}-1} K_{\alpha-k}\left(2\sqrt{\frac{\alpha I}{\gamma\beta+\Omega}}\right)$	Weak, medium, and strong
Ke	$P(I) = A_1 \times \frac{1}{\sqrt{2\pi}\times\sigma_1} \times \mathrm{e}^{\left[-\frac{(I-\mu_1)^2}{2\times{\sigma_1}^2}\right]} + A_2 \times \frac{1}{\sqrt{2\pi}\times\sigma_2} \times \mathrm{e}^{\left[-\frac{(I-\mu_2)^2}{2\times{\sigma_2}^2}\right]}$	Weak

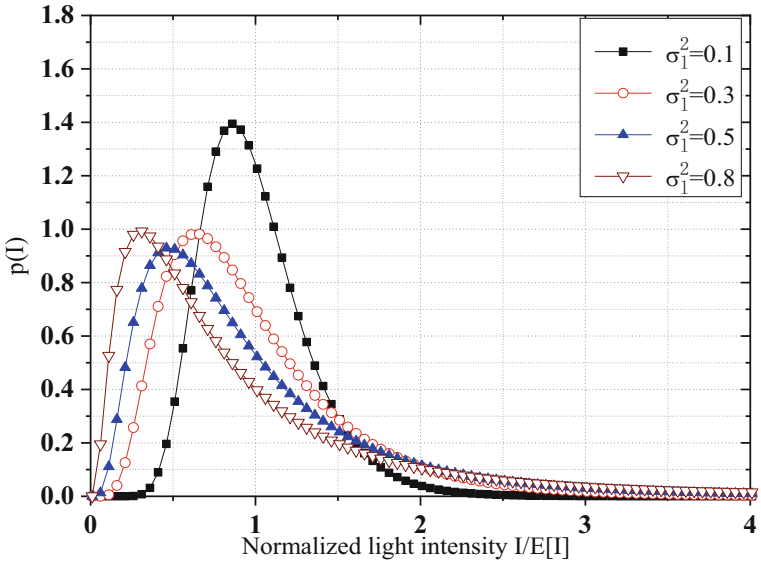

Fig. 14.20 Log-normal distribution probability-density function curve [3]

where σ_l^2 is the logarithmic light-intensity variance and I is the normalized light-intensity value reaching each receiver.

Figure 14.20 shows the probability-density function curve of the log-normal distribution under different σ_l^2 conditions. As can be seen from Fig. 14.20, with the increase in turbulence intensity σ_I^2, the curve gradually deviates from the mean value, and the tail becomes more serious, which is gradually inconsistent with the log-normal distribution. The log-normal distribution is only applicable to weak-turbulence conditions ($\sigma_I^2 < 1$) because the scattering effect is also considered with the increase in turbulence intensity.

Gamma–Gamma Distribution

Because the log-normal model is limited to weak turbulence, Shah produced another model based on the modified Rytov theory, called the gamma–gamma channel model [89], in which the light-intensity fluctuation was developed as the product of two random processes and the gamma–gamma distribution:

$$p(I) = \int_0^{+\infty} p_y(I|x)p_x(x)dx = \frac{2(\alpha\beta)^{(\alpha+\beta)/2}}{\Gamma(\alpha)\Gamma(\beta)} I^{(\alpha+\beta)/2-1} K_{\alpha-\beta}\left[2(\alpha\beta I)^{1/2}\right], \quad I > 0\,. \quad (14.35)$$

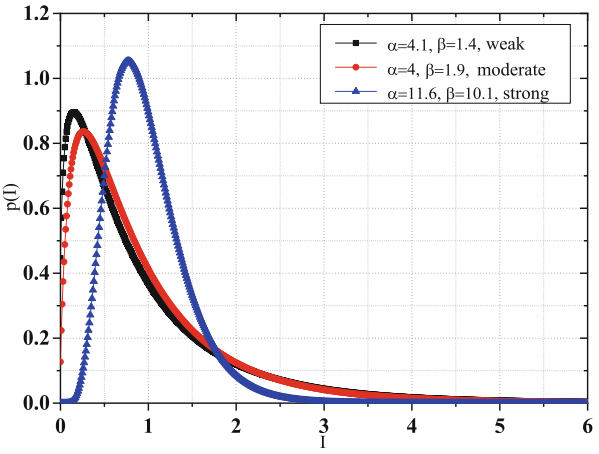

Fig. 14.21 Gamma–gamma probability-density function of distributed light intensity [3]

In the formula, the parameters α and β represent the large- and small-scale scattering coefficients, respectively, $K_n(\cdot)$ represents the second type of correction function, and $\Gamma(\cdot)$ represents the gamma function.

Figure 14.21 shows the probability-density function of the gamma–gamma distribution under different turbulence intensities. It can be seen from the figure that, compared with the log-normal distribution, the gamma–gamma distribution has a wider application scope and can accurately describe the statistical characteristics of light-intensity fluctuations in weak, medium, and strong turbulence regions.

As shown in Fig. 14.22, the scattering coefficients of the large and small scales are large when σ_I^2 is small. When σ_I^2 gradually increases to approximately 3, the scattering coefficients of the large and small scales decrease rapidly. When σ_I^2 gradually increases from 1 to 100, α increases, and β decreases and approaches 1.

Negative-Exponential Distribution

In the case of strong turbulence with a link length of several kilometers, an increase in the scattering number leads to fading, which is considered a random process. In this case, the signal amplitude follows the negative-exponential distribution of the signal strength. The negative-exponential probability-distribution function is

$$p(I) = \frac{1}{I_0} \exp\left(-\frac{I}{I_0}\right), \qquad I > 0, \tag{14.36}$$

where $I_0 = E[I]$ denotes the average light intensity. In the saturated state, the flicker index→1, and the negative-exponential distribution is shown in Fig. 14.23.

Figure 14.24 shows the light-intensity fluctuation probability-distribution curve of the gamma–gamma and log-normal distributions with different Rytov variances.

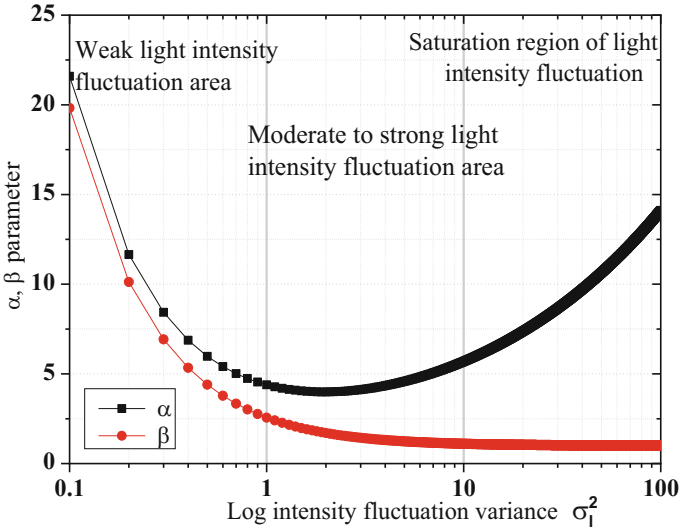

Fig. 14.22 Summation of α and β values under different σ_I^2 conditions [3]

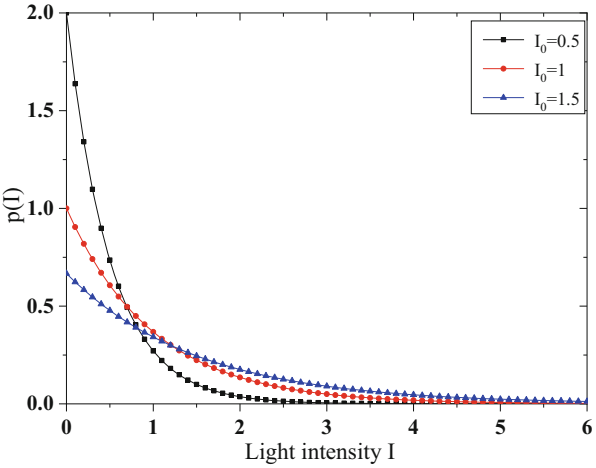

Fig. 14.23 Probability-density function of the negative-exponential distribution light-intensity fluctuation [89]

In the weak turbulent region, the log-normal distribution model is in good agreement with the experimental data; however, in the strong turbulent region, the tail phenomenon of the log-normal distribution model is significant, which deviates greatly from the experimental data. In the weak, medium, and strong turbulent regions, the gamma–gamma distribution model is more consistent.

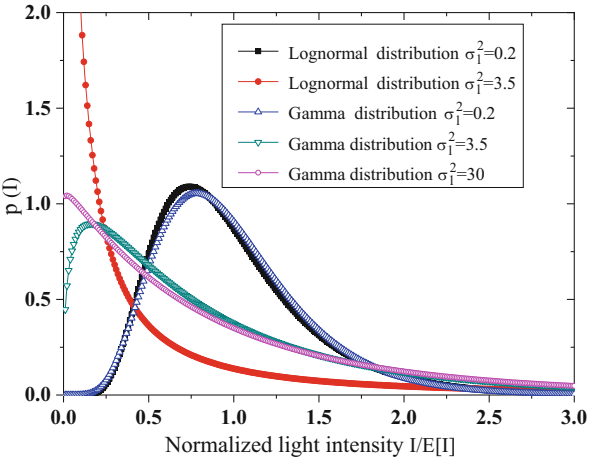

Fig. 14.24 Probability-density function of light-intensity fluctuation [89]

K Distribution

In the strong turbulence region, the atmospheric-turbulence channel model can be represented by the K distribution, and its probability-density function is [89]

$$f_I(I) = \frac{2a^{(a+1)/2}}{\Gamma(a)} I^{(a-1)/2} K_{a-1}\left(2\sqrt{aI}\right), \quad I > 0. \tag{14.37}$$

The K distribution function can be expressed as

$$F(S,a) = \int_{-\infty}^{s} \frac{2a^{(a+1)/2}}{\Gamma(a)} S^{(a-1)/2} K_{a-1}\left(2\sqrt{as}\right) dS, \tag{14.38}$$

where S is a random variable.

Figure 14.25a shows the slot error rate of the K-distribution channel with the SNR. It can be observed from Fig. 14.25a that when the SNR is small, the slot error rate of the two-dimensional K-distribution channel is lower than that of the one-dimensional K-distribution channel, whereas when the SNR is large, the difference between the two is not significant.

Figure 14.25b shows the channel capacity of the K-distribution channel changing with SNR when $a = 1$ and $a = 2$. It can be seen from Fig. 14.25b that the increase in SNR and a will increase the average channel capacity of the K distribution. When a is the same, the two-dimensional K-distribution channel has a larger capacity than the one-dimensional K-distribution channel [90].

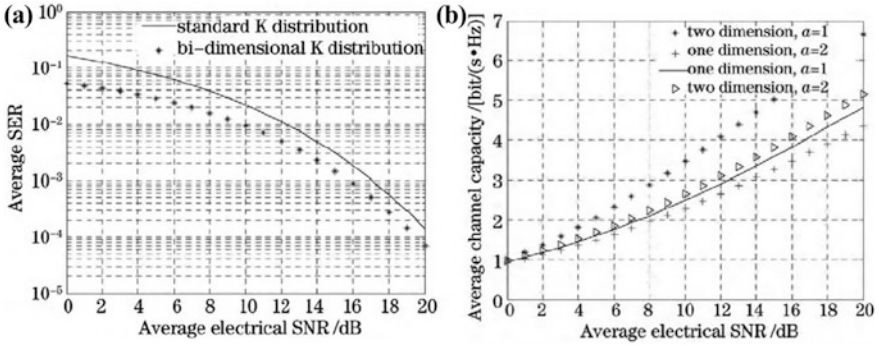

Fig. 14.25 K-distribution channel characteristics. (**a**) Slot error rate of K-distribution channel with SNR [91]. (**b**) Channel capacity of the K distribution channel varies with SNR when $a = 1$ and $a = 2$ [91]

Malaga Distribution

The Malaga channel model can describe various turbulence distributions, and its probability-density function is [91]

$$f_I(I) = A\sum_{k=1}^{\infty} a_k I^{\frac{\alpha+k}{2}-1} K_{\alpha-k}\left(2\sqrt{\frac{\alpha I}{\gamma\beta+\Omega'}}\right) \tag{14.39}$$

$$\begin{cases} A = \dfrac{2\alpha^{\frac{\alpha}{2}}}{\gamma^{1+\frac{\alpha}{2}}\Gamma(\alpha)}\left(\dfrac{\gamma\beta}{\gamma\beta+\Omega'}\right)^{\beta} \\ a_k = \dfrac{(\beta)_{k-1}(\alpha\gamma)^{\frac{k}{2}}}{[(k-1)!]^2\gamma^{k-1}(\Omega'+\gamma\beta)^{k-1}} \end{cases}, \tag{14.40}$$

where a and β are expressed as positive real and fading parameters, respectively, and the Ω' parameter is the coherent average optical power, φ_A represents the phase of the light-wave line-of-sight propagation component, and φ_B represents the phase of the light-wave line-of-sight propagation coupling component [92].

It can be seen from Fig. 14.26(a) that as the value of ρ increases, the value of $f_I(I)$ in the ellipse box correspondingly increases. In the case of strong turbulence, compared with the gamma–gamma distribution, $f_I(I)$ of the K distribution has a relatively slow downward trend and a relatively serious tail. It can be seen from Fig. 14.26(b) that in the case of weak turbulence, the $f_I(I)$ curve gradually moves to the right with an increase in the value of ρ, while the peak value increases and the tailing phenomenon decreases [92–94].

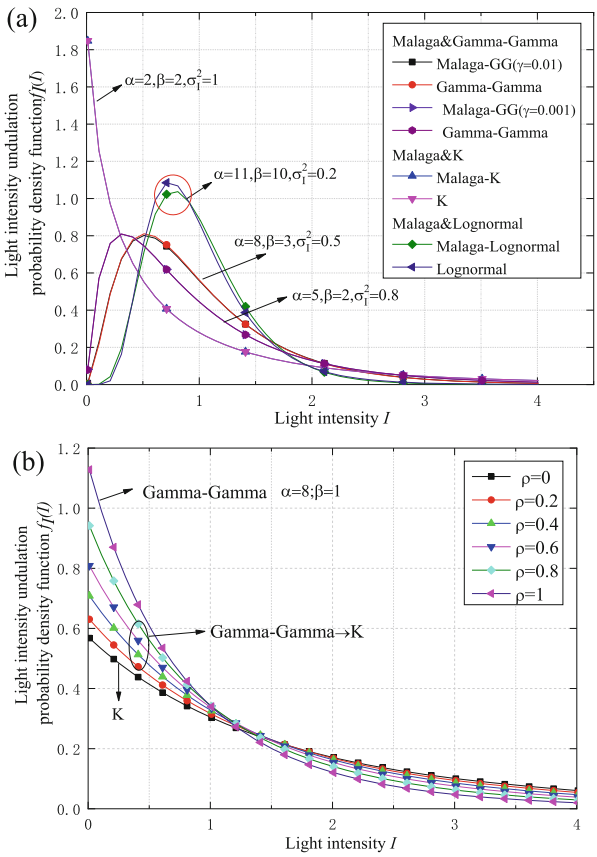

Fig. 14.26 Curve of the probability-density function of the light-intensity fluctuation of the Malaga distribution with values of ρ under different α and β conditions [92]. (**a**) $\alpha = 8$, $\beta = 1$. (**b**) $\alpha = 17$, $\beta = 16$

Ke's Model

For visible-light communication in the Internet of Vehicles, Ke Xizheng proposed a nighttime background-light noise model (Ke's model) that uses a double Gaussian function. It is called the Coriolis model [95]:

$$f(I) = A_1 \times \frac{1}{\sqrt{2\pi} \times \sigma_1} \times \mathrm{e}^{\left[-\frac{(I-\mu_1)^2}{2\times\sigma_1{}^2}\right]} + A_2 \times \frac{1}{\sqrt{2\pi} \times \sigma_2} \times \mathrm{e}^{\left[-\frac{(I-\mu_2)^2}{2\times\sigma_2{}^2}\right]} \tag{14.41}$$

Figure 14.27 shows the Coriolis distribution model. The two Gaussian curves in the figure correspond to the two Gaussian functions of Eq. (14.41), and the corresponding mean and variance are different. In Gaussian curve 1, the background noise mainly contains the current street-lamp background light component, whose

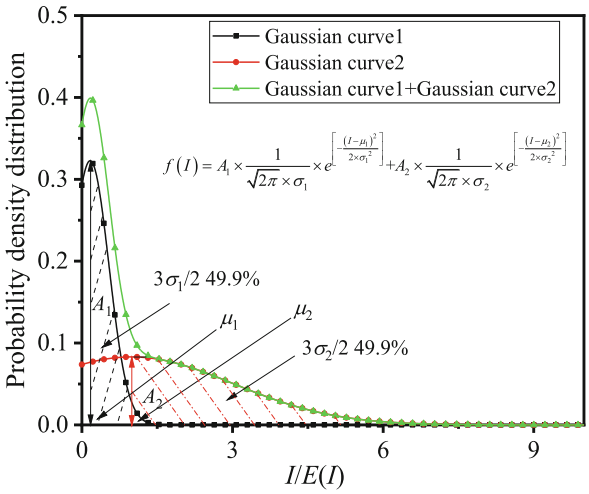

Fig. 14.27 Coriolis distribution model [95]

light intensity is weak and the light-intensity fluctuation variance is small. In Gaussian curve 2, the background noise mainly includes front and rear vehicle lights, extremely bright billboards, traffic lights, and other components with a strong intensity and large intensity-fluctuation variance [95].

Figure 14.28 shows the survey data for different cities. According to Fig. 14.28, the following can be seen:

1. The Coriolis distribution model can accurately describe the environmental noise model of visible-light communication.
2. The probability distribution for rainy days is no different from that of sunny days.
3. The light-intensity fluctuation generated by current street lamps is significantly smaller than that generated by other light sources.

Summary

It has been 81 years since the first publication of Kolmogorov's theory in 1941. During this period, scientific researchers from various countries have successively established various theoretical models of the atmospheric-turbulence spectrum. Research on the refractive-index power spectrum of atmospheric optical turbulence has developed, from the Kolmogorov refractive-index power spectrum (describing statistically uniform and fully developed ideal turbulence) to the non-Kolmogorov refractive-index power spectrum (describing nonclassic turbulence, such as stratification and turbulence that are not fully developed) [87]. However, considering the need for theoretical analysis, it is still necessary to study new reasonable turbulence-spectral models that can simplify the theoretical analysis of turbulence effects.

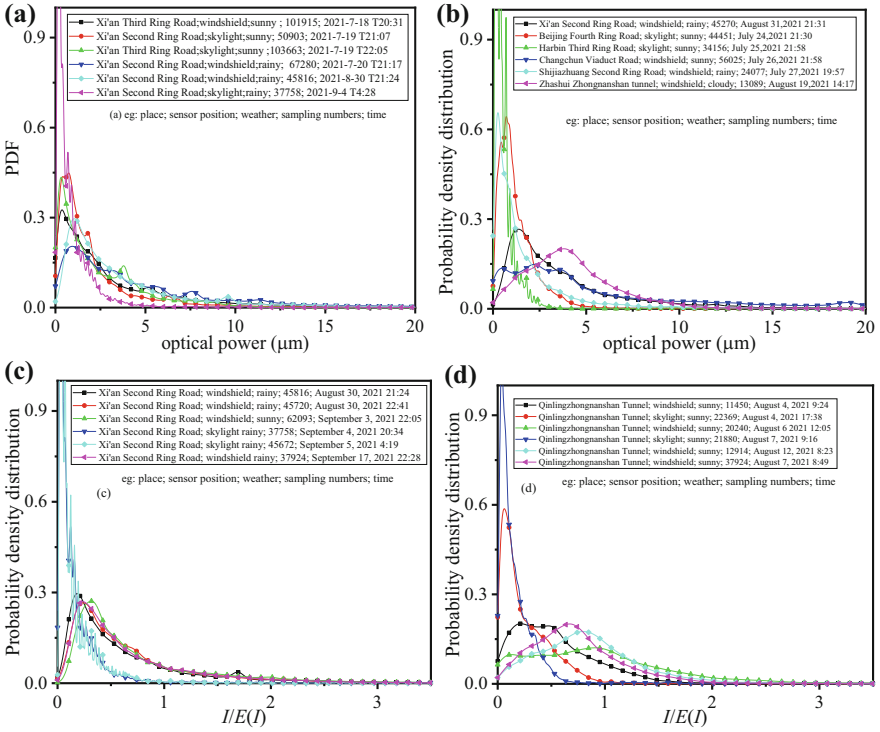

Fig. 14.28 Probability distribution of nighttime background-light noise for visible-light communication under different conditions [95]. (**a**) Different regions in Xi'an. (**b**) Different cities. (**c**) Rain. (**d**) Tunnel

This chapter systematically summarized the application and development of atmospheric-turbulence models. Researchers have been investigating and developing atmospheric turbulence in the following aspects.

1. Measuring and studying the characteristics of actual atmospheric turbulence, obtaining more statistical-characteristic parameters of atmospheric turbulence, and accelerating the research and development of optical wireless communication in actual atmospheric turbulence.
2. Analyzing and comparing the transmission characteristics of different light sources in different atmospheric-turbulence conditions, exploring the influence mechanism of atmospheric turbulence on optical signal transmission, and improving the ability to suppress atmospheric turbulence.
3. Researching high-accuracy atmospheric-turbulence parameter measurement instruments and developing high-sensitivity and high-resolution atmospheric-turbulence characteristic measurement technologies and methods to improve the accuracy of atmospheric-turbulence parameter measurements in the actual atmosphere.

Abstract

In optical wireless communication systems, the optical signal is affected by atmospheric turbulence during atmospheric-channel transmissions. Therefore, it is important to study methods for suppressing atmospheric turbulence in the development of optical wireless communication. This chapter analyzes the effects of atmospheric turbulence on optical wireless communication systems. It presents the current domestic and foreign research on suppressing atmospheric turbulence and finally presents future development trends and outlooks.

Introduction

Optical wireless communication [1] has the advantages of a high information-transmission rate, no need for frequency applications, and strong confidentiality. It has a wide range of application prospects in the future development of wireless communication. However, optical wireless communication signals are affected by atmospheric turbulence during transmission in the atmospheric channel, which produces effects, such as light-intensity fluctuation, beam expansion, beam drift, and phase fluctuation. This reduces the performance of optical wireless communication systems, making it difficult to utilize their advantages. Therefore, it is important to study the effects of atmospheric turbulence on optical communications [2].

Optical Wireless Communication Systems

A model diagram of an optical wireless communication system is shown in Fig. 15.1. As can be seen from the figure, the transmitter side is mainly used for channel coding, signal modulation, and output by a laser or amplifier and is then transmitted by a single or multiple antennas through different types of channels. The receiving end uses a single or multiple antennas for reception. After being detected, the signal passes through the spatial optical-coupling module and preamplifier. Finally, it is demodulated and decoded to produce the originally transmitted signal.

In the future, optical wireless communication will have broad market potential and unique attractions; however, optical wireless communication systems still have many areas that need improvement.

One of the main issues is the impact of the atmospheric channel on optical wireless communication. The atmospheric channel is very complex, and optical signals are affected by atmospheric turbulence during transmission. Atmospheric turbulence can lead to uncertain changes in the amplitude and phase of the received signal, which affects the stable performance of optical communication and greatly reduces the communication quality. To exploit the advantages of optical wireless communication, it is important to study methods for suppressing atmospheric turbulence.

Atmospheric Turbulence

Atmospheric-Turbulence Formation Mechanism

Factors in the atmosphere are constantly changing, such as random changes in wind speed and air pressure, which makes the atmospheric refractive index inhomogeneous, and also forms turbulent vortices [3]. Atmospheric turbulence originates from the continuous formation or dissipation of these turbulent vortices with the change in wind speed and their continuous overlapping. This produces an irregular turbulent motion.

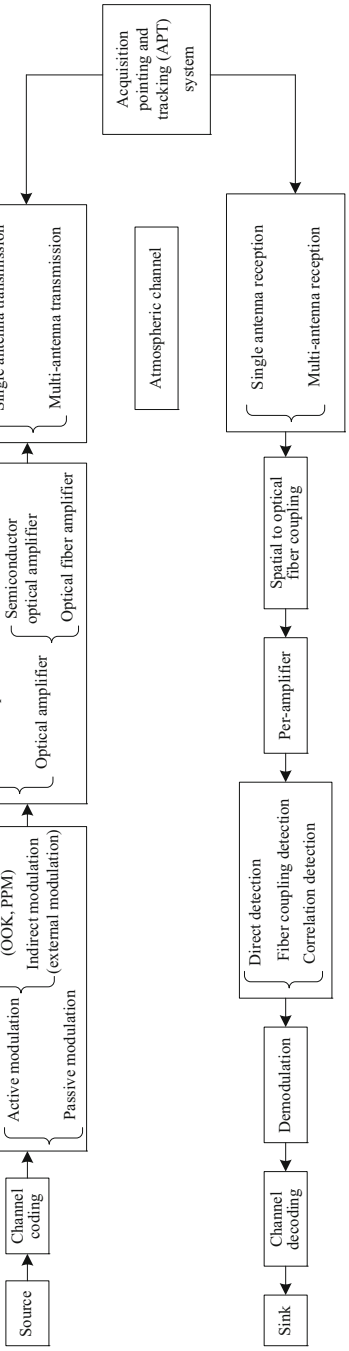

Fig. 15.1 Model of an optical wireless communication system [1]

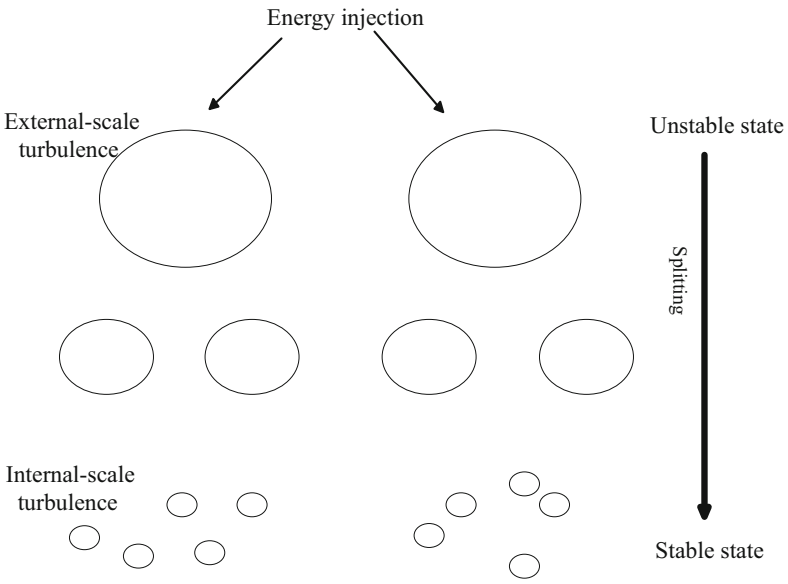

Fig. 15.2 Schematic diagram of the turbulent motion of the atmosphere [5]

The Reynolds number [4] well describes the characteristics of the turbulent energy conversion, as shown in Fig. 15.2. The outer turbulence scale has a large energy, which constitutes the initial turbulence energy. When the Reynolds number is large, it forms the outer turbulence scale. This state is very unstable so it splits into smaller turbulent vortices. The energy is dispersed to these small-scale turbulence vortices, and the splitting continues, with the Reynolds number decreasing accordingly, until it converges to a stable state.

Impact of Atmospheric Turbulence on Optical-Communication Systems

When a signal-bearing beam passes through a turbulent atmospheric channel, the atmospheric turbulence causes the optical power within the beam cross section to fluctuate randomly, as well as producing light-intensity scintillation, beam drift, and phase undulation. This reduces the communication performance of the optical communication system.

Figure 15.3 shows the impact of the atmospheric channel on the optical communication. Light-intensity flickering, beam drift, beam expansion, and phase fluctuation cause the optical signal to fluctuate randomly, which attenuates the optical power, decreases the signal-to-noise ratio, and reduces the communication quality. Considering the series of effects of atmospheric turbulence on optical wireless communication systems, it is important to study methods for suppressing atmospheric turbulence.

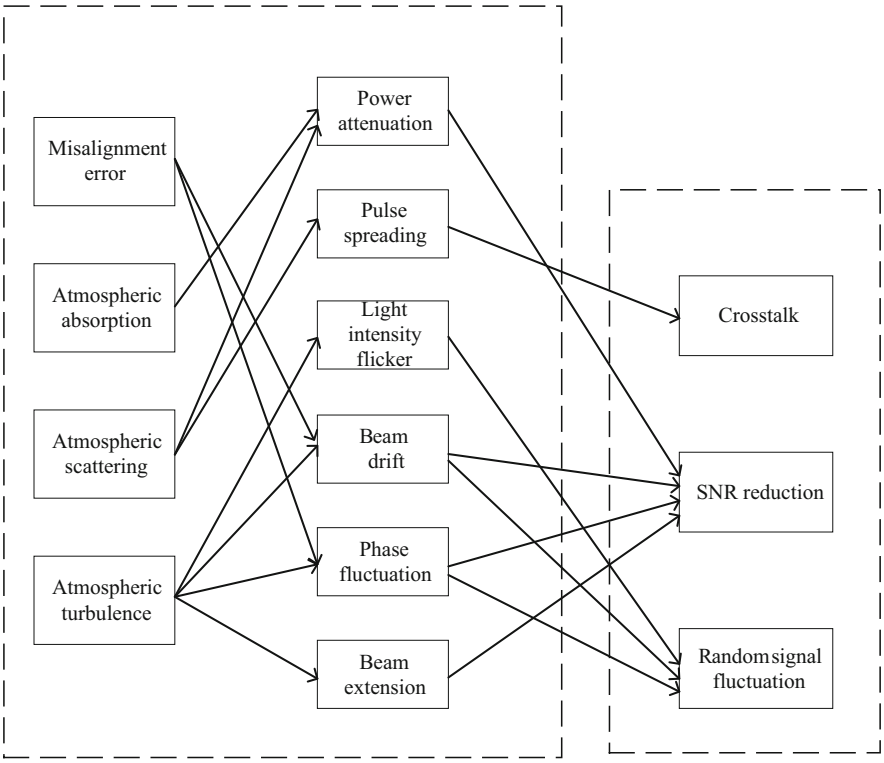

Fig. 15.3 Impact of the atmospheric channel on optical communication [6]

When a light beam passes through an atmospheric-turbulence channel, the light signal will be disturbed by turbulence, changing or even reducing the light power and resulting in the degradation of communication quality. Different atmospheric-turbulence scales will cause the light signal and beam quality to change differently; hence, the impact on the optical wireless communication system also differs. It has been shown that changes in the atmospheric-turbulence scale can have significant effects on optical wireless communication systems, including changes in the optical signal and beam quality, which, in turn, depend on the diameter of the laser beam and the geometry of the turbulence.

Light-Intensity Scintillation

When the cross-sectional diameter of the emitted beam is much larger than the geometric turbulence scale, the beam cross section includes many small-scale turbulence pairs, which causes the beam to have different effects, such as beam scattering and diffraction. At this time, the light intensity and phase will produce uncertain fluctuations, which affect the optical communication system performance and communication quality. This phenomenon is also known as light-intensity scintillation.

Beam Drift

As the beam passes through turbulence, it refracts. Multiple refractions will cause the beam to drift, and eventually lead to the beam not being irradiated vertically on the receiving surface. Beam drift causes random phase fluctuations in the transmitted optical signal, which greatly reduces the communication quality of the optical wireless communication system.

Beam Expansion

Atmospheric turbulence makes the atmospheric refractive index uncertain. This uncertain change and randomness expands the size of the beam in the transmission, resulting in the transmission of a beam whose cross-sectional energy is greatly reduced. When the energy of the beam is reduced to a certain degree, it cannot pass smoothly through the receiving lens to reach the photodetector. This reduces the communication quality of optical wireless communication.

Phase Fluctuation

In an atmospheric channel, the inhomogeneity of the transmission medium distorts the wavefront. This distortion makes it so the beam arrival angle does not match original arrival angle. It is also known as the arrival-angle fluctuation phenomenon. The wavefront of an optical signal in a uniform-medium transmission will not be distorted. Atmospheric turbulence can cause the distortion of the beam wavefront, it is called phase fluctuation.

Key Technologies for Suppressing Atmospheric Turbulence

Several technologies have been proposed to reduce the impact of atmospheric turbulence on optical wireless communication, and further improve the system performance and communication quality of optical wireless communication. Solutions and related technologies for suppressing atmospheric turbulence proposed by domestic and foreign scholars include large-aperture reception, adaptive optics, diversity, and partially coherent optical technologies. This section introduces several key technological principles for suppressing atmospheric turbulence and their research status.

Large-Aperture Receiving Technology

Large-aperture reception technology uses a large-diameter antenna or receiver to receive wireless signals. In the communication field, the main function of large-aperture receiving technology is to receive and process signals from different directions. Using a large-aperture antenna or receiver, the strength and accuracy of the received signals can be increased, and the quality and reliability of communications can be improved. Large-aperture receiving technology can be used in a variety

of applications, such as television and radio transmission, radar systems, satellite communications, and wireless laser communications.

Current Research Status

In 1973, Kerr et al. [7] showed that, under the same turbulence conditions, the fluctuation of the received optical power decreased as the receiving aperture increased, whereas when the emitted aperture was kept constant, the fluctuation of the received optical power decreased as the receiving aperture increased.

In 2006, Yuksel et al. [8] proposed an aperture-optimization method for optical antenna receivers that provided an optimal aperture size. They proved that the aperture-smoothing factor was independent of the aperture shape and was only related to the aperture area.

In 2008, Chen et al. [9] conducted a 16 km laser-communication link experiment to analyze the effect of atmospheric turbulence on the receiving system. They found that reception through a large-aperture antenna reduced turbulence-induced light-intensity fluctuations.

In 2009, Prokes [10] found that optical signals in optical wireless communication systems were affected by atmospheric turbulence as the communication distance increased. The scintillation effect of atmospheric turbulence could be suppressed by appropriately increasing the receiving-aperture size by using large-aperture receiving technology.

In 2009, Chen et al. [11] analyzed the relationship between the aperture-smoothing factor and the variance of light-intensity scintillation in a large-aperture receiving system. They determined the effect of different receiving-aperture sizes on the signal-to-noise ratio of the system with a given bit-error rate (BER), which laid the foundation for selecting the appropriate receiving-aperture size.

In 2011, Lou et al. [12] conducted a near-earth laser-transmission experiment and analyzed the effect of different receiving-aperture sizes on the optical-intensity fluctuation. The results showed that large-aperture receiving could receive a larger spot area, which effectively suppressed the optical-intensity scintillation effect of turbulence.

In 2012, Lu et al. [13] analyzed the effect of the antenna aperture on the quality of free-space optical communication and found that the signal scintillation index decreased with an increase in the receiving aperture, and the fading probability of the communication link similarly decreased.

In 2014, Wang [14] conducted experiments on atmospheric laser communication using different receiving-aperture sizes. They found that as the receiving-aperture size increased, the BER of the communication system decreased, suppressing the light-intensity fluctuation effect and improving the performance of the entire communication system.

In 2017, Li et al. [15] found that the scintillation index increased with an increase in turbulence intensity and conducted experiments on communication links at different turbulence intensities. They found that the scintillation index could be reduced with an increase in the receiving-aperture size, the scintillation index

could reach the saturation state, and an appropriate increase in the receiving-aperture size could effectively suppress the turbulence-scintillation effect.

In 2019, Soni et al. [16] studied the performance of a free-space optical communication system under different rainfall intensities using large-aperture reception and analyzed the suppression of atmospheric turbulence by the aperture-smoothing effect. This led to an average signal-to-noise ratio improvement of 1.58 dB using large-aperture reception.

In 2021, Dai [17] analyzed the effect of different aperture sizes on the light-intensity scintillation index in a wireless laser communication system using a large-aperture Cassegrain antenna as the receiving system. It was found that the light-intensity scintillation index of the large-aperture reception was small and stable, effectively suppressing the scintillation effect of atmospheric turbulence.

Suppression Principle

In optical wireless communication systems, because atmospheric turbulence caused by light-intensity flicker will lead to received optical-power fluctuation at the receiving end, the antenna size at the receiving end can be appropriately increased to reduce the optical power of the fluctuation variance. Large-aperture receiving technology increases the size of the receiving end of the aperture, which allows the receiving end to receive more light energy to inhibit the effect of atmospheric turbulence.

Large-aperture reception technology is widely used in optical wireless communication systems, and the suppression of the scintillation effect is particularly obvious. Large-aperture receiving technology reduces the flickering effect caused by atmospheric turbulence by increasing the receiving aperture at the receiver end; this phenomenon is known as the aperture-smoothing effect. Under different atmospheric-turbulence intensities, different receiving-aperture sizes have different effects on the scintillation effect. Therefore, the aperture-smoothing factor characterizes the aperture-smoothing effect. Considering the aperture-smoothing factor under different turbulence conditions, an optimal aperture size of the receiving antenna can be found to suppress the turbulence scintillation effect [18].

The Cassegrain-telescope receiving system is a typical and commonly used large-aperture receiving system. The Cassegrain telescope system is comprised of two mirrors. As shown in Fig. 15.4, the incident laser beam passes through the first primary reflector with a parabolic surface pattern and is then output by the secondary reflector with a hyperbolic surface pattern. The power of the received optical signal can be increased by appropriately increasing the aperture of the Cassegrain telescope. This also has an aperture-averaging effect, weakens the fluctuation, and effectively suppresses the effect of atmospheric turbulence on the beam.

To a certain extent, large-aperture receiving technology suppresses the impact of light-intensity scintillation on the optical communication link; however, the aperture size cannot increase infinitely. An increased aperture means an increase in the size and weight of the receiver; thus, applications with high portability requirements will be limited. Moreover, it increases the design difficulty of other parts of the system to a certain extent.

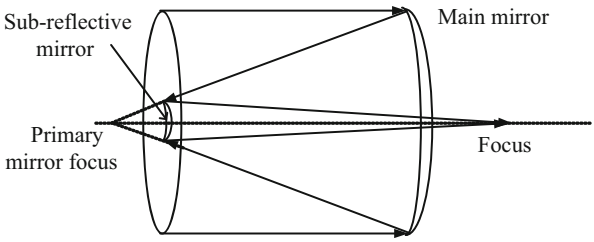

Fig. 15.4 Schematic diagram of a large-aperture Cassegrain telescope [19]

Partially Coherent Optical Technology

Partially coherent optical-transmission techniques have been applied in optical communication. The phase and amplitude of the signal may change, owing to atmospheric turbulence, and decrease the signal coherence. In a partially coherent optical-transmission technique, the phase and amplitude of the optical signal can change to some extent while still maintaining a certain degree of coherence. Partially coherent optical-transmission technology can process and repair signals using a series of modulation and demodulation techniques, thereby improving the transmission reliability and performance.

Current Research Status

In 1978, Wu et al. [20] discovered that partially coherent beams had a strong antiturbulence effect by analyzing the transmission characteristics of partially coherent Gaussian–Schell-model (GSM) beams under atmospheric turbulence.

In 2003, Ricklin et al. [21] investigated whether the BER of free-space optical communication systems was affected by the turbulence strength and degree of beam coherence. The final results demonstrated that reducing the beam coherence led to a reduction in the degree of optical power jitter at the receiver, which led to a reduction in the BER of the communication system.

In 2003, Aristide et al. [22] used partially coherent light for transmission in free-space optical communication systems. They showed that partially coherent light was less affected by atmospheric turbulence than fully coherent light, and the effect of turbulence could be better suppressed by appropriately reducing the beam coherence.

In 2010, Borah et al. [23] investigated optimizing the coherence length of a spatially partially coherent beam for free-space optical communication under weak turbulence conditions. The effects of different parameters on the coherence length were discussed. Optimizing the coherence length reduced the turbulence effect and improved the system performance.

In 2011, Drexler et al. [24] improved the performance of free-space optical communication systems by controlling the coherence of the transmitted beams. It was demonstrated that the use of partially coherent beams reduced the scintillation values by 50%, compared to fully coherent beams under different turbulence-intensity conditions.

In 2014, Zhang et al. [25] investigated the transmission characteristics of partially coherent Gaussian beams with different coherences and experimentally derived the scintillation index for beam transmission in atmospheric turbulence. The results showed that reducing the spatial coherence of the beam could suppress the light-intensity scintillation in turbulence.

In 2016, Zhang et al. [26] derived the Rayleigh-interval and turbulence-distance analytic equations for a radial partially coherent GSM array beam during atmospheric-turbulence transmissions. They showed that the atmospheric-turbulence effect could be effectively suppressed by appropriately reducing the beam coherence.

In 2019, Zhang [27] investigated whether anisotropic atmospheric turbulence could lead to poor optical-signal quality. They proposed a novel twisted rectangular Laguerre–Gaussian–Schell model (TRLGCSM) beam generated by partially coherent light superposition and verified that the beam could effectively suppress the effects of atmospheric turbulence.

In 2019, Yu et al. [28] found that part of a coherent beam was affected by atmospheric turbulence. The beam-drift phenomenon caused by atmospheric turbulence could be reduced by changing the coherent structure of the optical field and reducing the beam coherence.

In 2019, Zhang [29] conducted indoor simulation experiments using a liquid-crystal spatial light modulator (LC-SLM) to generate a partially coherent beam. Using the LC-SLM for atmospheric-turbulence simulation, they verified that the partially coherent beam generated by the LC-SLM had better turbulence resistance than a fully coherent beam.

In 2022, Yang et al. [30] analyzed the transmission characteristics of a partially coherent radially polarized twisted beam under atmospheric turbulence and derived its twist factor. They showed that the larger the twist factor of the beam, the better the resistance to turbulence.

In recent years, Xi'an University of Technology has conducted extensive research on partially coherent light transmissions in the atmosphere [31]. In 2014, the transport properties of partially coherent GSM beams in atmospheric turbulence were studied by Han et al. [32, 33]. They verified that partially coherent light had better turbulence resistance than fully coherent light. The experimental results showed that the beam was less affected by beam drift when its spatial coherence length was greater than 0.005 m within a transmission distance of 10 km.

In 2015, Zhang et al. [34] studied the scintillation effect of partially coherent light subjected to atmospheric turbulence and analyzed the variance in the light-intensity fluctuation of partially coherent light under different atmospheric-turbulence intensities. The experiments showed that partially coherent light had a better anti-turbulence effect under the same turbulent conditions, and that the turbulence effect could be effectively suppressed by reducing the coherence of the beam.

In the same year, Wang et al. [35, 36] studied beam-expansion expressions for partially coherent GSM beams and discussed the transmission characteristics when the beams were transmitted obliquely and horizontally. The light-intensity distribution when the beam was normalized for a horizontal transmission was the same as

that for an oblique-range transmission. The beam was less affected by turbulence during the oblique-range transmission.

Wang et al. [37] studied the transmission characteristics of a partially coherent electromagnetic Schell-model beam in upstream and downstream links in atmospheric turbulence. They demonstrated that the beam could transmit over longer distances in the downlink transmission.

In 2016, Wang et al. [38] studied the transmission characteristics of partially coherent vortex beams under atmospheric turbulence. It was demonstrated that the partial vortex beam had a better transmission performance than the full vortex beam. Zhang et al. [39] studied the transmission characteristics of a partially coherent GSM array beam under atmospheric turbulence. It was demonstrated that the array beam had a better turbulence-suppression ability than a single beam. Zhang et al. [40] studied and analyzed a partially coherent Gaussian–Schell-model pulsed beam (GSMP) and verified that its expansion was less affected by turbulence than that of a fully coherent beam.

In 2017, Wang et al. [41] derived an expression for the average scattering radius of a GSM beam at the receiving end. It was verified that the larger the initial radius of the GSM beam or the smaller the coherence, the less its average scattering radius was affected by atmospheric turbulence. In the same year, Xue et al. [42, 43] investigated the transmission characteristics of GSM beams at various turbulence scales and intensities. This study demonstrated the ability of an inclined-range transport to resist turbulence better than a horizontal transport under the same turbulence conditions.

Wang et al. [44] studied the transmission characteristics of partially coherent Airy beams. It was shown that the smaller the beam truncation factor, the less it was affected by turbulence and the more complete the light-intensity distribution. Zhang et al. [45] studied the transmission characteristics of partially coherent Airy beams and showed that they had less beam drift than Gaussian beams under the same turbulent conditions. Moreover, they had strong turbulence-suppression and recovery properties. Wang et al. [46] studied the transmission characteristics of partially coherent off-axis vortex beams and derived an expression for the light-intensity distribution.

In 2019, Wang et al. [47, 48] investigated a partially coherent electromagnetic Gaussian–Schell-model vortex (EGSMV) beam and verified that the larger the topological charge of this beam in an atmospheric-turbulence transmission, the more information the receiver side received, and the larger the midline dark spot of the beam.

Suppression Principle

It is commonly believed that an ideal point light source emits perfectly coherent light; however, as the laser propagates, its phase and amplitude fluctuate to varying degrees, and the coherence degree of the perfectly coherent light is reduced. Therefore, a fully coherent light source does not exist and partially coherent light, which lies between fully coherent and incoherent light, is prevalent.

Highly coherent laser light is prone to scattering in inhomogeneous media, especially in the atmosphere, where the transmission is affected by turbulence, resulting in an uneven light-intensity distribution. Therefore, the atmospheric-turbulence effect can be suppressed by appropriately reducing the optical coherence. Studies have shown that partially coherent light is less affected by turbulence effects in atmospheric transmission, its scintillation index is less than that of highly coherent light, and it has better turbulence resistance [49].

Partially coherent light can suppress turbulence because it has multicolor properties. Even if it is affected by atmospheric turbulence, its transmission effect is better than that of single-frequency coherent light, so that transmissions using partially coherent light have less scintillation, and more light energy can be received at the receiving end. However, coherent light transmission in turbulence causes the beam to refract in all directions; therefore, only part of the light energy is received at the receiving end. A schematic diagram of partially coherent–light turbulence suppression is shown in Fig. 15.5.

The GSM beam [50] is a typical partially coherent light beam with a spatial correlation structure. Regarding the evolutionary properties of this beam in atmospheric turbulence, it was found that the GSM beam had better turbulence resistance compared to a fully coherent beam. In addition, some partially coherent beams have other novel correlation structures, such as Hermite–Gaussian correlated Schell-Model (HGSM) beams [51], Cosine-Gaussian–Schell-Model (CGSM) beam arrays [52], and Multi-Gaussian–Schell-Model (MGSM) beams [53]. These beams can effectively suppress the influence of negative atmospheric-turbulence effects when transmitted through atmospheric turbulence. However, for some coherent light beams in the transmission process, the beam-divergence angle is larger, resulting in a correspondingly larger signal-energy loss.

Diversity Technology

Diversity is a technique for receiving signals in parallel through multiple independent receiving channels, and then combining these signals for processing. Its main

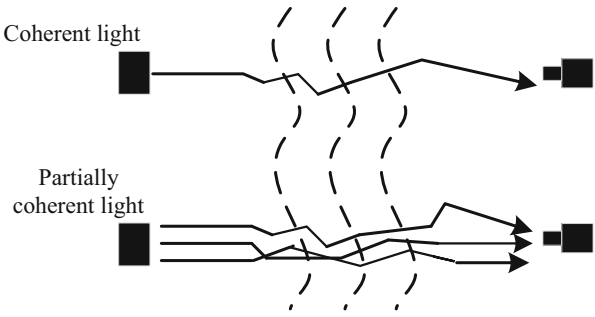

Fig. 15.5 Schematic diagram of partially coherent optical turbulence suppression [17]

purpose is to improve the reliability and performance of the signal reception. In communication systems, the diversity technique is commonly used to reduce the influence of multipath fading, interference, and noise on signal transmissions, thereby improving the signal quality and fault tolerance of the system. It reduces the signal distortion and degradation of the signal-to-noise ratio by simultaneously receiving multiple independent signal paths, and then processing and combining them.

Current Research Status

In 1996, Ibrahim [54] hypothesized that the output signals of small-aperture receivers faded independently of each other and investigated the spatial-reception diversity technique using multiple reception apertures.

In 2004, Pan et al. [55] analyzed the optical-intensity flicker characteristics of a transmission link using a multibeam transmission technique for a ground-to-ground optical communication system. They found that the multibeam transmission technique could effectively suppress the turbulence-induced optical-intensity flicker in the entire turbulence region from weak to strong.

In 2005, Trisno et al. [56] used a time-delay diversity technique to suppress the fading of optical signals due to atmospheric turbulence and obtained signal-to-noise gains of 3.8 dB, 4.3 dB, and 4.4 dB, by increasing the time delay.

In 2006, Anguita et al. [57] used a multibeam transmission technique, analyzed two space-time coding modes, and demonstrated that both modes had higher signal-to-noise gains compared to single-beam transmissions under the influence of atmospheric turbulence.

In 2008, Neda et al. [58] analyzed a ground-based optical-flux system using multibeam emissions and multiple avalanche-photodiode detection reception. They discussed the gain-size selection for merging multiple avalanche-photodiode output signals.

In 2011, Ke et al. [59] used a diversity technique at the receiver side, and the light-intensity flicker effect caused by atmospheric turbulence was effectively suppressed by multiaperture reception. They verified that the BER and aperture-smoothing factor of the system were further reduced with an increase in the number of reception apertures.

In 2012, Ke et al. [60] analyzed the light-intensity probability distribution of signals transmitted through multiple beams under different turbulent environments. The results showed that multiple-beam transmissions could reduce the BER of the system, decrease the light-intensity fluctuation effect, and improve the performance of the communication system under the same turbulent environment.

In 2014, Long [61] demonstrated that aperture diversity could reduce the optical-intensity flicker index and that the system performance was better than that of a large-aperture receiving system. They used a diversity technique and numerical simulations with a phase screen and compared it with a large-aperture receiving system.

In 2015, Kaur et al. [62] investigated the combined effect of atmospheric turbulence on optical wireless multiple-input multiple-output (MIMO) communication

systems under the influence of different weather conditions and compared the BER and outage capacity using aperture-averaging techniques under the same conditions. The results showed that MIMO techniques under different weather conditions effectively suppressed atmospheric turbulence.

In 2016, Bhatnagar et al. [63] studied the effect of alignment errors on an optical MIMO communication system under a gamma–gamma turbulence channel model. They analyzed the performance of a communication system under equal-gain merging and maximum-ratio merging and concluded that the maximum-ratio merging criterion could suppress alignment errors.

In 2017, Meng [64] investigated optical wireless communication systems using the split-set merging technique and showed through experimental simulations that the light-intensity flicker effect caused by atmospheric turbulence could be most effectively suppressed using the equal-gain merging technique.

In 2019, Kumar et al. [65] analyzed the performance of optical wireless MIMO systems under gamma–gamma turbulent channels using different diversity techniques. The results showed that the optical wireless MIMO system could reduce the system BER and improve its reliability under a gamma–gamma turbulent channel.

In 2019, Xu [66] used a diversity technique to derive the probability distribution of light intensity under multibeam emissions. Improved simulation experiments showed that under the same turbulent conditions, it had the right antiturbulence ability, compared to single-aperture emission, which effectively mitigated the light-intensity scintillation effect.

In 2021, Ding [67] analyzed the variation in the receiving-system performance by using a spatial-diversity technique for a partially coherent optical transmission system. The experimental results showed that the signal-to-noise ratio of the communication system could be improved by using a diversity technique, and the performance of the communication system was improved under the influence of turbulence.

In 2021, Dai [17] demonstrated that the scintillation effect could be suppressed by increasing the number of receiving apertures in a large-aperture Cassegrain receiving system. They reduced the light-intensity scintillation index through a diversity technique.

In 2022, Liu [68] investigated optical wireless MIMO communication technology, and the atmospheric-transmission characteristics of a single-input single-output (SISO) system and a MIMO system were comparatively studied using liquid-crystal spatial light modulators to simulate atmospheric turbulence. It was demonstrated that the MIMO communication system had a lower link cost and improved communication performance compared to the SISO communication system.

Suppression Principle

The application of diversity technology in optical wireless communication systems involves increasing the number of antennas at the transmitter and receiver ends. A block diagram of the system is shown in Fig. 15.6. The transmitter end of the system outputs the transmitted laser beam using multiple transmitting antennas. When it

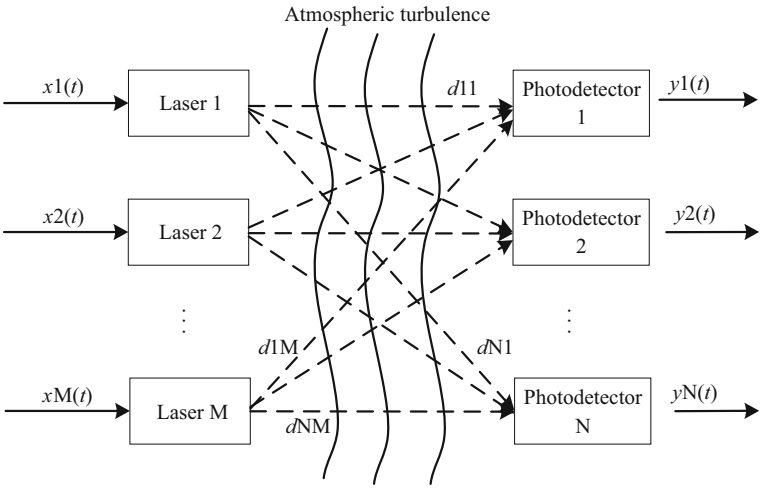

Fig. 15.6 Block diagram of the diversity system [68]

reaches the receiver end, it is received by multiple receiving antennas. The atmospheric-channel attenuation experienced by each signal is unrelated, which can effectively suppress the atmospheric-turbulence effect and improve the communication quality of the entire communication system.

Diversity technology includes transmit and receive diversity. Transmit diversity often uses multibeam transmission technology, which is a free-space laser transmission technology that can effectively suppress the scintillation effect by transmitting two or more superpositioned independent and incoherent lasers through different paths to the receiving end. This smooths the light-intensity scintillation on the far-field receiving plane.

For receiving diversity, antenna-array receiving technology is more commonly used, by setting multiple independent small-aperture receiver antenna arrays instead of large aperture receivers. Under the same receiving-area conditions, the method can receive multipath signals to a greater extent, reduce the impact of turbulent channels, and improve the reliability of the communication system. The structure is simple, flexible, and has a lower cost.

The receiver side combines the multiple received fading signals to obtain a gain signal, which improves the quality of the received signal. Therefore, the merging technique is the most important aspect of the diversity-reception technique. The most commonly used diversity-set merging techniques are maximum ratio, selection, and equal-gain combining [69].

Selection combining is a relatively simple merging technique, in which each branch is demodulated so that their signal-to-noise ratios are the same; then, a branch is selected at the receiving end for demodulation. This approach is difficult to implement in practice because the signal-to-noise ratio of the communication system is not easily measured.

Maximum-ratio combining uses the ratio of the voltage value of each branch signal and the noise power as the weight; then, at the receiving end of each signal, the weight is used for phase correction and according to the gain coefficient to make each signal sum. Finally, it is received in the detector for coherent detection. This reception method is not ideal. The signal can also be demodulated through the maximum-ratio merging method.

Equal-gain combining does not require the weighting of each signal. It directly assumes that each path has the same weight and the same signal is directly superimposed. The results obtained using equal-gain combining and maximum-ratio combining are similar.

The improvements in the gain and signal-to-noise ratio of the optical communication system differ among the three merging methods. Under the same experimental conditions, the improvement in system performance was most evident for maximum-ratio merging, followed by equal-gain merging, and selective merging had the least improvement in system performance.

Adaptive-Optics Technology

Adaptive optics adjusts the shape of optical elements and surface topography in real time, according to changes in the optical system. It is primarily used in astronomy, optical communication, laser processing, and other fields to improve the performance and effects of optical systems. Adaptive-optics technology can effectively improve the performance of optical systems, especially in environments with atmospheric turbulence, significantly reduce the aberration and blurring phenomena caused by atmospheric turbulence, and improve the resolution and transmission distance of astronomical observations and laser communication.

Current Research Status

In 1996, Tyson et al. [70] concluded from a turbulence-theory analysis that conventional adaptive-optics (AO) techniques were effective in reducing the optical-signal attenuation and fluctuations in the uplink and downlink of a ground-space free-space optical communication system under weak-turbulence conditions.

In 1998, Roggemann et al. [71] used adaptive optics and proposed the joint use of two deformation mirrors to correct the light-intensity scintillation effect caused by atmospheric turbulence in laser atmospheric transmissions.

In 1998, Barbier et al. [72] used adaptive-optics techniques to simulate the performance of communication systems using the phase-screen method. The effects of the dynamic range and adaptive-optical aperture size of the wavefront sensor on the mean and variance of the optical intensity were analyzed.

In 2001, Li et al. [73] proposed a correction method using two adaptive-optics systems in series. The control performance and noise-transfer characteristics of this approach were analyzed. The simulation results showed that the tandem structure could substantially improve the utility of the adaptive-optics system in controlling the wavefront aberrations of atmospheric turbulence.

In 2004, Thomas et al. [74] used adaptive optics to compensate for the tilt aberration of the wavefront using a tilt mirror and the higher-order aberration using a micro-electromechanical system (MEMS) deformation mirror. Using this dual-deformation-mirror correction method resulted in a twofold increase in the received signal intensity compared to when only the tilt aberration was corrected.

In 2010, Xia et al. [75] used an adaptive-optics technique to effectively correct the aberrated wavefront and experimentally demonstrated that this technique could improve the communication system gain, reduce the system transmit power, and lower the BER under the same BER conditions.

In 2011, Han [76] used adaptive optics to compensate for free-space optical communication systems and provided the corresponding expressions for the BER and coupling efficiency, as well as the relationship between the coupling efficiency and Strehl ratio.

In 2013, Wu [77] verified through simulation experiments that adaptive optics could effectively correct an aberrated wavefront and improve the phase matching of the local-oscillation light and signal light to reduce the system BER.

In 2014, Hashmi et al. [78] used adaptive-optical techniques to simulate an interstellar optical communication system under moderate background optical noise and strong turbulence. The results showed that the Strehl ratio of the system improved from 0.30 to 0.75 after reaching a steady state with adaptive-optical closed-loop control.

In 2015, Cvijetic et al. [79] conducted experiments using adaptive optics on coherent optical communication systems under the influence of atmospheric turbulence in the ocean. The results showed that the adaptive-optics technique could compensate for the phase distortion of the optical signal and reduce the BER of the communication system.

In 2015, Wright et al. [80] used adaptive optics to build an optical-communication telescope ground-observation communication system and corrected the aberrated wavefront, resulting in an improved Strehl ratio of the received beam from 0.03 to 0.66 after correction.

In 2017, Escarate et al. [81] designed a model-predictive controller to calibrate an adaptive-optics system with 140 units and two deformation mirrors spaced 3 m apart. The results showed that this method could effectively correct the amplitude and phase of the laser beam.

In 2018, Li [82] studied several methods to suppress atmospheric turbulence and completed a wavefront detection-free adaptive-optical atmospheric-turbulence suppression experiment using the stochastic parallel gradient-descent (SPGD) algorithm. The results showed that the corrected fiber-coupling efficiency could be improved from 2.7 dB to 9 dB at different turbulence intensities.

In 2019, Lin et al. [83] predictively estimated state variables for adaptive-optical systems and implemented closed-loop correction using a linear quadratic Gaussian control technique based on state regulation. The results showed that the method could better improve the system response speed and stability compared to a proportional–integral–derivative (PID) control algorithm.

In 2019, Chen et al. [84] used an adaptive-optics technique to apply a continuous-deformation mirror with 137 cells to an adaptive-optics system, which gave a BER of less than 10^{-6} for the communication system by correcting the aberrated wavefront. It was significantly reduced compared to the uncorrected BER.

In 2020, Banet et al. [85] proposed a method to compensate for the beacon using adaptive optics. Under the same turbulent conditions, compared to the uncompensated fiducial adaptive-optics system, the Shack–Hartmann wavefront sensor of the adaptive-optics system with compensated beacons had a 17% performance improvement.

In 2022, Yang et al. [86] analyzed a K-L-mode SPGD algorithm using adaptive optics to correct an optical-wavefront aberration under the influence of atmospheric turbulence. They verified that the convergence speed of the SPGD algorithm in this mode had improved by 47.5%, compared to the conventional SPGD algorithm.

In 2023, Li et al. [87] investigated free-space optical communication under the influence of atmospheric turbulence and proposed an advanced multifeedback SPGD (AMF-SPGD) algorithm to enhance the wavefront-aberration correction performance. They verified that the algorithm could improve the Strehl ratio and reduce the BER of the communication system.

Recently, Xi'an University of Technology has conducted research on many aspects of adaptive optics [88]. In 2018, Wu et al. [89] corrected a distorted wavefront using adaptive optics without wavefront detection, based on the SPGD algorithm. The corrected Strehl ratio was improved from 0.15 to 0.81, which resulted in a larger received spot and mitigated the effect of atmospheric turbulence on the wavefront distortion.

In the same year, Wang et al. [90, 91] used adaptive optics without wavefront detection based on the Gerchberg–Saxton (GS) and SPGD algorithms for wavefront correction of vortex beams. The simulation results showed that the GS algorithm outperformed the SPGD algorithm in terms of correction results.

In 2019, Ke et al. [92] used an adaptive-optics technique with wavefront detection based on double fuzzy control to correct an aberrated wavefront. The simulation results showed that this method could effectively correct the wavefront. In the same year, Yang et al. [93, 94] used adaptive optics with wavefront detection and effectively corrected aberrated wavefronts using computational optical-field imaging.

Zhang et al. [95] proposed an improved SPGD algorithm that used wavefront-sensor-free detection adaptive optics. By parallelizing the SPGD algorithm, the experimental results showed that this method could improve the algorithm-convergence and wavefront-correction speeds. Han et al. [96] used two liquid-crystal spatial light modulators for wavefront-aberration simulation and wavefront correction according to the principle of adaptive optics. The corrected Strehl ratio was improved from 0.38 to 0.82, and the method reduced the experimental cost.

In 2020, Li [97] used adaptive optics without wavefront detection and investigated a wavefront-correction method using the deformation-mirror eigenmode. The Strehl ratio of the correction result improved from 0.56 to 0.88, verifying that the

method effectively corrected wavefront aberrations caused by atmospheric turbulence and that the algorithm converged quickly.

In the same year, Cui [98] used a phase-diversity (PD)-based wavefront detection-free adaptive-optical technique for correcting vortex beams. The experimental results showed that this method could improve the signal power, reduce inter-code crosstalk, and effectively mitigate the turbulence effect.

In 2021, Cheng [99] used a PID control algorithm and a large-amplitude aberration wavefront residual-correction algorithm to correct the problem of insufficient range of the deformation mirror in an adaptive-optics system. The experimental results showed that the large-amplitude aberration wavefront could be effectively corrected using the residual correction algorithm.

Suppression Principle

Adaptive-optics technology can automatically improve the beam-wavefront quality. Therefore, the application of adaptive optics to optical wireless communication systems has great potential for suppressing the effects of atmospheric turbulence. Adaptive-optics systems are divided into two categories: those with wavefront sensors [100] and those without wavefront sensors [101].

Adaptive-Optics Systems with Wavefront Sensors

The adaptive-optics system with a wavefront sensor is shown in Fig. 15.7 and consists of three main components: a wavefront sensor, a wavefront controller, and a wavefront corrector. The general correction process is as follows: The emitted beam is affected by atmospheric turbulence, and the beam wavefront is distorted. The distorted beam passes through the corrector for the first time to collect information and then arrives at the beam splitter. Part of the beam is received, and part of the beam is transmitted to the wavefront sensor to measure the beam-wavefront information. This information is converted into electrical signals that are sent to the wavefront controller for wavefront reconstruction. A suitable control algorithm is selected to generate the control signal. Finally, the wavefront corrector receives the control signal, allowing the corrector to correct the distorted wavefront, forming a closed-loop system.

Wavefront sensors are one of the main components in adaptive-optics systems. Their role is to measure aberrated wavefront information in real time and send it to the wavefront controller. Commonly used wavefront sensors are transverse-shear interferometers [102], Shack–Hartmann sensors [103], curvature wavefront sensors [104], and point-diffraction interferometer sensors [105]. The wavefront controller processes the wavefront information from the wavefront sensor into a control signal and performs two functions: wavefront reconstruction and control-signal generation. Wavefront correctors are essential components of adaptive-optics systems to correct wavefront errors in a timely manner. Common wavefront correctors include liquid-crystal light modulators (LC-SLM) [106] and deformable mirrors (DM) [107].

In adaptive-optics systems with wavefront sensors, the correction accuracy of the distorted wavefronts varies between different control algorithms; commonly used ones are classic and iterative control algorithms. Among the classic control

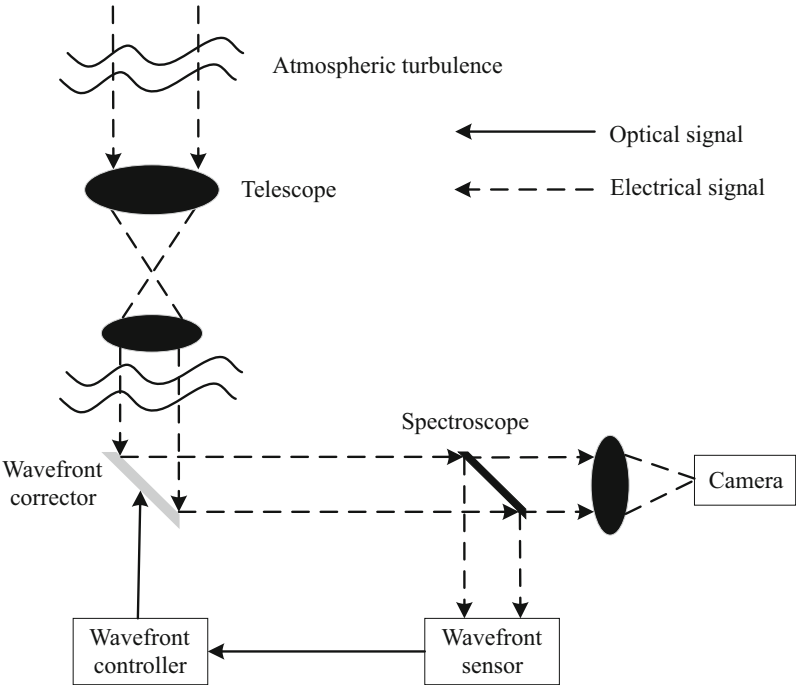

Fig. 15.7 Adaptive-optical system with wavefront sensor [88]

algorithms, the PID control algorithm [108] is widely used in adaptive optics as the most common algorithm.

The main principle of this control algorithm is as follows: First, the command matrix of the system is determined using the push–pull method. Subsequently, the command matrix receives the error slope and converts it into an error-voltage signal. The obtained voltage is then sent to the deformation mirror for wavefront correction by the PID control system. Finally, the wavefront sensor collects the wavefront slope again to achieve closed-loop control.

The Gauss–Seidel iterative algorithm is widely used in adaptive optics to correct aberrated wavefronts, and its effectiveness in adaptive optics is related to the accuracy of the iterative error. The Gauss–Seidel iterative algorithm [108] is based on calculating the information collected by the wavefront sensor, which is then repeated in the iterative formula until the value of the iterative judgment condition is less than the iterative accuracy error; otherwise, the feedback is repeated. Subsequently, the system can proceed to the next slope-acquisition process and repeat the above steps to complete the closed loop. The iterative learning-control (ILC) algorithm [108] is a new iterative algorithm that establishes a relationship between the Zernike polynomial [109] and the control voltage signal of the calibrator to correct the wavefront.

However, the iterative algorithm suffers from problems, such as the range of values used for the parameters. Therefore, its practical applications are limited. In contrast, the PID control algorithm is simple in principle and has better overall performance.

Adaptive-Optics Systems Without Wavefront Sensors

Figure 15.8 shows an adaptive-optics system that does not require a wavefront sensor for wavefront sensing and reconstruction. The wavefront sensor-free system consists of an imaging detector, a wavefront corrector, and a wavefront controller.

The calibration process is as follows: The wavefront calibrator first calibrates the received beam. Then, the beam is projected incident on the imaging detector to collect the information and transmit it to the controller. The controller calculates the voltage signal required by the calibrator using a suitable control algorithm and iterates until calibration is achieved. Adaptive-optical intelligent optimization algorithms for wavefront sensor-free detection fall into two main categories: mode-free and mode optimization methods.

The mode-optimization method involves selecting a suitable base mode to describe the wavefront error and correcting the wavefront distortion by optimizing the base = mode coefficients. Mode-free optimization directly controls a deformable mirror to correct wavefront distortions and optimize system performance-evaluation metrics. Currently, the SPGD algorithm [110], simulated-annealing (SA) algorithm [111], and genetic algorithm (GA) [112] are commonly used among pattern-free optimization algorithms. The SPGD algorithm can estimate the gradient, has fast convergence, is more stable, has simple parameters, and is easy to implement.

The basic working principle of the SPGD algorithm [89] is to estimate the control parameters based on the change values of the performance-evaluation index, and to search for the control parameters in the gradient-descent direction using an iterative approach. It first generates the initial voltage signal of the deformed mirror and the

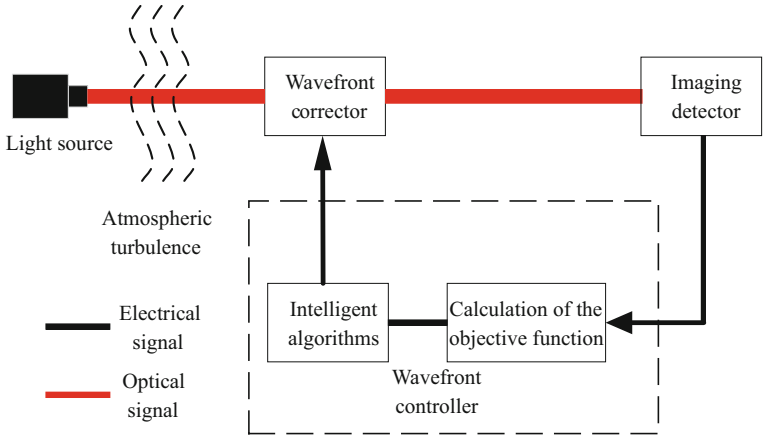

Fig. 15.8 Adaptive-optics system without wavefront detection [89]

random-disturbance voltage signal conforming to the Bernoulli distribution. Next, it adds a positive disturbance voltage and a negative disturbance voltage, respectively, and based on the initial voltage signal calculates the change in the system objective function under the voltage. Finally, it calculates the voltage signal to be loaded in this iteration according to the iterative formula. This is done until the target function satisfies the initial conditions set by the system, so that the system-evaluation index reaches the optimal value, thus, correcting the distorted wavefront.

Many researchers have proposed improved SPGD algorithms [87, 95], all of which can ultimately be very effective in improving the performance of communication systems and enhancing the convergence speed and correction effect of algorithms.

Development Trends

Optical wireless communication systems are susceptible to atmospheric turbulence, which distorts the transmitted beam wavefront and reduces the optical power of the transmitted beam, thereby increasing the BER of the communication system and reducing its quality. Researchers have adopted techniques, such as large-aperture reception, partially coherent light technology, diversity technology, and adaptive optics, to suppress the effects of atmospheric turbulence on optical wireless communication.

For large-aperture receiving technology, the size of the antenna at the receiving end can be appropriately increased to reduce the light-intensity flicker. Currently, many scholars use large-aperture receiving technology to suppress the flicker effect of turbulence, establish different smoothing-factor models according to the different turbulence intensities to design large-aperture receiving systems, and select the appropriate aperture to reduce the weight of the receiving end as much as possible.

Partially coherent light techniques are also highly effective in suppressing atmospheric turbulence, and it is important to investigate new types of partially coherent beams to suppress atmospheric turbulence.

Diversity is a fundamental technique for antifading in wireless communications [113] and can effectively suppress the fading caused by atmospheric turbulence. This technique is low-cost, technically simple, and easy to apply in engineering and has broad development prospects in the future.

Adaptive optics is one of the most widely used techniques for suppressing atmospheric turbulence. It can directly improve the quality of communication systems by correcting distorted wavefronts in real time. Various improvements have been proposed to improve the efficiency of single-mode fiber coupling through adaptive optics to improve communication quality. In recent years, multiple deformation mirrors have been used in adaptive-optics systems and suitable control algorithms have been optimized to improve calibration results. New techniques and methods have been used to improve the calibration of adaptive-optics systems, making them more valuable.

Summary and Outlook

This chapter analyzed domestic and foreign research on suppressing atmospheric-turbulence effects in optical wireless communication systems. The main technologies for suppressing atmospheric-turbulence effects were large-aperture receiving, partially coherent light, diversity, and adaptive-optics technology.

This chapter analyzed the principle of each technology for suppressing atmospheric turbulence. To a certain extent, these technologies can effectively suppress atmospheric turbulence, compensate for distorted wavefronts, and improve the performance of optical wireless communication systems. However, they are not perfect in engineering practice. Table 15.1 shows the advantages and disadvantages of each key technology.

Therefore, further research and discussion on methods to suppress atmospheric turbulence are of great importance.

Table 15.1 Advantages and disadvantages of key technologies for suppressing atmospheric turbulence

Related technology	Advantages	Disadvantages
Large-aperture receiving technology	An appropriate increase in the size of the receiving aperture reduces the variance of the optical-power fluctuations and effectively suppresses the light-intensity flicker effect of atmospheric turbulence	The increased aperture makes the receiver larger and heavier, making it less portable
Partially coherent light technology	Partially coherent light has good resistance to turbulence and effectively suppresses light-intensity flicker effects	It has a large beam-divergence angle and severe beam extension at the receiving end
Diversity technology	Multibeam emission with incoherent superposition at the receiving end smooths the optical power and effectively suppresses the light-intensity flicker caused by atmospheric turbulence	Multitransmitter and multireceiver diversity systems are complex and limited in their practicality
Adaptive optics with wavefront sensors	Automatically improves the optical-wavefront quality, enabling the effective correction of distorted wavefronts	When the communication distance is long, it is difficult for the wavefront sensor to measure the wavefront-aberration information, which makes it impossible to reconstruct the wavefront and compensate for the aberration in real time
Adaptive optics without wavefront sensors	Corrects distorted wavefronts without wavefront reconstruction	Higher cost, requiring additional equipment, and increased system complexity

1. Optical wireless MIMO technology can make full use of spatial spectrum resources and effectively suppress atmospheric-turbulence effects; however, this technology is not yet mature in the optical wireless field, and further research is necessary.
2. Partially coherent vortex beams have a better suppression effect on atmospheric turbulence, and further research on their generation is required.
3. For adaptive-optics technology, further study is needed on deformation mirrors and control algorithms, as well as using multiple deformation-mirror combinations for correction. Finally, the algorithm convergence should be studied to improve the accuracy of deformation-mirror correction.
4. In addition to the aforementioned techniques, new methods for suppressing atmospheric turbulence should be studied.

Abstract

When light waves propagate in the atmosphere, due to the random changes of atmosphere refractive index, turbulence effects such as scintillation, beam expansion, and beam wander will be caused, which seriously affect the performance of laser communication and tracking and imaging systems. Partially coherent beam is less affected by atmospheric turbulence, which makes its propagation characteristics become a research hotspot in recent years. In this chapter, the research progress of partially coherent beam in atmospheric turbulence at home and abroad is summarized; the research work of Xi'an University of Technology in this field is also introduced, including the intensity distribution, beam spread, beam wander, scintillation, arrival angle fluctuation, polarization and scattering properties, etc. Finally, the development direction of the field is prospected.

Optical wireless communications · Partially coherent beam · Atmospheric turbulence · Propagating characteristics · Research progress

Introduction

Owing to the unique directionality, monochromaticity, and high coherence of lasers, laser technology has been increasingly used in the fields of laser guidance, tracking, laser weapons, laser communications, radar, laser ranging, aerial surveying and mapping, and satellite remote sensing and monitoring [1–7].

When a laser propagates in atmosphere, owing to the random fluctuation of the atmospheric refractive index, the beam may expand or drift, the angle of arrival may fluctuate, the light intensity may flicker, and other turbulence effects may occur. These seriously affect the stability and reliability of an atmospheric laser communication system [8–11]. The more coherent the laser is, the more it is affected by atmospheric turbulence; it is easily scattered, making the light intensity distribution uneven. Therefore, to improve the performance of optical communication, the turbulence effect must be reduced.

Partially coherent light, with low coherence, can better suppress these turbulence effects, which means that it should be investigated, theoretically and experimentally. In addition, the polarization state of partially coherent light changes when propagating in atmospheric turbulence. This change is related to atmospheric turbulence and the coherence of the light source [12].

In practical applications, with a long transmission distance and strong atmospheric turbulence, the coherence of laser light in atmospheric turbulence is severely damaged and it becomes partially coherent. Thus, the study of the transmission characteristics of partially coherent light in atmospheric turbulence is becoming increasingly important.

Research History and Current Situation

Foreign Research Progress

The theory of the transmission and scattering of optical waves in atmospheric turbulence can be traced back to the 1960s.

In 1960, Chernov [13] used a geometrical optics approximation method to construct the wave equation of a random continuous medium; however, the finite size of the wave beam was not considered. Therefore, the method had a limited application scope.

In 1961, Tatarskii [14] introduced the turbulence theory developed by Kolmogorov and Obukhov, and used the Rytov approximation method to describe an electric field in an exponential form and expand it into a series. By solving the

exponential series, the process of solving amplitude and phase fluctuations was simplified, and the experimental phenomena of light waves propagating in turbulent media were successfully explained. Therefore, this approximation method has become a classic theory for studying the propagation properties of light in weak turbulence.

After the 1970s, researchers began to experiment with different wave sources, such as sound waves, radio waves, lasers, etc., and found many new experimental phenomena, such as the saturation effect of light wave undulations and the rise-and-fall phenomenon. Unfortunately, Tatarskii's classic theory was not suitable for strong turbulence.

To better explain these phenomena, research theories for strong fluctuation were proposed, such as the Markov approximation [15], generalized Huygens–Fresnel principle [16], path-integration method [17], heuristic theory [18, 19], thin-screen theory [20], etc. The main analytical methods used are illustrated in Fig. 16.1 [21]. However, effective treatment methods are lacking for the critical fluctuation of weak and strong transitions, and it is difficult to obtain a universal theoretical system and results.

In 1970, Whitman et al. [22] derived an expansion formula for laser propagation in a random medium, based on the scalar wave equation, and provided a specific analysis using the Kolmogorov spectrum. They concluded that the larger the transmission distance, the larger the spreading radius.

In 1971, Lutomirski and Yura [16] applied the generalized Huygens–Fresnel integral method to the propagation of plane waves with finite apertures in turbulent media. This method easily dealt with the average optical intensity properties, beam spreading, and coherence degradation of different modes of beams in turbulence; therefore, it is still widely used.

In 1972, Klyatskin [15] proposed a Markov approximation method for solving the statistical moment equation of an optical field. It treated the light propagation process as a Markov process and then derived the equations of each order moment. This method well handled the problem of light propagation in strong turbulence.

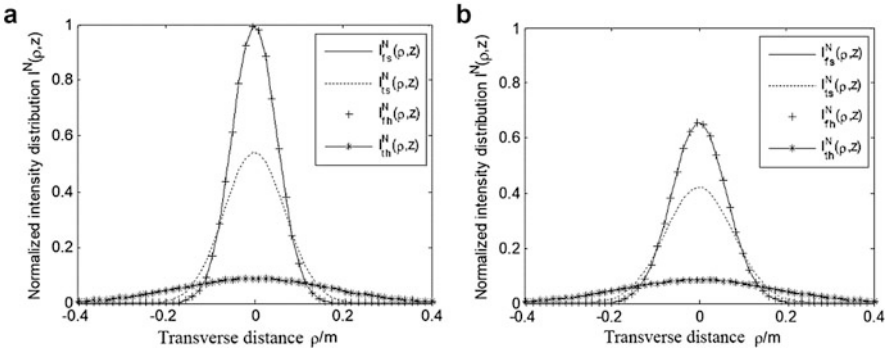

Fig. 16.1 Normalized intensity distribution of fully coherent and partially coherent GSM beams propagating in turbulence. (**a**) Fully coherent GSM beam. (**b**) Partially coherent GSM beam [101]

Poitier et al. [23] applied the Born approximation method to the spreading effect of a focused beam in turbulence.

In 1974, Clifford [24] proposed a simple physics-based, first-order perturbation method to investigate the beam scintillation saturation phenomenon under strong turbulence.

In 1975, Gardner et al. [25] studied the effects of turbulence on the propagation of pulsed laser beams. Fante [26] used the modified von Kármán spectrum to obtain a long-term beam expansion formula and derived a short-term beam expansion formula using the mutual coherence function. Richard J [27] used Ehrenfest's theorem to obtain an expression for the arrival angle of the beam in a turbulent medium with inhomogeneous weak undulation region and applied the Von Karman spectrum to analyze the arrival angle undulation drift of Gaussian focused and collimated beams.

In 1977, Wolf [28] proposed a typical partially coherent source, namely, the Gaussian–Schell mode beam, which has Gaussian intensity and spatial coherence distributions. Subsequently, Foley [29] studied the influence of the initial radius and coherence of the beam on its directionality.

In 1979, De Santis et al. [30] irradiated the light emitted by a laser onto rotating ground glass to generate pseudo-thermal light and formed a Gaussian–Schell mode beam through a Gaussian filter.

By the end of the 1970s, studies on the transmission properties of partially coherent beams in atmospheric turbulence had been initiated. The earliest was in 1978, when American scholar Leader [31] noticed the change in spatial coherence when he studied the scattering of laser irradiation on rough surfaces.

In 1983, Wang et al. [32] considered the intensity scintillation factor of a partially coherent beam transmitted through a weakly turbulent atmosphere. He smoothed the aperture at the receiving surface, using a method similar to that of Leader. Later, Soviet scholars Banakh et al. [33, 34] studied the scintillation of partially coherent beams in atmospheric turbulence.

In 1990, Wu et al. [35, 36] concluded that a partially coherent beam was less sensitive to turbulence than a fully coherent beam through the theoretical study of partially coherent Gaussian–Schell model (GSM) beam propagation in turbulent media. The conclusion greatly increased interest in partially coherent beams.

In 1999, Santarsiero [37] derived an expression for the quality factor of a Schell source beam. They analyzed the variation of the far-field intensity distribution and coherence of a partially coherent Gaussian–Schell beam and a J_0-correlated Schell-model beam during transmission.

Before 2000, research on the transmission properties of partially coherent beams in atmospheric turbulence was rare, and few results were published. With the rapid development of applications such as optical communication and light detection and ranging (LIDAR), the study of the transmission characteristics of partially coherent beams in atmospheric turbulence entered a new stage.

In 2002, to further verify Wu's conclusion, Ponomarenk et al. [38] and Gbur et al. [39] analyzed the propagation characteristics of partially coherent beams in

atmospheric turbulence, in terms of the radius and diffusion angle, respectively, and provided the standard and reason for this insensitivity. Subsequently, Ricklin et al. [40] used a partially coherent GSM beam as a laser source to study the properties of quasi-monochromatic partially coherent Gaussian beams during transmission, such as the average intensity, wavefront coherence length, and beam width, as well as the effects of the turbulence intensity and spatial coherence on an optical wireless communication link.

In 2003, Salem et al. [41] and Dogariu et al. [42] respectively proved theoretically and experimentally that partially coherent beams have more advantages for propagating in atmospheric turbulence. Shirai et al. [43] explained the conclusion that partially coherent beams are less affected by turbulence by studying the Hermi–Gaussian mode propagation of coherent Gaussian beams in atmosphere. Borghi et al. [44] discovered some coherence properties of partially coherent beams by measuring the intensity of partially coherent quasi-monochromatic light.

In 2004, Korotkova [45] studied the influence of a partially coherent light source and its signal-to-noise ratio (SNR) on the link SNR and bit error rate (BER), using theoretical analysis and experimental verification, and proved that the transmission performance of partially coherent light sources was better than that of coherent light sources under the same transmission channel.

In 2005, Andrews [46, 47] produced a drift model suitable for weak turbulence conditions, based on the Rytov and geometric optical approximations, introduced the Gaussian filter function, and attempted to extend it to a strong turbulence mode.

In 2006, Xiao [48] verified by modeling that partially coherent beam propagation in a weak-turbulent atmospheric channel effectively reduced the flicker index and improved the link-transmission quality.

In 2007, Lu et al. [49] studied the variation in the coherence of partially coherent electromagnetic Gaussian–Schell model beams. They found that with fixed source parameters and a specific atmospheric turbulence model, the coherence tended to maximize after propagating a certain distance. The effective width of the spectral coherence was also coherent.

In 2008, Mottagh [50] analyzed the influence of atmospheric turbulence on the SNR and BER of optical wireless communication systems under different turbulence conditions.

In 2010, Borah et al. [51] analyzed the relationship between parameters, such as the beam coherence length, curvature radius of the wavefront, and beam width, and the performance of a communication system. They found that using a partially coherent beam was more beneficial for improving the communication performance when the initial beam width was larger, the transmission distance was shorter, and the beam wavelength was shorter.

In 2012, Voelz et al. [52] studied the spot drift of focused partially coherent beams in atmospheric turbulence, based on a geometric optical approximation, and discussed the average intensity distribution and scintillation index of traceable and untraceable beams. The results were verified by numerical simulations.

In 2014, Chen [53] quantitatively studied the influence of turbulence on the diffusion of porous partially coherent beams by testing the relative mean-square width and obtained a turbulence-independent transmission range.

In 2015, Öztan and Baykal [54] carried out analytical derivations and numerical calculations of the scintillation index of partially coherent annular and flat-topped array beams under strong turbulence conditions. They concluded that the array beams had less scintillation than non-array beams. In the same year, Efimov [55] experimentally demonstrated that the scintillation index of partially coherent beams was lower than that of fully coherent beams at a transmission distance of 1.5 km–6.5 km.

Since 2016, the propagation of partially coherent beams in atmospheric turbulence has been studied extensively, and the beam polarization properties have also attracted attention. In the early days, the coherent and polarization properties of beams were investigated independently of each other. It was not until 1994 that James [56] first suggested that the polarization characteristics of partially coherent beams are altered when they are transmitted in free space.

In 1998, Gori [57] proposed a beam coherence–polarization matrix and calculated the polarization characteristics of spatial points in the time domain, which confirmed a conclusion similar to that of James.

In 2003, Wolf [58, 59] proposed a unified coherence–polarization theory, which was highly significant for studies on beam polarization properties. Subsequently, they used Young's interference experiment to verify that the difference in the degree of beam polarization at the detection plane was related to the degree of beam coherence at the incident end. They concluded that the polarization and coherence characteristics of the electromagnetic beam changed during the transmission in free space, which again proved the unified coherence–polarization theory [60, 61].

In 2005, Korotkova et al. [62, 63] used the unified coherence–polarization theory to derive a formula for the degree and angle of beam polarization during propagation and analyzed the change in the beam polarization state in free space and atmospheric turbulence.

In 2007, Eyyuboglu et al. [64] analyzed the variation in the polarization degree of partially coherent beams in atmospheric turbulence with the transmission distance, for different source parameters using a coherence–polarization matrix.

In 2009, Zhao et al. [65] investigated the polarization shift keying modulation technique in free-space optical communication systems and found that the BER could be reduced if the polarization state did not change during the beam transmission.

In 2014, Zhang [66] and Gao et al. [67] investigated the polarization properties of partially coherent Hermite–Gaussian beams propagating in a slanted path and partially coherent electromagnetic Gaussian–Schell pulsed beams in atmospheric turbulence, respectively. In 2019, they discussed the variation of polarization states of partially polarized and partially coherent pulsed electromagnetic beams as they propagate along a horizontal path in anisotropic turbulence. They compared and analyzed the change in spectral polarization between non-polarized, partially

polarized, and partially coherent pulsed electromagnetic Gaussian–Schell model beams in turbulence [68].

In 2021, Moreno and Castañeda [69] proposed the modeling of nonparaxial electromagnetic wave fields with partially spatially correlated amplitudes and polarization. They explained electromagnetic wave fields from the mathematics and physics perspectives (Table 16.1).

Domestic Research Progress

Many domestic scholars have extensively researched the transmission of partially coherent light in atmospheric turbulence.

In 1986, Zhang [70] discussed the influence of the spatial coherence degree of the light source, turbulence spectrum, and wavelength on the beam wander, and analyzed the drift variation of different turbulence intensities and transmission distances.

In 2004, Liu and Wu [71] derived and numerically simulated the scintillation index of a partially coherent beam under strong turbulence.

Feng et al. [72] studied the evolution of the polarization of a partially coherent beam propagating in random media, according to the generalized Huygens–Fresnel principle. They analyzed the influence of the coherence properties on the beam's polarization evolution and found that the polarization degree of partially coherent beams in random media was relatively less affected by random disturbances.

In 2005, Zhang and Tao [73] first derived a formula for the fluctuation variance of the angle of arrival of partially coherent Gaussian–Schell beams in atmospheric turbulence, and then derived an expression for the intensity distribution of a finite beam through atmospheric turbulence on a slanted path. The results showed that the average intensity was not only related to the half plane of the emission aperture, the transmission distance, and the long-term lateral coherence length but also to the radius of the emission aperture [74].

In 2006, Shi et al. [75] expressed the polarization state of a partially coherent electromagnetic beam propagating in a turbulent medium and analyzed the effect of turbulence on the polarization state of the beam.

In 2007, Gao et al. [76] developed a formula for the variance of beam wander suitable for a strongly fluctuating region based on that for weak fluctuation, which was in good agreement with the experimental data in the published literature. In addition, the spatial coherence length, wavelength, and turbulence intensity of the light source were numerically simulated for the wander, and the influence of these factors on the beam wander was discussed.

In the same year, Wang et al. [77] designed a spot drift detection system to detect the wandering of a He–Ne laser beam at close range. They adopted a charge-coupled device (CCD) camera with an image acquisition card to capture the output spot of the He–Ne laser at close range and used special software to process the digital image. Finally, the size of the spot drift was analyzed, as well

Table 16.1 Major methods of analyzing optical transmissions in atmospheric turbulence [21]

Theoretical research methods	Equation types	Processing procedure	Solving for parameters	Scope of application	Research applications
Rytov perturbation method	Parabolic equation	Assume that the optical field complex phase has a smooth change	Optic field distribution	Weak fluctuation, forward small-angle scattering	Amplitude and phase fluctuations
Geometrical optics method	Ray equation	Geometric optical approximation	Optic field distribution	Weak fluctuation, short-distance transmissions	Arrival angle fluctuation and beam wander
Huygens–Fresnel phase approximation	Generalized Huygens–Fresnel principle	Add a complex phase term to Green's function	Optic field distribution, optical field of moments of each order	Weak fluctuation, forward small-angle scattering	Finite-beam effect, imaging, phase correction analysis
Path-integration method	Parabolic equation	Solve parabolic equations by the path-integral method	Optic field distribution	Weak and strong fluctuation, forward small-angle scattering	Various effects, asymptotic analytical solutions
Feynman diagraming method	Green's function	Solve multiple-scattering equation using the Feynman diagram method	Optical field of moments of each order	Multi-scattering	Checking the reliability of various approximation methods
Statistical moments solved directly as Markov approximations	Statistical moment of the field equation	The view equation is a Markov process, assuming that only forward scattering exists	Moments of each order of the field	Strong fluctuation, forward small-angle scattering	Light intensity fluctuation, spatial distribution of light intensity

as the drift of the laser beam in the X and Y directions, and a spatial stereo angle was obtained.

In 2008, Qian et al. [78] numerically simulated the expansion and wandering of laser beams with different wavelengths using a multilayer phase screen method. The results showed that the larger the zenith angle, the stronger the turbulence effect, and the more the beam was affected by turbulence. The shorter the wavelength, the more the beam was affected by turbulence. The spot drift decreased with the increase of the initial beam radius and was independent of the wavelength.

Chu et al. [79] studied the average intensity and expansion of multi-Gaussian beams though atmospheric turbulence in a slanted path and analyzed the changes of intensity and expansion with parameters such as altitude, beam coherence length, and beam waist width. Wang et al. [80] studied the polarization characteristics of the entire optical field when an electromagnetic Gaussian–Schell model beam propagated in atmospheric turbulence.

In 2009, Yang et al. [81] investigated the beam width and angular expansions of a Hermite–Coulomb–Gaussian beam when it propagated horizontally in atmospheric turbulence. They analyzed the effects of the transmission distance, atmospheric refractive index structure constant, beam order, and beam waist width on the two expansions and provided corresponding physical explanations for the obtained results. Ji [82] studied the polarization, coherence, and spectral intensity of a partially coherent electromagnetic flat-topped beam propagating in atmospheric turbulence.

In 2010, Qian and Rao et al. [83] researched the beam expansion, wander, and scintillation of partially coherent beams by numerical simulation and once again verified that turbulence has less effect on partially coherent beams.

In 2011, Wu et al. [84] studied the propagation characteristics of electromagnetic partially coherent Gaussian–Schell beams in atmospheric turbulence with a slanted path. Chen et al. [85] analyzed and summarized the research progress of optical coherence and polarization.

In 2012, Zhang et al. [86] used a partially coherent flat-topped beam as an example to analyze the influence of parameters, such as the beam order, spatial coherence, and zenith angle, on the width of a beam that propagated in atmospheric turbulence on a slanted path. Li et al. [87] studied the expansion and wander of a GSM beam, using the beam center-of-mass distribution, and concluded that the longer the wavelength, the more obvious the wander.

In 2013, Duan et al. [88] studied the average intensity and mean-square beam width of a GSM beam when propagating in atmospheric turbulence with three different paths (uplink, downlink, and horizontal), and found that the beam was least affected by turbulence in the downlink path.

In 2014, Zhang et al. [89] studied the intensity distribution of a nonparaxial multicolor partially coherent Laguerre–Gaussian beam propagating in free space and found that the intensity distribution of the beam was determined by the initial parameters of the beam. They also found that the spectral displacement of the beam when propagating in free space was related to the initial beam parameters and the transmission distance.

In 2015, Fang et al. [90] experimentally generated a spatially coherent and controllable Besinc coherent vortex beam and studied the intensity and coherence distributions of the beam propagating in free space. Hou et al. [91] numerically calculated and analyzed the BER of a partially coherent optical transmission channel under different atmospheric turbulence conditions and proved that partially coherent optical transmissions effectively reduced the communication BER.

In 2017, Zhang et al. [92] studied the transmission characteristics of Gaussian inhomogeneous partially coherent beams in atmospheric turbulence and found that the change of its coherence was closely related to the Gaussian modulation half-width of the source plane and the transmission distance.

In 2018, Wang [93] summarized the research foundation and theoretical methods of partially coherent beams in atmospheric turbulence and introduced the phase screen numerical simulation method of a beam propagating through turbulent atmosphere.

In 2019, Zhou et al. [94] investigated the evolution rules of transmission characteristics, such as the intensity distribution, root-mean-square beam width, and beam wander, when a crescent-shaped beam was propagated in atmospheric turbulence.

In 2021, Zhang and Ma et al. [95] studied the effect of atmospheric turbulence on a twisted Laguerre–Gaussian correlated beam with different distortion factors, cross-sectional coherence, and beam orders.

In 2022, Yang et al. [96] studied the M2 factor of partially coherent twisted vortex beams in anisotropic atmospheric turbulence and conducted numerical simulations.

The transmission characteristics of partially coherent beams in atmospheric turbulence still require extensive research, and they are no longer limited to a single typical beam. In recent years, the following domestic universities and research institutes have investigated the transmission of partially coherent beams in atmospheric turbulence: University of Electronic Science and Technology of China, Changchun University of Technology, Xi'an University of Electronic Science and Technology, Taiyuan University of Technology, Anhui Institute of Optics and Precision Machinery, Institute of Optoelectronic Technology, Chinese Academy of Sciences, and Southwest Institute of Optoelectronics. The Optoelectronics Laboratory of Professor Ke Xizheng of Xi'an University of Technology has also studied the transmission characteristics of partially coherent beams in atmospheric turbulence and made progress [97].

In 2014, based on the formula of the beam width of a GSM beam in strong turbulence, Han [98] used the general expression of the beam wander variance models of Andrews and Phillips to derive the wander variance expression of a horizontal path propagating partially coherent beam in atmospheric turbulence. The spreading and wander of a partially coherent beam through the entire atmospheric turbulence were discussed.

In early 2015, based on the modified Rytov variance, Zhang [99] used a GSM beam and the Andrews model to study the effect of partially coherent beams through atmospheric turbulence on the log-intensity variance. In March of the same year, Han [100] further studied the spreading and wander of a coherent GSM beam while considering the outer turbulence scale in a slanted path.

Subsequently, Wang [101, 102] discussed the impact of the turbulence intensity, zenith, beam coherence length, and other parameters on a beam propagating on slanted and horizontal paths. They were compared from the perspective of the normalized intensity distribution and relative expansion. Wang [103, 104] compared and analyzed the influence of light source parameters and turbulence on the effective radius and average speckle radius of a GSM beam by numerically calculating their formulas.

In 2016, Xue [105, 106] studied the arrival angle fluctuation of partially coherent Gaussian–Schell beams in horizontal atmospheric turbulence. They contrasted and analyzed the influence of various parameters on the arrival angle fluctuation variance, including the inner and outer turbulence scales, turbulence intensity, transmission distance, source coherent parameter, and wavelength. Wang [107] analyzed and discussed the influence of the transmission distance, turbulence intensity, and beam parameters on the intensity distribution of a vortex beam.

Zhang [108] analyzed the transmission characteristics of partially coherent array beams in optical wireless communication systems. Zhang [109] conducted a detailed numerical analysis on the pulse spreading of partially coherent GSM pulsed beams propagating horizontally in atmospheric turbulence.

In 2017, Wang Song [110] simulated the effect of partially coherent Airy light intensity distribution in terms of propagation distance and turbulence intensity, and performed relevant experimental verification of the effect of the beam's own parameters on the light intensity distribution. Then, Lin Zhang [111] discussed and analyzed the expansion and drift characteristics of partially coherent Airy beams. Chaozhen Wang [112] extended the study of the transmission characteristics of off-axis vortex beams based on vortex beams.

In 2019, Wang [113, 114] studied the far-field distribution, intensity distribution, and polarization of a new partially coherent vortex beam after transmission through atmospheric turbulence. They also investigated the intensity distribution of a partially coherent vortex beam array transmitted in atmospheric turbulence.

During research, owing to factors such as the ground, high-altitude wind speeds, atmospheric temperature, and air pressure, the experimental conditions are limited, expensive, and difficult to achieve. Therefore, the transmission characteristics of partially coherent beams in atmospheric turbulence are mostly studied by theoretical analysis, numerical calculation, or software simulation. The Gaussian–Schell model (GSM), as a typical partially coherent beam, has excellent characteristics, such as more uniform light intensity and reduced

scattering; thus, it is typically studied when investigating partially coherent beam problems [115].

Gaussian–Schell Model of a Partially Coherent Beam

The coherence of a beam includes spatial and temporal coherence. Generally, a partially coherent light source is generated by superimposing a time-varying random amplitude and phase distribution onto a fully coherent beam field. The added random amplitude and random phase distribution represent the temporal and spatial coherence of the optical field.

Assuming that the optical field distribution of the initial fully coherent light source is D_{12}, the time-varying amplitude and phase distribution are expressed as $(\omega_1 - \omega_2)/(\omega_1 + \omega_2) \leq 1$. The optical field distribution of the partially coherent beam at the emission can be written as [117, 118]:

$$\begin{aligned} U'(x, y, 0, t) &= U_0(x, y, 0) t_A(x, y, t) \\ &= U_0(x, y, 0) \exp[i\xi(x, y, t)], \end{aligned} \tag{16.1}$$

where $\xi(x, y, t)$ is a random phase that varies with time and represents the partial coherence of the optical field of the light source.

The two-point cross-spectral density function of a partially coherent light source is defined as [40]:

$$\begin{aligned} W_0(\rho_1, \rho_2) = \left\langle U_0^*(\rho_1) U_0(\rho_2) \right\rangle &= U_0^*(\rho_1) U_0(\rho_2) \\ &< \exp[i\xi_1(\rho_1, t)] \exp[i\xi_2(\rho_2, t)] > , \end{aligned} \tag{16.2}$$

where $\rho_1 = \left(x_1^2 + y_1^2\right)^{1/2}$, $\rho_2 = \left(x_2^2 + y_2^2\right)^{1/2}$, and $\rho = \mid \rho_1 - \rho_2 \mid$ represent the two-dimensional vectors at the plane of the light source.

For partially coherent Schell beams, the cross-spectral density function is expressed as:

$$W_0(\rho_1, \rho_2) = \left\langle U_0^*(\rho_1) U_0(\rho_2) \right\rangle = \sqrt{I_0(\rho_1)} \times \sqrt{I_0(\rho_2)} \mu_0(\rho_2 - \rho_1), \tag{16.3}$$

where $I_0(\rho)$ is the average light intensity and $\mu_0(\rho_2 - \rho_1)$ represents the coherence degree of the beam at $z = 0$. When the beam satisfies

$$I_0(\rho) = A \exp\left(-\frac{2\rho^2}{w_0^2}\right), \mu_0(\rho) = \exp\left(-\frac{\rho^2}{2\sigma_g^2}\right), \tag{16.4}$$

it is called a partially coherent Gaussian–Schell model beam. A is a constant, w_0 is the initial beam radius, and σ_g represents the degree of beam coherence. The larger the σ_g, the higher the degree of coherence. In contrast, the coherence of the beam is worse.

Properties of Partially Coherent Beam Propagation in Atmospheric Turbulence

Intensity Distribution

When a beam is transmitted in atmospheric turbulence, owing to the random fluctuation of the atmospheric refractive index, the light intensity on the receiving surface weakens, which affects the reliability of the laser communication system.

Comparison of the Intensity Distributions of a GSM Beam on Horizontal and Slanted Transmission Paths

The transmission of a beam in atmospheric turbulence can be divided into horizontal and slanted paths, according to the size of the zenith angle. The beam is affected by turbulence to different degrees for different transmission paths. When the beam is propagating in free space, the light intensity is weakened, owing to the influence of vacuum diffraction, and the light intensity on the receiving surface will differ, depending on the beam coherence.

As shown in Fig. 16.1 [101], the normalized intensity distributions of fully coherent and partially coherent GSM beams in free space are independent of the transmission path, while the intensity distribution of a slanted path in atmospheric turbulence is more concentrated. Whether propagating in free space or in atmospheric turbulence, the intensity distribution of a fully coherent GSM beam is more concentrated. The intensity distribution of a partially coherent beam is less affected by turbulence than that of a fully coherent beam, which is consistent with the results obtained in the literature [43] when the beam is transmitted horizontally through the atmosphere.

Influence of Light Source Parameters on the Intensity Distribution

The normalized light intensity distribution during atmospheric turbulence propagation differs when the relevant parameters of the light source, such as beam coherence length and wavelength, are different. Figures 16.2, 16.3, and 16.4 [101] demonstrate the effects of various factors, such as the beam coherence length, beam waist width, and wavelength, on the normalized intensity distribution of partially coherent GSM beams propagating in atmospheric turbulence and free space.

It can be seen that when the GSM beam propagates in a slanted path, the smaller the beam coherence length, the smaller the influence of turbulence on the light intensity. The smaller the beam wavelength, the stronger its normalized light intensity, and the larger the wavelength, the stronger the light intensity. This is due to the different in-band attenuations caused by the atmospheric absorption of beams of different wavelengths.

Effect of Atmospheric Turbulence on the Intensity Distribution

The influence of atmospheric turbulence is generally studied theoretically by changing the atmospheric refractive index structure constant (atmospheric turbulence intensity) and the internal and external turbulence scales. Figures 16.5 and 16.6

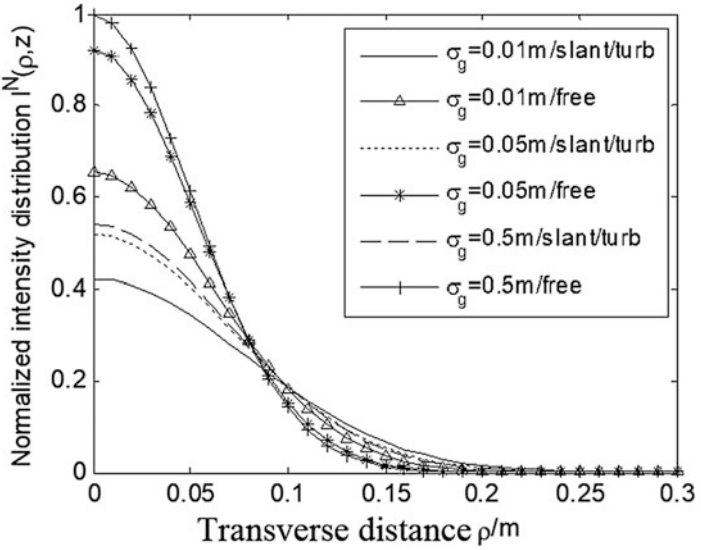

Fig. 16.2 Normalized intensity distribution of partially coherent GSM beam transmitted in turbulence with different coherent lengths [101]

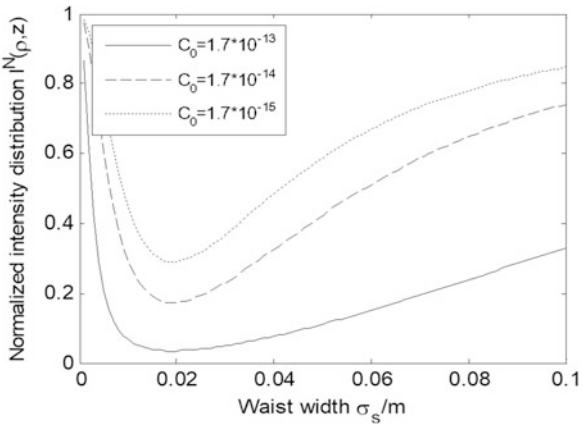

Fig. 16.3 Normalized intensity distribution of a partially coherent GSM beam transmitted in different turbulence conditions [101]

[101] show the normalized intensity distribution of partially coherent GSM beams propagating in atmospheric turbulence with different atmospheric structure constants and internal and external turbulence scales, respectively.

The results show that under the same turbulence condition, the intensity distribution of the beam on the slanted path is more concentrated than that of the horizontal path. The stronger the turbulence intensity, the more dispersed the intensity distribution; the larger the inner turbulence scale, the more concentrated

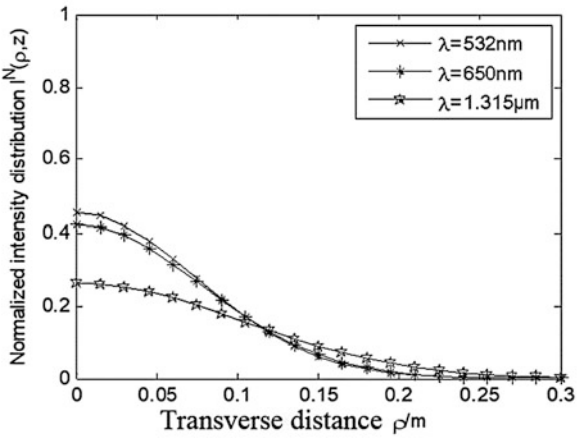

Fig. 16.4 Normalized intensity distribution of a partially coherent GSM beam transmitted through turbulence with different wavelengths [101]

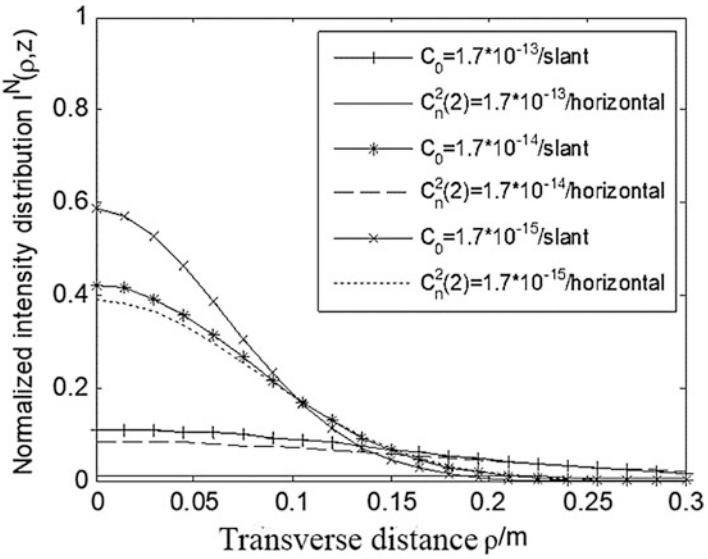

Fig. 16.5 Normalized light intensity distribution during partially coherent GSM beam propagation under different turbulence intensities [101]

the intensity distribution. Changes to the outer scale had little effect on the beam intensity distribution. Therefore, when analyzing the influence of atmospheric turbulence on the intensity distribution, only the internal scale need be considered; the outer scale can be ignored.

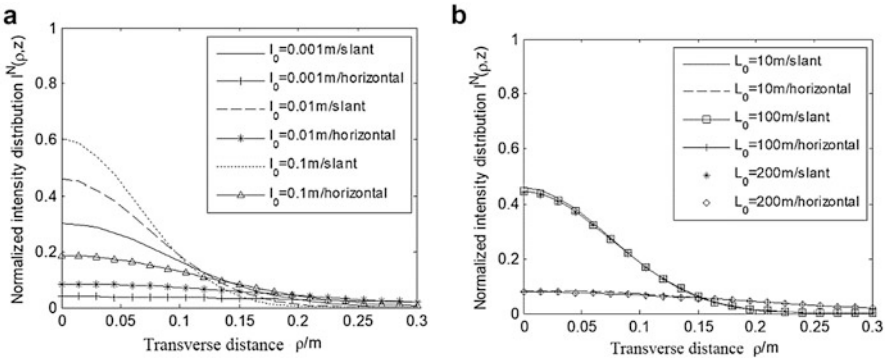

Fig. 16.6 Normalized intensity distribution of GSM beams transmitted in turbulence with different inner and outer scales. (**a**) Different inner scales. (**b**) Different outer scales [101]

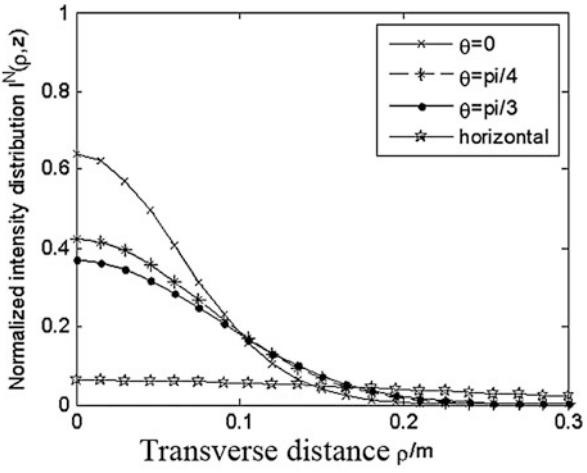

Fig. 16.7 Normalized intensity distribution of a partially coherent GSM beam propagating in turbulence with different zenith angles [101]

Effect of the Zenith Angle on the Intensity Distribution

When the beam passes through the atmosphere at different zenith angles, owing to different transmission distances, the influence of atmospheric attenuation and turbulence also differs. The normalized intensity distribution of a partially coherent GSM beam propagating in turbulence with different zenith angles is shown in Fig. 16.7 [101].

It can be seen from the figure that the zenith angle is 0°, i.e., when the beam propagates vertically, the intensity distribution is the most concentrated, while it is dispersed on the horizontal path. The larger the zenith angle, the more dispersed the light intensity distribution. The closer the beam is to the ground, the greater the influence of turbulence, and the worse the beam quality. Moreover, the larger the zenith angle, the more scattered the light intensity distribution.

Beam Spreading

Because of the influence of the atmospheric refractive index and beam wavefront phase distortion, the beam spreads when it propagates in atmospheric turbulence. The turbulence scale also affects it. When the beam scale is smaller than the turbulence scale, many small turbulence vortexes appear in the beam cross section. This part of the corresponding beam is diffracted, leading to random fluctuations of the beam in time and space, and eventually to spreading.

Spreading of a GSM Beam in Horizontal and Slanted Paths

The effective beam radius at the receiving end directly reflects the change in beam spreading. As shown in Figs. 16.8 and 16.9 [98] and Figs. 16.10 and 16.11 [100], when the beam is transmitted horizontally, the smaller the initial beam radius, the more the beam is affected by turbulence. A partially coherent beam transmitted horizontally is less affected by turbulence—i.e., it spreads less—than a fully coherent beam, which is consistent with the conclusions drawn in the literature [116], taking a partially coherent Hermite–Gaussian beam as an example.

During slanted propagation, a partially coherent beam expands more rapidly than a fully coherent beam and is also less affected by turbulence. The larger the initial radius and the higher the receiver height, the smaller the beam spreading, which is in agreement with the conclusions drawn from the numerical simulation of partially coherent beams in the literature [78].

In addition, Ke and Wang [102] discussed beam spreading from the perspective of the relative beam width (ratio of the beam width in turbulence to a free-space beam width) and concluded that when the beam propagates along a downlink, it is least affected by turbulence. The relative beam width increases with the increase in

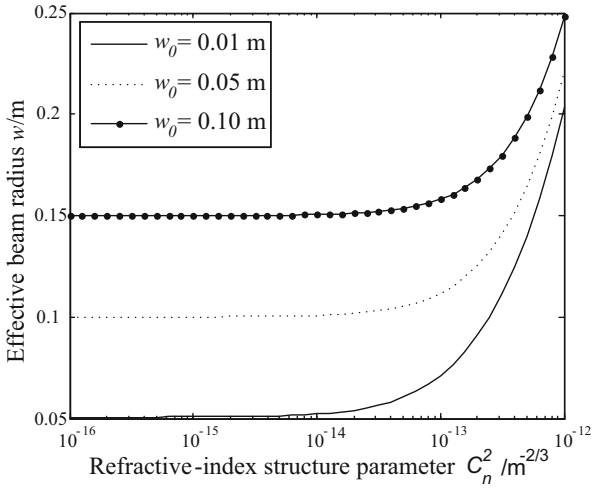

Fig. 16.8 Effective beam radius versus refractive index structure parameter [98]

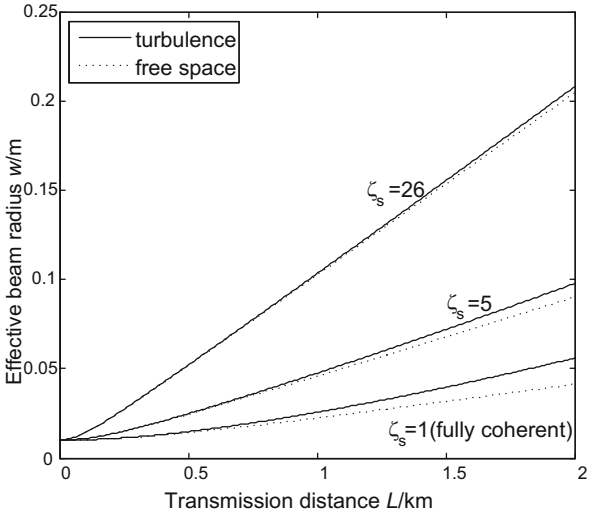

Fig. 16.9 Effective beam radius versus propagation distance [98]

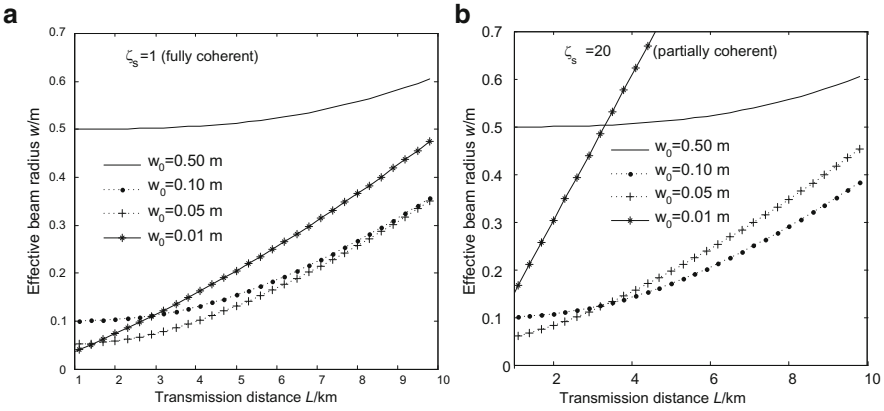

Fig. 16.10 Effective beam radius versus propagation distance with different initial beam radii. (**a**) Fully coherent beam. (**b**) Partially coherent beam [100]

turbulence intensity, zenith angle, and coherence length. It also increases with the decrease in wavelength and internal scale; thus, turbulence has a larger influence on the beam.

Angle Spreading of a GSM Beam in Horizontal and Slanted Paths

The angular spread variation can also reflect the spreading effect of atmospheric turbulence on the beam from another perspective. Figures 16.12, 16.13, 16.14, and 16.15 [102] demonstrate the effects of parameters, such as the zenith angle,

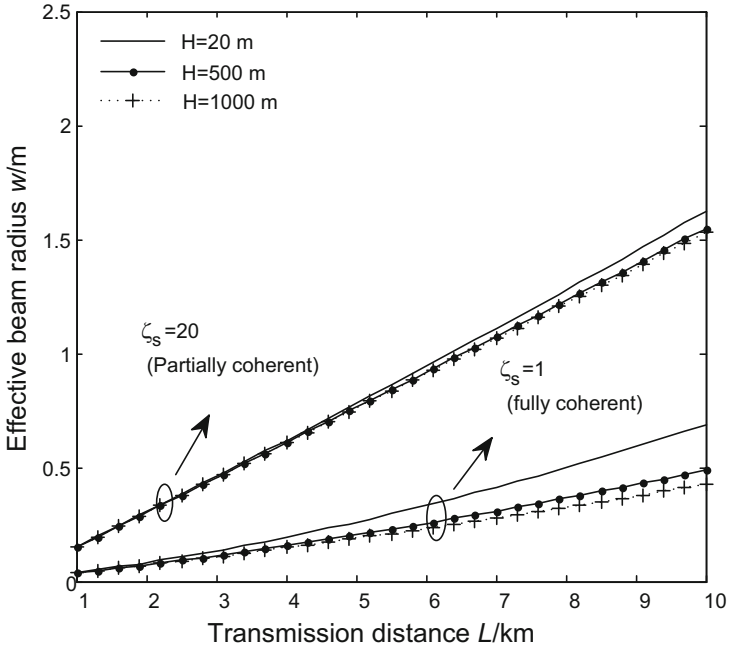

Fig. 16.11 Effective beam radius versus propagation distance with different receiver heights [100]

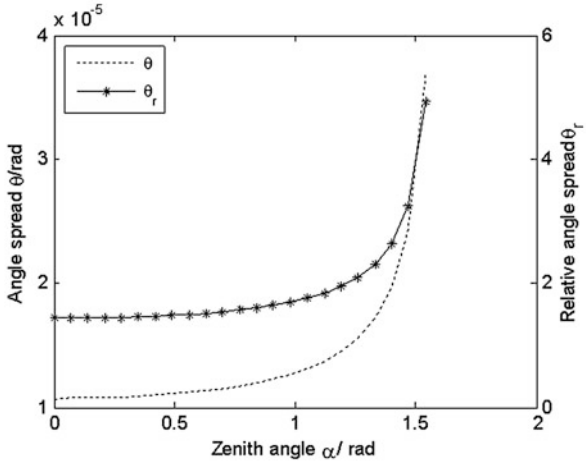

Fig. 16.12 Angular spread and relative angular spread versus zenith angle [102]

transmission distance, turbulence intensity, and coherence length, on the angular and relative angular spreading [119].

As can be seen from the figures, the angular spreading of the beam on the slanted path through atmospheric turbulence is less affected by the turbulence than that on

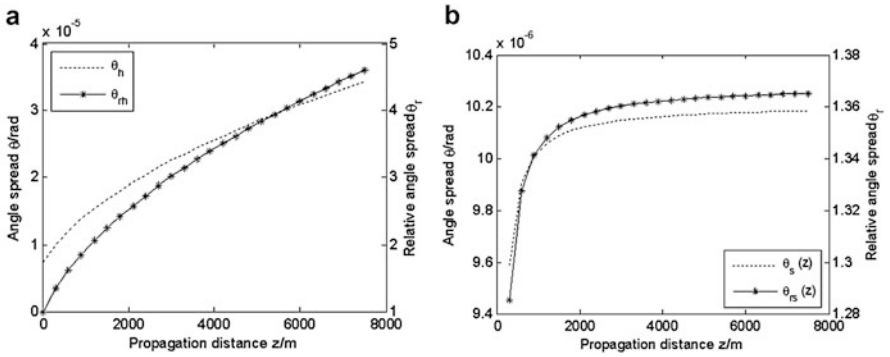

Fig. 16.13 Angular spread and relative angular spread versus propagation distance. (**a**) Horizontal transmission. (**b**) Slanted transmission [102]

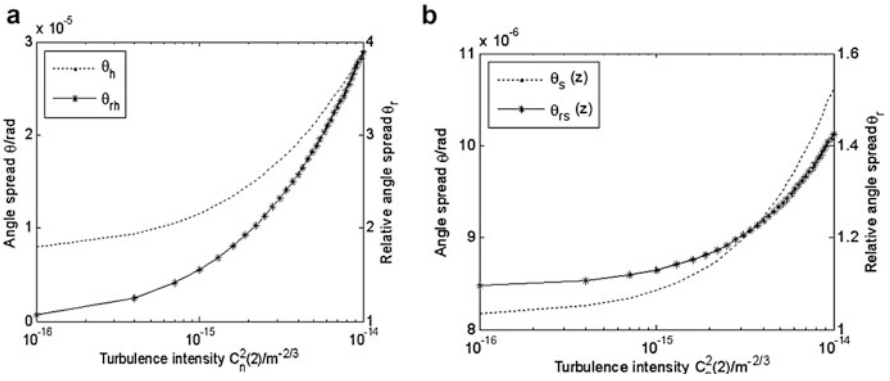

Fig. 16.14 Angular spread and relative angular spread versus turbulence intensity. (**a**) Horizontal transmission. (**b**) Slanted transmission [102]

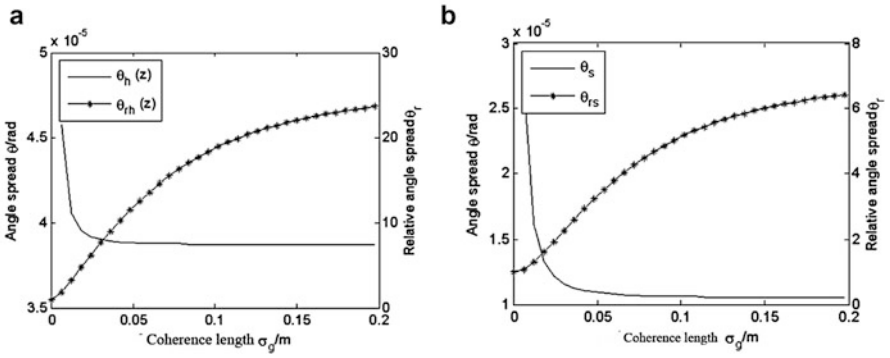

Fig. 16.15 Angular spread and relative angular spread versus coherence length. (**a**) Horizontal transmission. (**b**) Slanted transmission [102]

the horizontal path, and the smaller the zenith angle of the slanted transmission, the less the beam is affected by turbulence. The spreading of the beam angle and relative angle increase faster at transmission distances less than 1 km. The stronger the turbulence intensity, the greater the influence of turbulence on the beam angle spreading and the more obvious the angle spreading.

Beam Wandering

Beam wandering is mainly due to the refraction of large-scale turbulent vortices. When the beam diameter is much smaller than the turbulence size, i.e., when the turbulence is relatively weak, the turbulence causes random beam deflections and deviations from the original propagation direction. At this time, the beam propagation direction or the projection position on the receiving surface is randomly floating, i.e., the beam wanders.

Beam Wandering of a GSM Beam on a Horizontal Transmission Path

Beam wandering is inseparable from large-scale turbulence. A turbulence power spectral density function that considers large-scale factors needs to be selected in the research. As shown in Figs. 16.16 and 16.17 [98], the wavelength has little effect on wandering in the visible and near-infrared bands for short-range transmissions. The difference in wandering variation due to different wavelengths decreases as the initial radius increases. Therefore, to reduce the impact of atmospheric turbulence, the transmitter should choose a large initial radius, long wavelength, and higher position from the ground for transmitting.

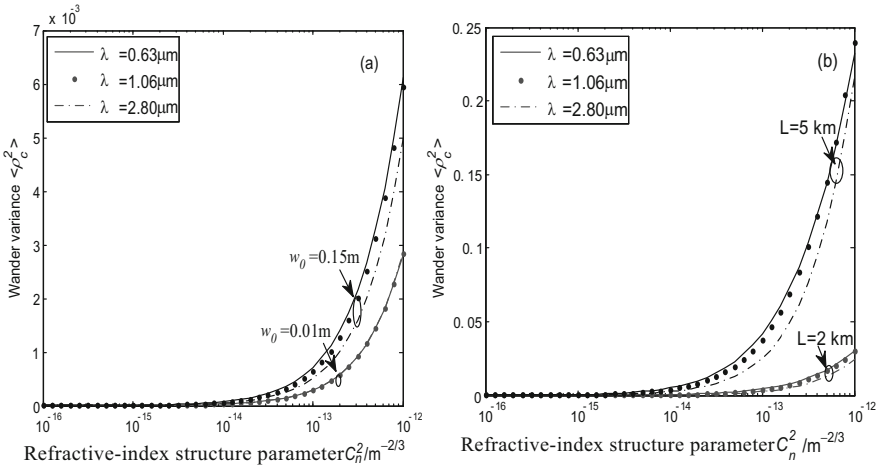

Fig. 16.16 Beam wandering variance versus refractive index structure parameter. (**a**) Different wavelengths and initial beam radii. (**b**) Different wavelengths and transmission distances [98]

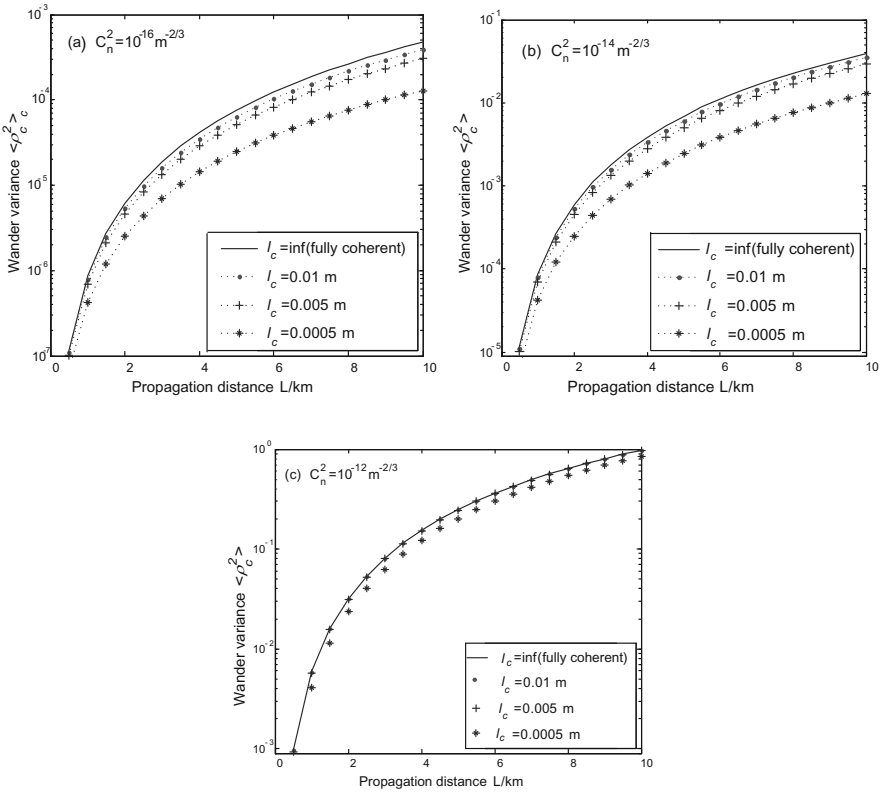

Fig. 16.17 Relationship of the beam wander variance and spatial coherence length. (**a**) $C_n^2 = 10^{-16}\mathrm{m}^{-2/3}$. (**b**) $C_n^2 = 10^{-14}\mathrm{m}^{-2/3}$. (**c**) $C_n^2 = 10^{-12}\mathrm{m}^{-2/3}$ [98]

When the transmission distance is greater than 2 km, the beam wandering in medium and strong turbulence is related to the wavelength, and the wandering is more obvious in the strong turbulence region. When the spatial coherence length of the beam is greater than 0.005 m, the spatial coherence length of the light source has little effect on the beam wandering within a transmission distance of 10 km, which is consistent with the conclusions in the literature [83].

GSM Beam Wandering on a Slanted Transmission Path

The atmospheric refractive index structure constant varies with height during a slanted transmission. Figure 16.18 [100] shows the variation in the wandering variance of partially coherent and fully coherent beams in atmospheric turbulence under different conditions during an uplink transmission. The beam wandering of the fully coherent beam is slightly affected by the wavelength, which is consistent with the numerical simulation results in the literature [83]. The longer the wavelength of the partially coherent beam, the more obvious the wandering, which agrees with the conclusion drawn from the spot centroid distribution diagram in the literature [87].

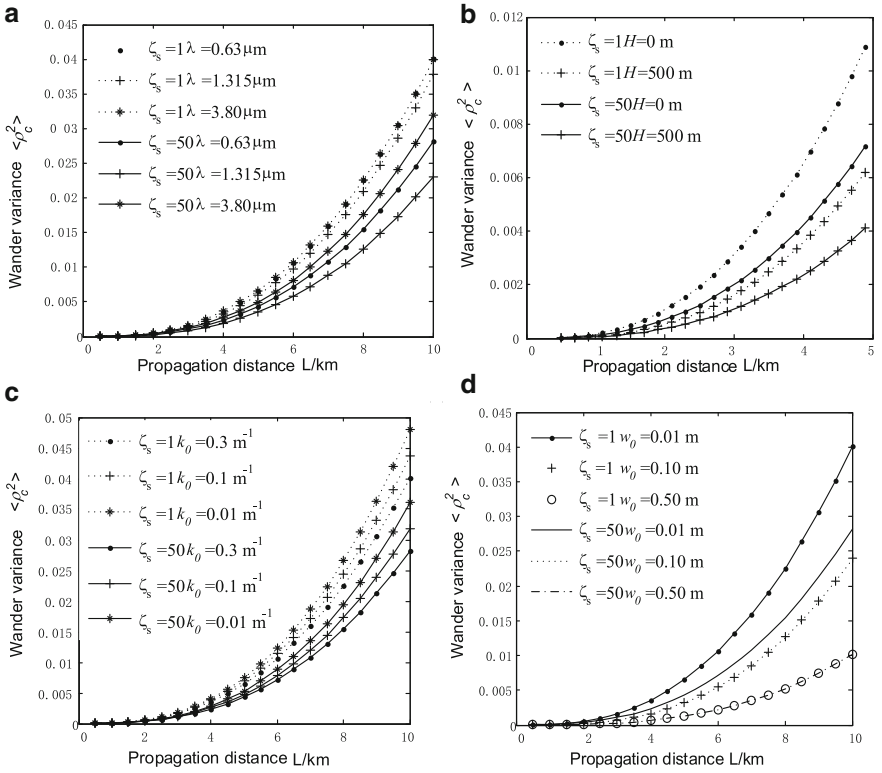

Fig. 16.18 Partially and fully coherent beam wander variance versus propagation distance. (**a**) Different wavelengths. (**b**) Different receiver heights. (**c**) Different large turbulence scales. (**d**) Different initial radii [100]

When the transmission distance is the same, the higher the height of the receiver, the smaller the wander effect.

Compared with a horizontal transmission, a slanted transmission is obviously less influenced by turbulence. When the receiver height is constant and the transmission distance is within 5 km, the worse the coherence, the smaller the wander variance, and the wandering is even smaller for short-distance transmissions. The larger the outer turbulence scale, the more apparent the wander is, and the partially coherent beam has a smaller wander effect than the fully coherent beam. When the transmission distance is greater than 2 km, the wander variance decreases with the increase of the initial beam radius.

GSM Beam Scintillation

When a laser propagates in atmospheric turbulence and the beam diameter is much larger than the turbulence scale, the beam cross section contains multiple turbulent

vortices, each of which independently scatters and diffracts the portion of the beam irradiated on it. This produces continuous spatial and temporal variations in the optical density in the detector plane. The beam intensity fluctuates from large to small, and the light spot is bright and dark. This change is called scintillation of the light intensity (light intensity fluctuation).

Scintillation in Strong and Weak Turbulence

According to Davis's classification approach, strong and weak turbulence are divided by the range of values of C_n^2: weak turbulence is when $C_n^2 < 6.4 \times 10^{-17} m^{-3/2}$ and strong turbulence is when $C_n^2 > 2.5 \times 10^{-13} m^{-3/2}$. The log-intensity variance of a partially coherent beam with the transmission distance under strong and weak turbulence is shown in Figs. 16.19 and 16.20 [99].

The log-intensity variance of a partially coherent beam is lower than that of a fully coherent beam under the same turbulence conditions. Moreover, as the light source coherence worsens, the log-intensity variance and the influence of the turbulence

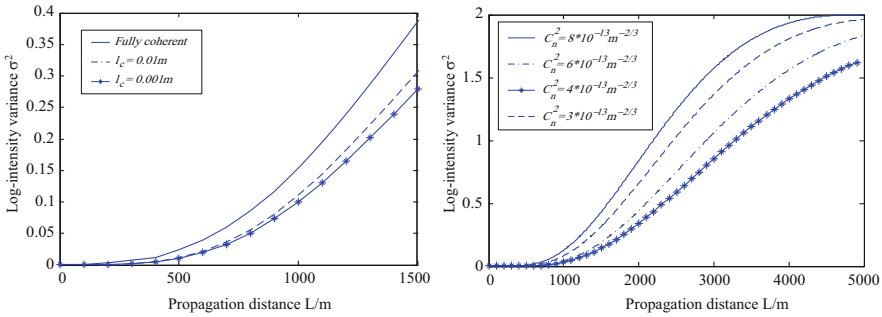

Fig. 16.19 Log-intensity variance of a partially coherent beam versus vector-propagation distance in strong turbulence [99]

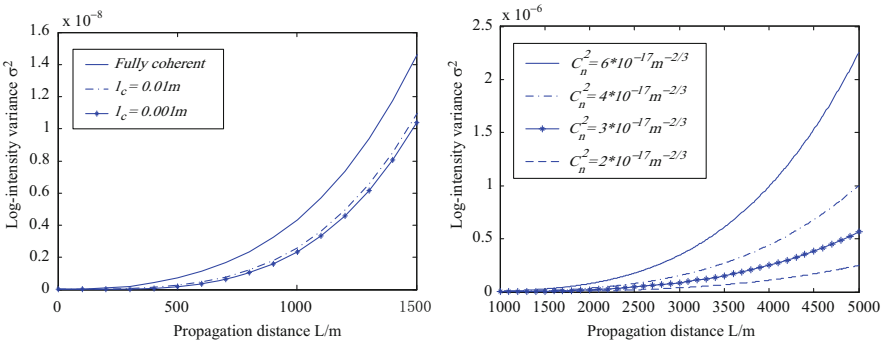

Fig. 16.20 Log-intensity variance of a partially coherent beam versus propagation distance in weak turbulence [99]

plane decrease. The light source coherence, atmospheric refractive index structure constant, and other parameters have a significant effect on the scintillation in both weak and strong turbulence. Regardless of turbulence, the scintillation of fully and partially coherent beams increases with the increase in transmission distance and atmospheric refractive index structure constant, and the partially coherent beam increases less than the fully coherent beam.

Scintillation of Fully and Partially Coherent Beams

To better compare and analyze the scintillation of partially and fully coherent beams in strong and weak turbulence, Ke and Zhang [99] introduced the modified log-intensity variance ratio α, which is defined as the ratio of the log-intensity variance of partially and fully coherent beams under the same conditions.

It can be observed from Fig. 16.21 that the value of α in weak turbulence is 0.91116 at a 2.5-km transmission distance, i.e., the log-intensity variance of a partially coherent beam is reduced by about 9.9%, compared with that of a fully coherent beam. The value of α in strong turbulence is 0.75281, i.e., the log-intensity variance of a partially coherent beam is reduced by about 24.7%, compared with that of a fully coherent beam. It can be seen that the partially coherent beam is significantly less affected by turbulence than the fully coherent.

Angle-of-Arrival Fluctuation

When a partially coherent Gaussian–Schell beam propagates in atmosphere, large and small vortices appear in its cross section, resulting in random disturbances that cause a phase shift in the wavefront. The phase change causes the angle of arrival to fluctuate. In practical applications, the angle-of-arrival

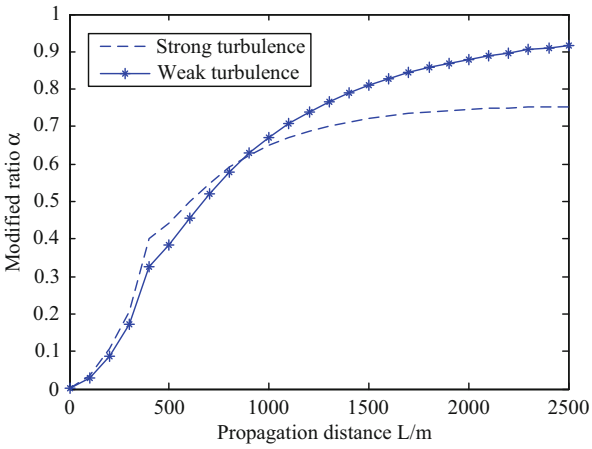

Fig. 16.21 Modified log-intensity variance ratio versus propagation distance [99]

fluctuation reduces the efficiency of coherent detection and can render a coherent-detection system invalid.

Effect of Light Source Parameters on the Angle-of-Arrival Fluctuation

The angle-of-arrival fluctuation of a partially coherent beam transmitted along a horizontal path in atmospheric turbulence differs depending on the coherent parameters and wavelengths of the light source. This is shown in Figs. 16.22 and 16.23 [106], respectively. The results show that the greater the wavelength, the smaller the angle-of-arrival fluctuation.

The angle-of-arrival fluctuation of a partially coherent Gaussian–Schell beam in atmospheric turbulence reaches a maximum at a certain initial radius. When the

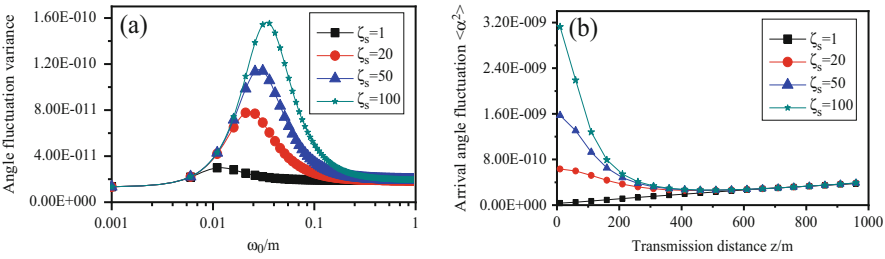

Fig. 16.22 Angle-of-arrival fluctuation with (**a**) waist radius and (**b**) transmission distance under different source coherence parameters [106]

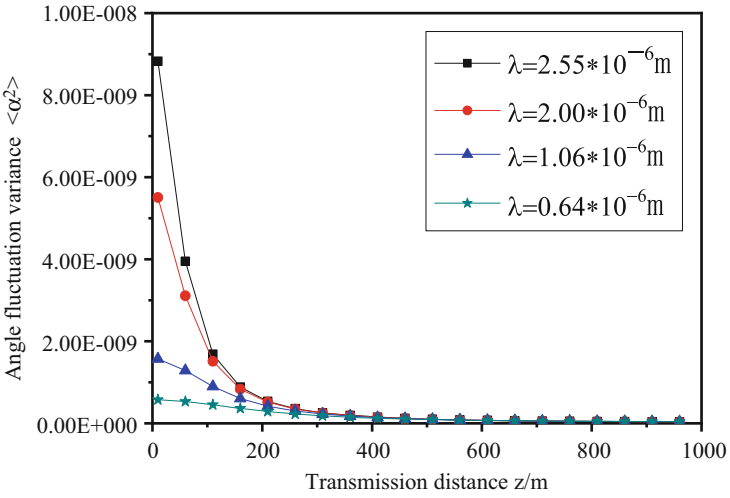

Fig. 16.23 Angle-of-arrival fluctuation variance with the transmission distance at different wavelengths [106]

initial radius of the beam waist is greater than 0.01 m, the arrival angle fluctuation of the beam varies significantly with the initial radius; the larger the beam coherence, the more obvious the phenomenon. As the transmission distance increases, the arrival angle fluctuation increasingly decreases. Compared to a partially coherent beam, the angle-of-arrival fluctuation of a fully coherent beam is less affected by turbulence.

Effect of Atmospheric Turbulence on the Angle-of-Arrival Fluctuation

In addition to the influencing light source parameters, the turbulence intensity and inner and outer turbulence scales also affect the arrival angle fluctuation. From the simulation results in Figs. 16.24 and 16.25 [106], it can be concluded that when the transmission distance is constant, the beam angle-of-arrival fluctuation first increases and then decreases. The smaller the inner turbulence scale, the greater the impact on

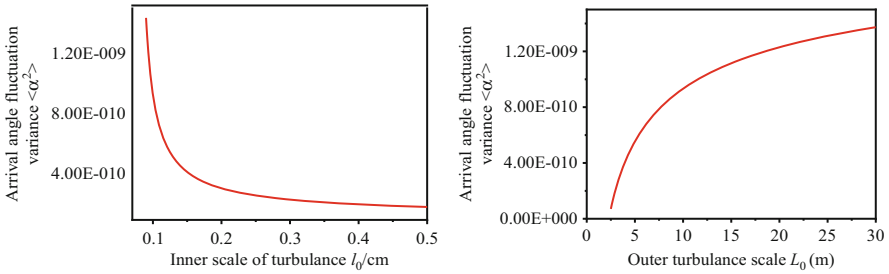

Fig. 16.24 Angle-of-arrival fluctuation with different internal and external scales [106]

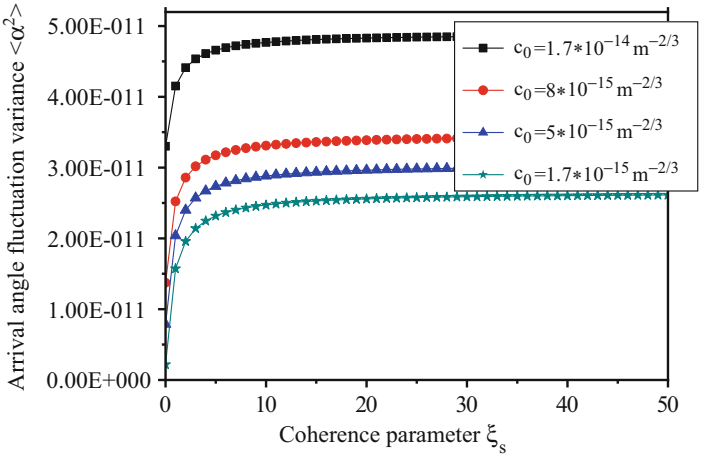

Fig. 16.25 Angle-of-arrival fluctuation variance with different source coherence parameters and atmospheric refractive index structure constants [106]

the angle-of-arrival fluctuation; the larger the outer scale, the greater the angle-of-arrival fluctuation. When the source coherence parameter is greater than 10, the variance of the angle-of-arrival fluctuation changes very little. The greater the turbulence intensity, the greater the angle-of-arrival fluctuation.

Polarization Characteristics

Existing studies have shown that the polarization characteristics of a beam in atmospheric turbulence change to various extents [56], and such variation is closely related to the coherence of the light source component and turbulence intensity. Polarization control is indispensable in wireless laser coherent optical communication systems. Only when the polarization states of the signal beam and local oscillator beam are the same or similar can the coherent light-detection sensitivity be high.

Polarization Characteristics of Partially Coherent EGSM Beams in Uplink and Downlink Paths

The degree of polarization (DoP) and polarization angle are two important parameters that describe the polarization characteristics; therefore, they are often used for the theoretical analysis of the polarization characteristics of various beams. Ke and Wang [104] analyzed the polarization characteristics in uplink and downlink paths by calculating the two parameters of a partially coherent electromagnetic Gaussian–Schell model (EGSM) beam propagating through turbulence.

Comparison of the Polarization Degree

The distribution curves of the DoP at the receiving end for partially coherent EGSM beams transmitted in uplink and downlink paths through atmospheric turbulence are shown in Figs. 16.26 and 16.27 [103]. This shows that, under

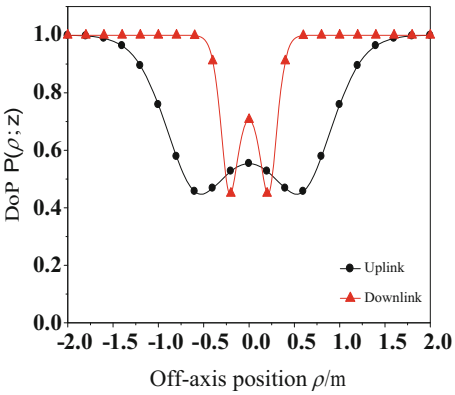

Fig. 16.26 Distribution curve of the DoP in uplink and downlink transmissions [103]

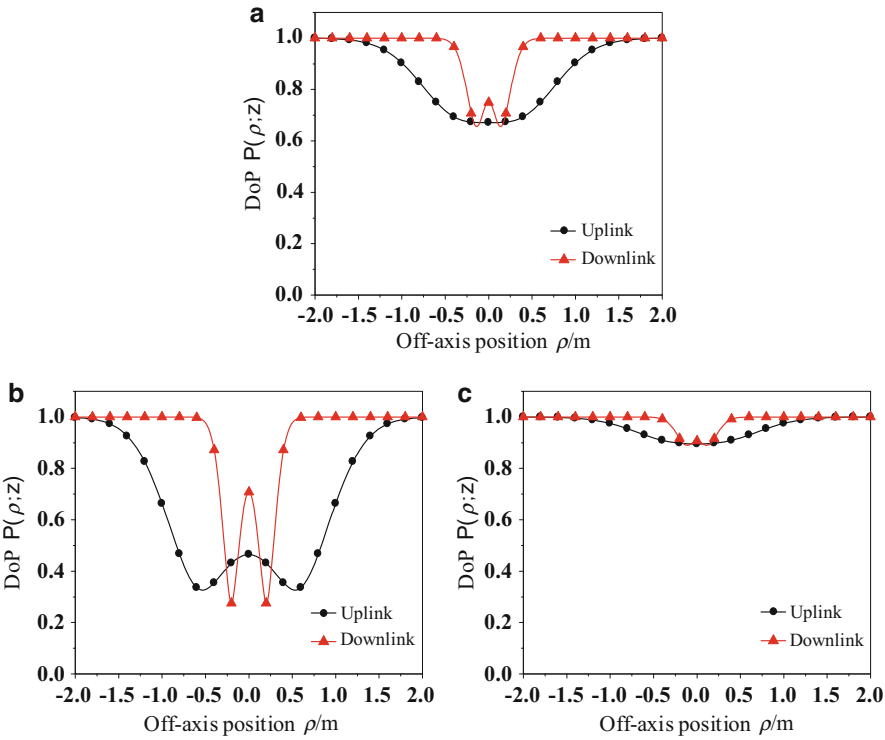

Fig. 16.27 Distribution curve of DoP in uplink and downlink transmissions when (**a**) $A_x/A_y = 1$, (**b**) $A_x/A_y = 2$, and (**c**) $A_x/A_y = 1/2$ [103]

the same conditions, the DoP distribution at the receiving end is more concentrated for downlink transmissions of an EGSM beam than for uplink transmissions.

At a transmission distance of 10 km, whether it is an uplink or downlink path, the DoP at the receiving end first decreases, with an increase in the deviation from the axial position, and then increases and approaches 1. This result is consistent with the conclusions of Fig. 3 in Ref. [6]. In addition, in Figs. 3 and 4 of Ref. [103], the DoP of the point on the receiving end axis is simulated and analyzed with different transmission distances. The results show that when the transmission distance is very short or very long, the DoPs of the uplink and downlink transmissions at the receiving end are almost the same for an equal amplitude ratio.

When the DoP of a point on the axis reaches the maximum value in a downlink transmission, the corresponding transmission distance is longer than the uplink transmission. In other words, when the EGSM beam is transmitted along the downlink path, the detector can receive the beam transmission information from

a longer distance. This is consistent with the results obtained in Fig. 2 in Ref. [62].

Comparison of Polarization Direction Angles

Figures 16.28 and 16.29 [103] show the polarization direction angle of a partially coherent EGSM beam transmitted in uplink and downlink paths to the receiving end with different transmission distances. It is obvious from the figure that in atmospheric turbulence, as the receiving height increases, the polarization direction angle in a downlink transmission changes faster than that in an uplink transmission. However, regardless of how it changes, the polarization direction angles of both uplink and downlink transmissions at the receiving end tend to have the same value at a long distance.

Polarization Comparison of Partially Coherent EGSM Beams on Horizontal and Slanted Paths

The parameters that affect the DoP distribution at the receiving end and the point change on the receiving end axis mainly include the initial beam radius, beam amplitude ratio, direction, wavelength, and turbulence intensity.

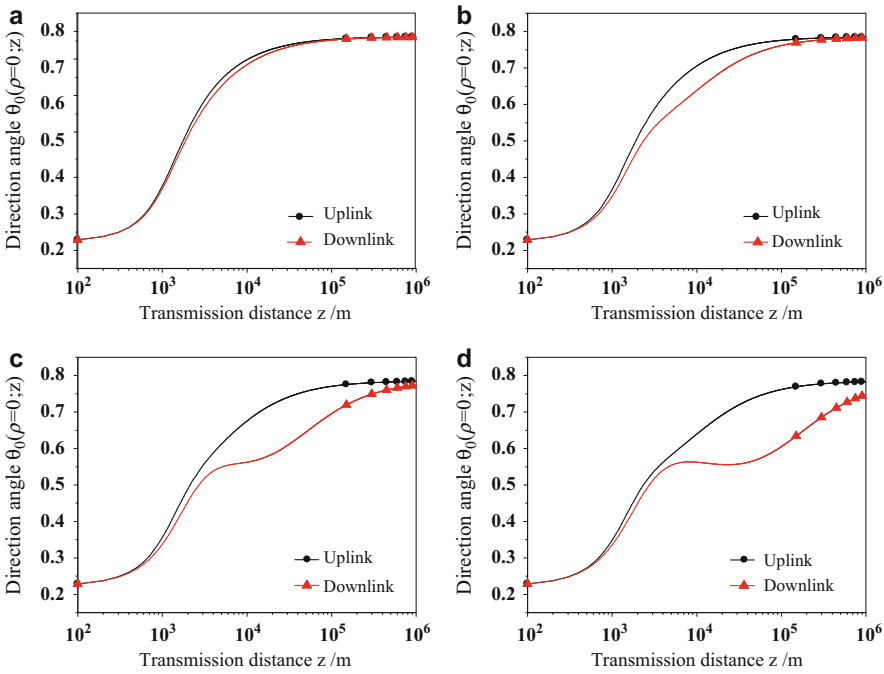

Fig. 16.28 Polarization direction angles with different transmission distances in uplink and downlink transmissions when $\sigma_x = \sigma_y = 0.01$ m. (**a**) H = 50 m; (**b**) H = 200 m; (**c**) H = 500 m; (**d**) H = 1000 m [103]

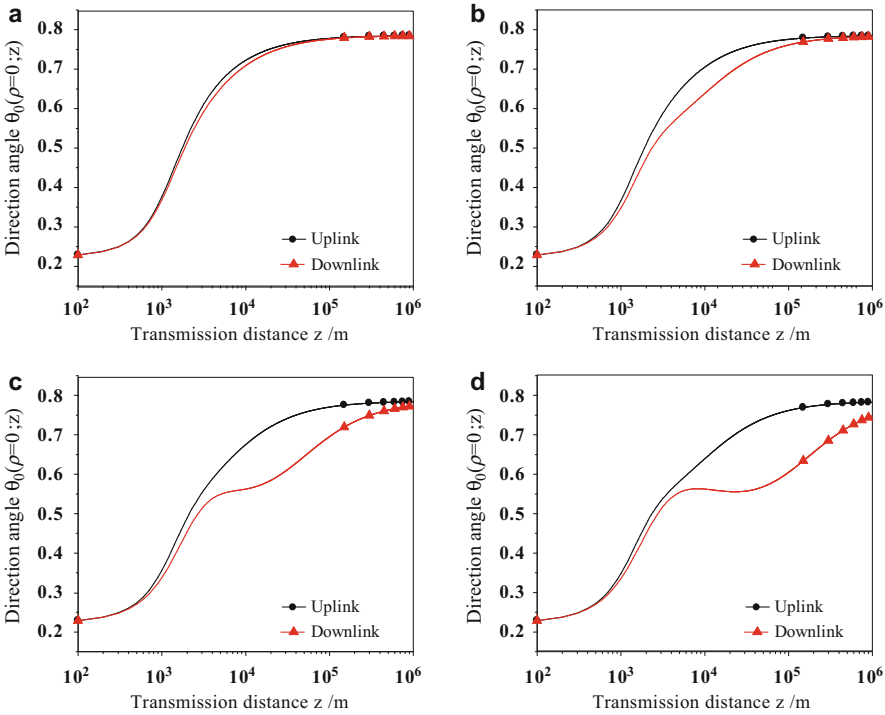

Fig. 16.29 Polarization direction angles with different transmission distances in uplink and downlink transmissions when $\sigma_x = 0.01$ m and $\sigma_y = 0.02$ m. (**a**) H = 50 m; (**b**) H = 200 m; (**c**) H = 500 m; (**d**) H = 1000 m [103]

1. Influence of the initial beam radius. When the initial radius components of the EGSM beam are equal, there is an optimal initial radius that most concentrates the distribution of the DoP at the receiving end. Regardless of how the initial beam radius changes, the DoP change of the entire optical field at the receiving end is more concentrated in a slanted transmission than in a horizontal transmission. Moreover, the corresponding transmission distance is longer when the DoP of the point on the receiving end axis reaches the maximum value. Whether the EGSM beam is transmitted along a slanted or horizontal path, the DoP at the receiving end first decreases with an increase in the distance from the axis, and then increases and tends to a fixed value of 1 [104].
2. Effect of the amplitude ratio. Regardless of how the amplitude ratio changes, the DoP change of the entire optical field at the receiving end in a slanted transmission is more concentrated than that in a horizontal transmission. When the DoP of the point on the receiving end axis reaches the maximum value, the corresponding transmission distance is longer than that in a horizontal transmission [104].

3. Effect of the turbulence intensity. Under the same turbulence condition, the DoP change of the entire optical field at the receiving end in a slanted transmission of an EGSM beam is more concentrated than that in a horizontal transmission. Regardless of a horizontal or slanted path, the DoP distribution of the entire optical field becomes more concentrated with the weakening of turbulence; however, the change in speed of a horizontal transmission is greater than that of a slanted transmission. As the transmission distance increases, the smaller the turbulence, the greater the variation of the DoP at the point on the axis [104].
4. Effect of the wavelength. When the beam wavelength is the same, the DoP change in the entire optical field at the receiving end in a slanted transmission of an EGSM beam is more concentrated than that in a horizontal transmission, and the detector can receive further information. As the wavelength increases, the DoP distribution of the entire optical field becomes more concentrated, regardless of the horizontal or slanted path. As the transmission distance increases, the longer the beam wavelength, the greater the variation of the DoP at the point on the axis [104].

Speckle Characteristics

When a beam propagates in atmospheric turbulence, the turbulence effect randomly modulates the beam intensity and phase and finally forms speckles in the far field. In space optical communication systems, the speckle effect directly affects the spot centroid detection accuracy of acquisition, pointing, and tracking (APT) systems. Therefore, it is necessary to conduct a detailed theoretical analysis of the speckle characteristics of the beam caused by atmospheric turbulence and provide a theoretical reference for the design of space optical communication systems.

Influence of Light Source Parameters

The average speckle radius of a beam is related to the initial radius, wavelength of the light source, and coherence length. Figures 16.30 and 16.31 [105] show the effects of the beam waist radius, coherence length, and light source wavelength on the effective beam radius and the average speckle radius, respectively. It is clear that the smaller the initial radius, the faster the beam spread, which is consistent with the conclusion given in reference [98].

Under the same transmission distance, the better the beam coherence, the larger the average speckle radius of the beam at the receiving end and the greater the beam diffusion. The smaller the wavelength, the smaller the effective beam radius and average speckle radius change with an increase in the transmission

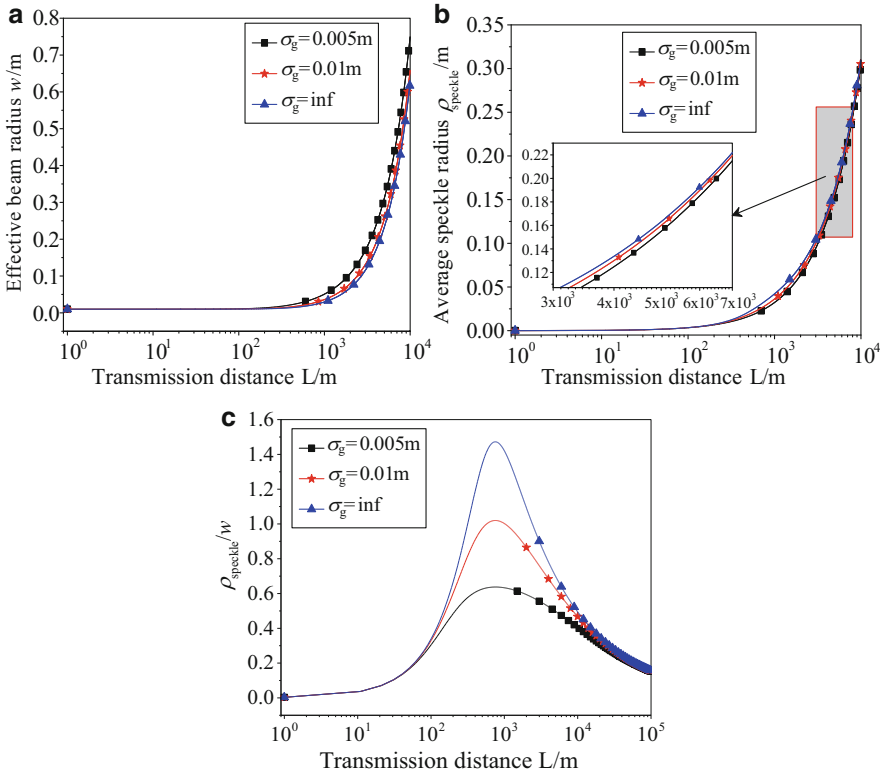

Fig. 16.30 Beam characteristics at the receiving end with different coherence lengths. (**a**) Effective beam radius; (**b**) average speckle radius; and (**c**) ratio of the average speckle radius to the effective beam radius [105]

distance, and the less the beam is affected when it propagates in atmospheric turbulence.

Influence of Atmospheric Turbulence Parameters

The turbulence intensity and inner and outer turbulence scales also affect the average speckle radius of the beam. Figures 16.32 and 16.33 [105] show that after the beam is transmitted for a certain distance, as the turbulence intensity increases, the beam spreads, owing to the phase distortion caused by the atmospheric refractive index fluctuation, which leads to a more dispersed spot at the receiving end. The effective beam radius and average speckle radius are greatly affected by the inner turbulence scale. The influence of the outer turbulence scale is negligible. This is consistent with the fact that the outer scale shown in Fig. 3 of Ref. [107] has little effect on the beam spreading.

Summary

This chapter introduced the research progress of partially coherent beam propagation in atmospheric turbulence at home and abroad. It mainly focused on the research results of Xi'an University of Technology on the transmission characteristics of partially coherent GSM beams through the atmosphere in recent years. Compared with a fully coherent beam propagating in atmospheric turbulence, a partially coherent beam can suppress turbulence effects, such as beam spreading, light intensity fluctuation, and arrival angle fluctuations. Therefore, research on the effect of turbulence on partially coherent beams is of great significance.

In recent years, research on the transmission of partially coherent beams in the atmosphere has focused on the relationship between light source parameters and turbulence, partly to discuss and analyze the basic physical properties between different types of light sources and turbulence. More importantly, it has

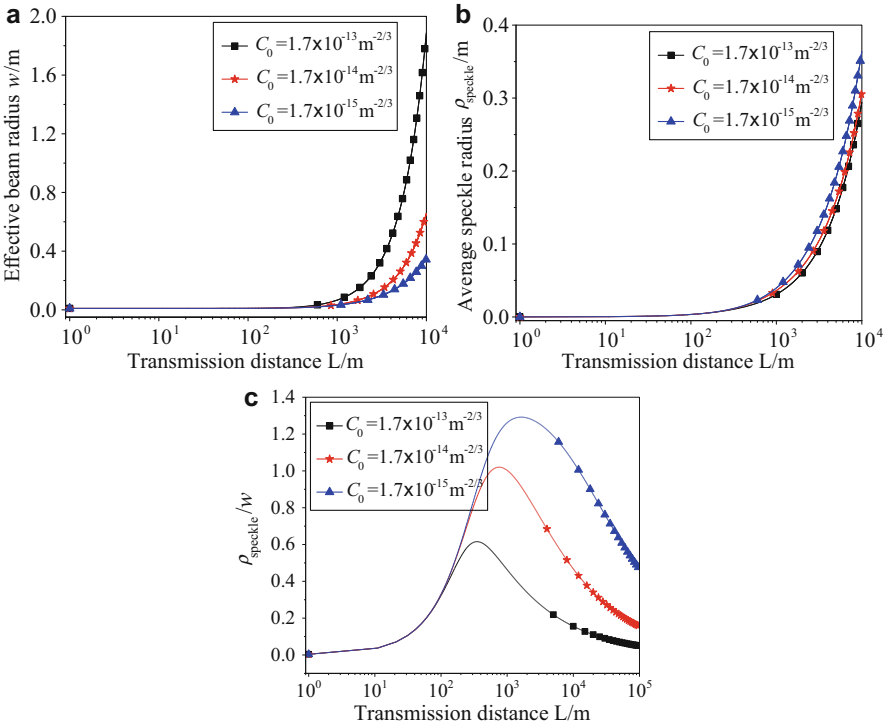

Fig. 16.32 Beam characteristics at the receiving end with different atmospheric refractive index structure constants. (**a**) Effective beam radius; (**b**) average speckle radius; and (**c**) ratio of the average speckle radius to the effective beam radius [105]

optimized the experimental results by changing the light source parameters in practical laser communication, such as improving the energy reception efficiency, reducing the light intensity scintillation, and reducing beam spreading and wandering.

However, most literature on partially coherent beam transmission properties is the result of theoretical calculations and simulation analyses, and most of them are ideal beams with definite mathematical analytical forms, such as partially coherent Gaussian–Schell beams, partially coherent flat-topped Gaussian beams, and partially coherent vortex beams. A large number of hypotheses and approximations have been used in the research process. The research results are still far from actual engineering applications and have certain limitations.

In addition, many of these findings have not yet been verified through numerical simulations or experiments. Although some verification methods have been proposed, they are generally inadequate. Therefore, whether theoretical, numerically simulated, or experimental, research on the transmission properties of partially coherent beams in atmospheric turbulence must be further improved.

Abstract

In optical wireless communication, undesirable channel is the main factor affecting system reliability, and placing an equalizer with opposite channel characteristics at the receiving end can offset the negative impact of the channel on the signal, so as to correct the inter-code crosstalk problem caused by multipath delay and other factors, and enable the signal to be recovered and reconstructed at the receiving end. On the basis of summarizing the research progress of equalization techniques both domestically and internationally, the chapter compares and summarizes various typical channel equalization techniques for reference, including zero-forcing equalization, minimum mean square error equalization, decision feedback equalization, Volterra equalization, etc. In practical applications, appropriate equalizers can be selected based on specific requirements and equalization algorithm characteristics to achieve channel equalization. Finally, the development prospects of channel equalization technology in optical wireless communication are prospected, providing new ideas and reference value for future researchers to explore in this field.

Introduction

Optical wireless communication is a new communication method that combines the advantages of fiber-optic and microwave communications and does not require spectrum licensing. Therefore, it has a wide range of applications [1] and has become a cutting-edge topic in the communication field, gradually attracting the attention of industry professionals.

Channel equalization is an anti-fading measure that suppresses the reduction in system-transmission performance caused by multipath delays and other issues. Channel equalization in optical wireless communication can be divided into multiple structures, based on different methods. Channel equalization technology is divided into two categories: linear and nonlinear, depending on whether the equalizer output is used for feedback control.

The former mainly eliminates the distortion and attenuation generated in the channel by filtering the signal but has high sensitivity to noise and signal interference. The latter mainly eliminates the distortion and attenuation generated in the channel by nonlinear signal processing. It can effectively improve the quality and reliability of the signal transmission and is little affected by noise and signal interference. However, the computational complexity is high and more computational resources are required.

Typical linear equalization techniques include minimum mean square error equalization, zero-forcing equalization, etc. Typical nonlinear equalization techniques include decision feedback equalization, maximum-likelihood sequence estimation, and maximum-likelihood symbol detection. Different equalization methods are suitable for different channel environments and signal characteristics and must be selected and applied according to actual needs.

The optical wireless communication environment is more complex and uncertain than that of wired transmission. Thus, it is usually necessary to calibrate or compensate the channel at the receiving end, because of the negative impact of imperfect channel conditions, to ensure efficient signal transmission and a low bit-error rate (BER). Imperfect channel conditions have become the main obstacle restricting the development and application of optical wireless communication [1–6]; therefore, studying channel equalization technology is an important topic in the field of optical wireless communication.

Foreign Research Progress

In 1994, Uysal et al. [7] proposed an optical wireless communication system based on adaptive equalizers that could adaptively adjust the equalizer parameters to offset distortion and interference in the channel, thereby improving the communication quality and reliability. This was considered a classic research study on channel equalization technology in the field of optical wireless communication and gradually attracted widespread attention from scholars. Subsequently, stochastic gradient

(SG) training algorithms were proposed for blind equalization algorithms, such as recursive least squares algorithms.

In 1994, Kechriotis et al. [8] found an adaptive recurrent neural network equalizer with a small size and high performance suitable for high-speed channel equalization. The results showed that when the channel interference was relatively small, the equalizer had performance comparable to traditional linear filter-based equalizers. When the channel's transfer function had a spectral zero or severe nonlinear distortion, the equalizer's performance was several orders of magnitude better.

In 1995, Cha et al. [9] proposed a random gradient training algorithm applicable to all the free parameters of the network. They found that complex radial basis function networks (CRBFNs) could be used as part of the equalization solution for complex nonlinear channels. The simulation results showed that the CRBFN using the gradient descent algorithm was highly effective for channel equalization.

In 1999, Patra et al. [10] proposed a computationally efficient single-layer functional link artificial neural network (FLANN), for adaptive channel equalization in nonlinear channels. Among three neural network equalizer structures, FLANN performed the best in terms of convergence speed, bit-error rate, and computational complexity for linear and nonlinear channel models over a wide range of signal-to-noise ratios.

In 2002, Deng et al. [11] proposed a complex radial basis function neural network for quadrature amplitude modulation (QAM) signal equalization. The network utilized the sequential learning algorithm of the complex minimum resource allocation network (CMRAN), and the simulation results showed its performance in nonlinear channel balancing problems. CMRAN had superior performance in terms of the symbol-error rate and network complexity. Compared with existing methods, CMRAN reduced the network complexity and therefore required less time for balancing.

In 2005, Pandey [12] proposed a new blind equalization scheme using a recursive least squares algorithm. The output layer weights were trained using an improved version of the constant modulus algorithm cost function. For weight training in the hidden-layer neuron space, the proposed scheme enabled the equalizer to converge more quickly.

In 2005, Patra et al. [13] introduced a Chebyshev-based equalizer structure for adaptive channel equalization in 4-QAM signal constellations. Simulation results showed that, compared with equalizers based on a multilayer perceptron and the least mean squares algorithm, its single-layer structure provided a faster convergence speed.

In 2007, Özden et al. [14] proposed a model-based Volterra-type nonlinear communication channel decision feedback equalization method. During the design, the nonlinear decision feedback equalization problem was visualized as a linear multichannel equalization problem. The elements of the required signal vector were estimated using the sigmoid activation function, which improved the error probability of the proposed equalizer, thus realizing a polynomial perceptron equalizer. The computational complexity calculations and performance results of the proposed decision feedback equalizer were presented.

In 2007, Al Awami et al. [15] used particle swarm optimization (PSO) to design adaptive equalizers, studied the effectiveness of PSO in channel equalization, discussed different modifications to the original PSO technology, and proposed new modification schemes. The performances of various PSO algorithms were compared with those of traditional least mean squares algorithms. The simulation results showed that, compared with adaptive equalizers based on the least mean squares and other algorithms, the proposed PSO algorithm converged faster under almost the same misalignments.

In 2011, Acolatse et al. [16] proposed a modified form of single-carrier frequency-domain equalization for diffuse optical wireless (DOW) communication. They proposed three different methods of using single-carrier frequency-domain equalization in DOW communication and demonstrated that they exhibited a lower peak-to-average power ratio (PAPR) and better bit-error rate performance in the case of LED nonlinearity.

In 2012, Diana D.C et al. [17] proposed a channel equalization method using inertial weights based on fitness-based PSO. A modified inertial weight PSO algorithm effectively eliminated the impact caused by multipath propagation, co-channel interference, and channel noise, and greatly reduced the time required to reduce errors; thus, a channel with dynamic characteristics was suitable for reliable transmission.

In 2014, Das et al. [18] proposed an equalizer based on an artificial neural network trained using a PSO algorithm. The algorithm was used to optimize the number of layers, input and hidden neurons, and transfer-function types. A large number of simulations showed that the proposed equalizer performed better in all noise conditions than other equalizers based on artificial neural networks and neuro fuzzy equalizers.

In 2015, Panda et al. [19] proposed a neural network training method. The training used directed search optimization (DSO) as a trainer for neural networks. It was then applied to nonlinear channel equalization problems, and a new nonlinear channel equalization strategy was introduced. Numerous simulation results indicated that the proposed channel equalization method outperformed other artificial neural network equalizers, in terms of the mean squared error and bit-error rate.

In 2016, Kaur et al. [20] proposed a radial basis function network for the adaptive channel equalization of a coherent optical orthogonal frequency-division multiplexing (OFDM) system and compared the simulation results with those of an artificial neural network based on a multilayer perceptron, which also had good performance.

In 2017, Nanda et al. [21] produced an equalizer based on wavelet neural networks and weighted it using metaheuristics (a symbiotic-biology search algorithm). The performance of the proposed equalizer was compared with that of a wavelet neural network trained by cat swarm optimization, a clonal selection algorithm, particle swarm optimization, and a least mean squares algorithm. This demonstrated the robustness and superior performance of the equalizer in handling sudden error conditions.

In 2018, Dai et al. [22] developed a channel equalization method based on a set membership filter and a binormalized modified-norm algorithm. Its performance advantages in convergence speed and eliminating intersymbol interference were verified by comparing it with existing channel equalization methods. This algorithm was theoretically significant for channel equalization in high-speed free-space optical communication systems.

In 2019, Saidani et al. [23] proposed a new method for optimizing the neural network weights for channel equalization. The update strategy in the local search of the standard leapfrog algorithm was replaced with the update strategy of the directed search optimization algorithm. The proposed method was compared with standard PSO, an improved modified shuffled frog-leaping (MSF) algorithm, and a directed search-optimization algorithm to evaluate its performance in nonlinear channel equalization. The experiment showed that this method achieved the best results and outperformed other algorithms.

In 2019, Wu et al. [24] proposed a kernel recursive maximum Versoria-like criterion (KRMVLC) algorithm that considered the advantages of the logarithmic second-order error and symmetric maximum Versoria criterion (MVC) in a reproducing kernel Hilbert space (RKHS). The proposed KRMVLC algorithm was derived for nonlinear channel equalization (NCE) problems under different non-Gaussian interference. The results verified that KRMVLC was robust to non-Gaussian interference.

In 2020, Caciuaru et al. [25] proposed a new unsupervised neural network blind channel equalization algorithm that simultaneously considered linear and nonlinear noise intersymbol interference channels. The results were then extended to the joint equalization and decoding of low-density parity codes using iterative algorithms. Compared with the baseline algorithm, it demonstrated a significantly improved bit-error rate performance.

In 2020, Linsalata et al. [26] proposed the design of linear and nonlinear receivers for generalized frequency-division multiplexing (GFDM) transmissions using gradient diffusion film technology on frequency-selective channels. They analyzed and compared the maximum-likelihood, zero-forcing, and minimum mean squared error equalization schemes. A Monte Carlo simulation was used to measure the bit-error rate performance of linear and nonlinear receivers considering frequency- and non-frequency-selective channels. The numerical results indicated that this design improved performance compared to other methods.

In 2021, Uma et al. [27] introduced a new theory to distinguish the step sizes based on evolutionary programming algorithms. This method produced a high overall efficiency and did not require presetting the considerations involved in signal-based numerical characteristic solutions. The weighted-variance weighting-coefficient deviation depended on changes in the algorithm. The simulation results showed that this algorithm had good performance.

In 2022, Mohapatra [28] proposed a hybrid algorithm integrating the PSO algorithm and the gray wolf optimization algorithm to improve the flexibility of all algorithm variants and made use of appropriate weights, network topologies, and neural network transfer functions in channel equalization. Experimental simulations

showed that the performance of this equalizer was superior to that of existing neural network-based equalizers and neural fuzzy equalizers.

In 2022, Mohapatra et al. [29] proposed a new nonlinear channel-modeling method that used a radial basis function neural network to train a new cuckoo search algorithm for equalization in nonlinear channels. The experimental simulation results showed that the algorithm improved the equalization efficiency during the search process, and the equalizer performance of this nonlinear channel was superior to that of existing neural network-based equalizers.

In 2022, Badal et al. [30] developed a naturally inspired butterfly optimization algorithm and applied its training strategy to channel equalization. It was found that this equalizer performed better than previously known equalizers in terms of the bit-error rate and mean square error.

In 2022, Mohapatra et al. [31] proposed a new training strategy for channel equalization using a fuzzy firefly algorithm (FFA). By using an appropriate network topology and parameters, the training system provided stronger development and exploration skills, as well as the ability to solve local minimum problems. The simulation results showed that the proposed method validated a wide range of signal-to-noise ratios and outperformed existing neural network-based equalizers.

Research on optical wireless communication channel equalization has been ongoing since 1994, with a shift in focus from the initial linear channel equalization methods to nonlinear channel equalization methods to improve the communication quality. The research content also developed from theoretical derivations and simulations to practical applications. As research has gradually developed from traditional channel equalization methods to combining channel equalization in the field of neural networks, the performance of bit-error rates and other aspects has improved.

Domestic Research Progress

In 2003, Cai et al. [32] proposed an improved minimum mean square algorithm with good equalization performance for time-varying channels.

In 2005, Sun [33] proposed a wavelet neural network with a new initialization method and applied it to channel equalization. It was found that this method had better anti-nonlinearity ability than linear equalizers.

In 2006, Zhang et al. [34] proposed a channel equalization method using PSO to adaptively adjust the equalizer coefficients; this method also achieved good equalization results.

In 2007, Long [35] proposed a method based on linear precoding technology. Simulation experiments showed that this equalization method could effectively improve the BER performance of a system under a high signal-to-noise ratio.

In 2007, Mi et al. [36], in order to further verify the ability of decision feedback equalizer to eliminate intersymbol interference, simulated in Matlab and compared it with the learning curve of linear equalizer, and found that the equalization effect of decision feedback equalizer is better than that of linear equalizer.

In 2008, Chen et al. [37] proposed a decision feedback equalizer based on unscented Kalman filtering (UKF), which reduced the mean squared error of the system.

In 2008, Xu et al. [38] proposed a new constant modulus algorithm (CMA) with a variable step size that could effectively reduce system errors.

In 2010, Li [39] proposed a variable step-size algorithm and a variable step-size normalization algorithm based on decorrelation. Experimental simulations showed that this algorithm effectively solved the slow convergence speed problem of the variable step-size algorithm, and the algorithm performance was also significantly improved.

In 2010, Zhao et al. [40] proposed a second-order Volterra adaptive algorithm based on lattice filtering. The simulation results showed that the proposed algorithm had a faster convergence speed and better steady-state performance for both linear and nonlinear channels than the domain second-order Volterra-series adaptive equalizer under nonlinear channels.

In 2011, Wang et al. [41] proposed a channel equalization method based on turbo iterations. The simulation results showed that this method could significantly reduce the error rate of communication systems.

In 2011, Wang [42] realized an unconstrained linear equalization algorithm using a factor graph. The performance of this algorithm was superior to that of traditional equalization algorithms, and the computational difficulty was reduced to a linear function of the data length.

In 2012, Wang [43] proposed a modified constant modulus algorithm (MCMA) based on the constellation matching error, the decision-guided dual-mode MCMA algorithm, and the stop-and-go-based MCMA algorithm. These blind equalization algorithms reduced the intersymbol interference and improved the convergence speed.

In 2013, Zhang [44] proposed a single-carrier minimum mean square error equalization algorithm based on iterative thinking, after considering two types of interference: intersymbol interference (ISI) and noise interference. This algorithm considered noise interference based on a decision feedback algorithm and was compared with traditional equalization algorithms. The performance curves of the minimum mean square error residual ISI cancellation (MMSE RISIC) decision feedback equalization algorithm were simulated and compared with the traditional algorithms. It was found that the combined algorithm outperformed the latter two in terms of signal-to-noise ratio and bit-error rate.

In 2014, Yang et al. [45] proposed an improved equalization method for sparse multipath channels and a greedy algorithm to obtain an approximate optimal solution. The simulation results showed that this method significantly improved the system error rate performance compared to the traditional minimum mean square linear method and achieved a power margin of approximately 10 dB at a signal-to-noise ratio of 15 dB.

In 2015, Luo [46] proposed an MMSE equalization algorithm that combined symbol reconstruction at the receiver and compared it with zero-forcing equalization, minimum mean square error equalization, decision feedback equalization, and

maximum-likelihood sequence estimation equalization analysis. It had a lower bit-error rate and an improved signal reuse rate.

In 2016, Li [47] verified the excellent performance of an adaptive algorithm based on the reproducing kernel Hilbert space (RKHS) and found that the algorithm was suitable for the time-varying nonlinear channel equalization field.

In 2016, Wang [48] studied a frequency-domain equalization method based on channel and noise estimation, which compensated for the channel in the frequency domain and compared it with frequency-domain zero-forcing equalization and frequency-domain minimum mean square error equalization. Simulation results showed that the algorithm could effectively improve the performance of atmospheric laser communication systems in the frequency domain.

In 2017, Chen et al. [49] proposed a neural network-based channel equalization algorithm. Compared with the recursive least square (RLS) and multilayer-perceptron algorithms, the symbol-error rates of the algorithm for quadrature phase-shift keying (QPSK) recovery were reduced by 20% and 5%, respectively.

In 2017, Sun et al. [50] constructed a nonlinear equalizer based on a kernel method under stable distribution noise. Simulation results showed that this algorithm reduced the steady-state error while the convergence speed remained unchanged. The nonlinear channel distortion under stable distribution noise had a better effect.

In 2018, Li [51] proposed an equalization algorithm based on adaptive bit modulation that could effectively improve the signal output gain and reduce the communication error rate.

In 2019, Guo [52] proposed a new chromaticity dispersion-compensation algorithm, three new polarization-mode dispersion-equalization algorithms, and a cascaded multimode algorithm with adaptive momentum terms. All three algorithms had better bit-error rate performance and equalization effects than the traditional algorithms.

In 2019, Ma et al. [53] proposed an equalization algorithm based on compressed sensing. This algorithm had a similar robustness and better equalization performance than traditional linear equalization algorithms.

In 2020, Yang et al. [54] used the minimum mean squared error criterion to design a linear equalizer and tested it on a universal software radio peripheral (USRP) platform. The experimental results showed that the error rate remained around 10^{-5} after equalization, and the stability and reliability were improved to some extent.

In 2020, Li et al. [55] built an adaptive equilibrium system model and analyzed the improved normalized minimum mean square algorithm with an orthogonal correction factor. They simulated and compared the traditional algorithm and the improved algorithm. The proposed algorithm had better convergence characteristics.

In 2020, Lü [56] used the least mean square (LMS) algorithm in a sliding autoregressive model to verify the convergence performance of the LMS algorithm through simulation under second-order conditions. It achieved better equalization performance in the finite impulse response (FIR) structure under QPSK modulation channels.

In 2021, Baiguo et al. [57] jointly optimized channel estimation, noise power estimation, and channel equalization to propose a single-carrier frequency-domain

equalization algorithm. The simulation results showed that this algorithm had a lower bit-error rate compared to traditional algorithms.

In 2021, Chen et al. [58] proposed a crosswalk detection network (CD net) channel equalization method based on artificial neural networks. The simulation results showed that, compared with traditional equalization methods, this algorithm provided a better bit-error rate performance.

In 2022, Wang [59] proposed an equilibrium algorithm based on complex Gaussian-process regression, which applied the idea of kernel recursion to complex Gaussian processes. This algorithm exhibited better equilibrium performance than other traditional equilibrium algorithms.

In 2022, Marina et al. [60] proposed an improved *k*-means algorithm based on the nonlinear transmission equation of the Volterra series using the traditional *k*-means algorithm to achieve channel equalization in orthogonal frequency-division multiplexing/offset quadrature amplitude modulation systems (OFDM/OQAM). Experimental comparisons and simulations were conducted before and after the improvement, indicating that the improved *k*-means algorithm required significantly fewer iterations than the traditional algorithms, had a simple structure, located the centroid faster, and significantly reduced linear and nonlinear distortions.

In 2022, Xie [61] used a turbo equalization algorithm to process the receiver signal and added a loop-head structure to the traditional minimum equalization error algorithm, which improved the performance and efficiency of the original algorithm in the frequency domain. The experimental results showed that the error rate performance of the improved algorithm improved by approximately 5 dB, compared to that of the previous algorithm.

In 2022, Chen [62] designed a channel equalization method based on a long short-term memory (LSTM) neural network in combination with an LSTM network. The proposed scheme was experimentally verified and analyzed. It was found that under medium and strong turbulence, the performance of the LSTM equalizer maintained a stable improvement in the bit-error performance of the system and remained stable in the face of a turbulent random environment.

In 2022, Menda [63] proposed a method based on a backpropagation (BP) neural network algorithm. Simulation experiments were conducted using three types of equalizers: the recursive least squares algorithm, minimum mean square algorithm, and BP neural network algorithm. The simulation results showed that the algorithm constructed using the BP neural network had the best equalization effect, could adapt to real-time channel changes in visible light systems, and compensated for channel characteristics. The error rate reached 10^{-6}.

In 2022, Shi [64] improved structure based on neural networks and compared the rectified linear unit (ReLU), tanh, leaky ReLU, and other activation functions. They found through simulation experiments that the neural network adaptive equalization scheme constructed by the maxout activation function had a better effect and the ability to effectively nonlinearly compensate for the received signal, resulting in a faster convergence speed and smaller mean square error.

In 2022, Chen et al. [65] proposed a zero-value attraction sparse-control proportional minimum symbol-error rate decision feedback equalization (ZA-SC-PMSER

DFE) algorithm to improve the convergence of complex underwater acoustic channel equalization algorithms and reduce their bit-error rates. The convergence speed and other performance metrics were superior to other algorithms, such as ZA-SC-PMSER DFE without a phase-locked loop and ZA-SC-PMSER DFE with a phase-locked loop, based on the minimum mean square error criterion.

In 2022, Duan et al. [66] showed that three deep learning channel equalization algorithms had lower bit-error rates and better overall performance than traditional channel equalization algorithms. Among them, the algorithm based on convolutional neural networks exhibited the best performance. Under this algorithm, when the input-sequence symbol length was 2000, the bit-error rate reached the minimum value, which was equivalent to 3.65 times the channel length.

Various channel equalization algorithms in optical wireless communication are interrelated, and each algorithm is proposed and improved, based on the shortcomings of existing algorithms. However, the new algorithm also has limitations. Thus far, nearly 20 channel equalization methods have been presented for optical wireless communications, and they still have unresolved problems. In future research on channel equalization, additional algorithms will be proposed to suppress the performance losses caused by imperfect channels during signal transmission.

Key Channel Equalization Technologies

The main purpose of channel equalization technology is to eliminate intersymbol crosstalk and compensate for channel distortion, thereby improving the transmission performance of communication systems.

Two main channel equalization techniques are used in optical wireless communication: linear and nonlinear, with various structures. The structures are illustrated in Fig. 17.1. The equalizer is essentially a reciprocal filter for the channel transfer function. According to the different channel characteristics and application scenarios, suitable linear or nonlinear channel equalization methods can be selected to

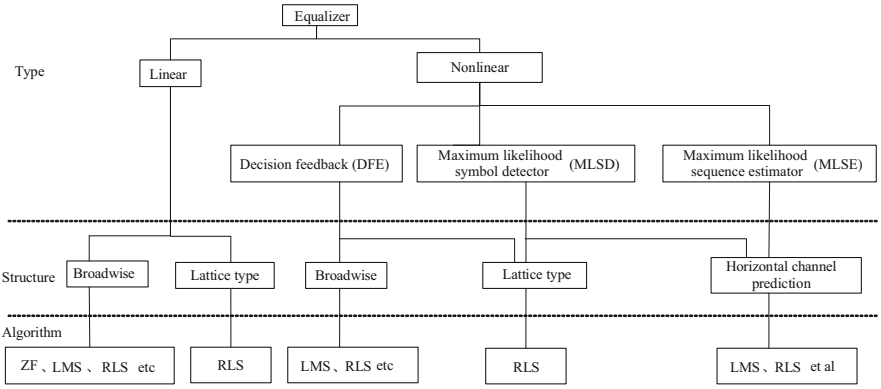

Fig. 17.1 Common equalizer structures [47]

improve the performance and reliability of optical wireless communication. This chapter introduces several typical linear and nonlinear equalization methods.

Linear Equalization

In optical wireless communications, linear channel equalization can eliminate signal distortion and interference through a linear transformation, thereby equalizing the channel. Typical linear equalization algorithms include zero-forcing and minimum mean square error equalization.

The basic structure of a linear equalizer is represented by a transverse filter, as shown in Fig. 17.2. The transverse filter mainly consists of $2N$ delay units T_s, $2N + 1$ tap coefficients, a tap-gain adjustment algorithm, and an adder. Each tap coefficient can be adjusted, and different tap coefficients can be set according to the channel characteristics to compensate for the loss caused by intersymbol interference in the channel.

Assuming that the sequence of input signal sampling values is $\{x_k\}$, after passing through $2N$ delay units T_s, each sampling value is multiplied by its corresponding tap coefficient C_N to obtain the balanced output signal sampling value sequence $\{y_k\}$. The balanced output is used as the input of the tap-gain adjustment algorithm to adjust the numbers of the tap coefficients, such that equalization can be achieved at different sampling values. The output signal sampling value sequence $\{y_k\}$ is calculated using the following formula:

$$y_k = \sum_{i=-N}^{N} C_i x_{k-i}, \quad k = -2N, \cdots, 0, \cdots, +2N, \tag{17.1}$$

where C_{-N}, C_{-N+1}, $\cdots$, C_N are the tap coefficients of the equalizer, x_k is the input of the equalizer, and y_k is the output of the equalizer.

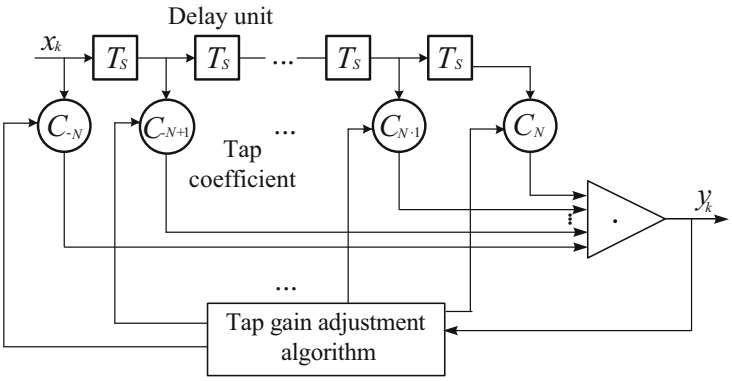

Fig. 17.2 Transverse filter structure [1]

Designing a transverse filter is a key approach to linear equalization. Two commonly used methods are the zero-forcing equalization algorithm, based on the minimum peak distortion, and the mean square error equalization algorithm based on the minimum mean square error [1]. The key to equalization is to design appropriate equalization algorithms to adaptively adjust the tap coefficients based on the channel characteristics.

Zero-Forcing Equalization Algorithm

Lucky proposed a linear equalization filter for zero-forcing equalization in 1965 [1]. The minimum peak distortion is an important criterion for measuring the equalization effect, and its calculation formula is

$$D = \frac{1}{y_0} \sum_{\substack{k=-\infty \\ k\neq 0}}^{\infty} |y_k|. \tag{17.2}$$

When $k \neq 0$, D represents the ratio of the sum of y_k absolute values at all sampling times to the sampling time y_0 when $k = 0$. According to Eq. (17.2), the input peak error is defined as

$$D_0 = \frac{1}{x_0} \sum_{\substack{k=-\infty \\ k\neq 0}}^{\infty} |x_k|. \tag{17.3}$$

The output peak error is defined as

$$D = \frac{1}{y_0} \sum_{\substack{k=-\infty \\ k\neq 0}}^{\infty} |y_k|. \tag{17.4}$$

When the input peak error $D_0 < 1$, the minimum value of the output peak error function appears near $\begin{cases} y_0 = 1 \\ y_k = 0, 1 \leq |k| \leq N \end{cases}$; the $2N + 1$ linear equation that the tap coefficient must meet is known from Eq. (17.5):

$$\begin{cases} \sum_{i=-N}^{N} C_i x_{k-i} = 0, k = \pm 1, \pm 2, \cdots, +N \\ \sum_{i=-N}^{N} C_i x_{-i}, k = 0 \end{cases}. \tag{17.5}$$

Here, it is written in matrix form:

$$\begin{bmatrix} x_0 & x_{-1} & \cdots & x_{-2N} \\ \vdots & \vdots & & \vdots \\ x_N & x_{N-1} & \cdots & x_{-N} \\ \vdots & \vdots & & \vdots \\ x_{2N} & x_{2N-1} & \cdots & x_0 \end{bmatrix} \begin{bmatrix} C_{-N} \\ C_{-N+1} \\ \vdots \\ C_0 \\ \vdots \\ C_{N-1} \\ C_N \end{bmatrix} = \begin{bmatrix} 0 \\ \vdots \\ 0 \\ 1 \\ 0 \\ \vdots \\ 1 \end{bmatrix}. \tag{17.6}$$

When the input sequence $\{x_k\}$ is known, the tap coefficient C_N of the equalizer can be calculated according to the matrix equation system of Eq. (17.6). At a later stage, the tap coefficient can also be adjusted to force the output sampling values $\{y_k\}$ of the equalizer to zero, optimizing the equalization effect [1].

The zero-forcing algorithm is suitable for channels with light multipath fading, mainly because it ignores the additive noise in the channel. Therefore, the tap coefficient value obtained when the channel contains additive noise is not optimal; however, its implementation is relatively simple.

Minimum Mean Square Error Equalization Algorithm

The core concept of this method is to equalize the channel by minimizing the mean square error (MSE) between the received and original signals. The channel equalization effect can be measured using the mean square distortion; its calculation formula is

$$e^2 = \frac{1}{y_0} \sum_{\substack{k=-\infty \\ k \neq 0}}^{\infty} {y_k}^2, \tag{17.7}$$

where y_k represents the sample value after equilibrium is reached. The transmission sequence is set to $\{a_k\}$, and after equalization, it is output to y_k, where the error signal is

$$e_k = y_k - a_k. \tag{17.8}$$

At this point, the mean square error is defined as

$$\overline{e^2} = E(y_k - a_k)^2. \tag{17.9}$$

Substituting Eq. (17.7) into Eq. (17.9),

$$\overline{e^2} = E\left(\sum_{-N}^{N} C_i x_{k-i} - a_k\right)^2. \tag{17.10}$$

The mean square error $\overline{e^2}$ is a function with each tap coefficient as the independent variable. It can be adjusted to achieve equalization by adjusting each tap coefficient of the equalizer such that they satisfy

$$\frac{\partial \overline{e^2}}{\partial C_i} = 0, \quad i = \pm 1, \pm 2, \cdots, \pm N. \tag{17.11}$$

According to Eqs. (17.10) and (17.11),

$$\frac{\partial \overline{e^2}}{\partial C_i} = 2E[e_k x_{k-i}] = 0, \quad i = \pm 1, \pm 2, \cdots, \pm N. \tag{17.12}$$

In the equation,

$$e_k = y_k - a_k = \sum_{i=-N}^{N} C_i x_{k-i} - a_k. \tag{17.13}$$

According to Eq. (17.12), when the cross-correlation function between the error signal and the input sampling value is zero, the derivative of the mean square error is zero. At this point, the error reaches its minimum value, and the resulting tap coefficient is the best. The least mean squares algorithm can not only equalize the intersymbol interference caused by multipath transmission delay but also the influence of channel additive noise on the signal; however, this method cannot completely eliminate the intersymbol interference [1].

Nonlinear Equalization

In nonlinear channels, the interference and distortion of the signals transmitted through the channel are nonlinear. Linear channel equalization methods cannot eliminate the nonlinear distortion and interference, and often do not achieve satisfactory equalization results. Therefore, nonlinear channel equalization methods should be used to equalize the channel. Nonlinear channel equalization can eliminate signal distortion and interference through nonlinear transformations, thereby equalizing the channel. Typical nonlinear equalization algorithms include decision feedback equalizers and neural network channel equalizers.

Decision Feedback Equalizer

The decision feedback equalization structure was formally proposed by Austin in 1969 [1]. Its implementation complexity is low, which reduces the impact of channel intersymbol interference and additive Gaussian white noise on the system, and improves the system performance to a certain extent.

The basic principle of decision feedback equalization is to subtract the signal values received at the current sampling time from the signal values received at the signal-receiving end at other sampling times to eliminate the intersymbol interference

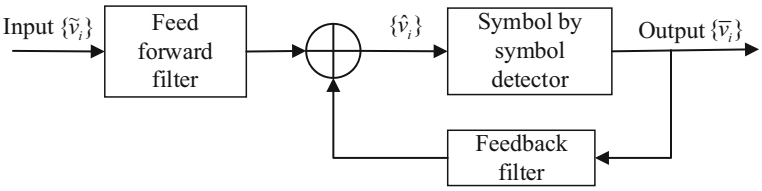

Fig. 17.3 Decision feedback equalization structure [31]

generated by other sampling times on the current sampling time and equalize and recover the data.

Decision feedback equalization is achieved by cascading a feedforward filter and a feedback filter, as shown in Fig. 17.3. Assuming that the input signal sequence is $\{\tilde{v}_i\}$, the input of the feedforward filter is $\{\tilde{v}_i\}$; and the input of the feedback filter is the output $\{\overline{v}_i\}$ of the decision feedback device. The output of the DFE is

$$\hat{v}_i = \sum_{k=-K_1}^{0} c_k \tilde{v}_{i-k} + \sum_{k=1}^{K_2} c_k \overline{v}_{i-k} \qquad i = \ldots, -2, -1, 0, 1, 2, \ldots. \tag{17.14}$$

In the equation, $\{c_k\}$ is the equalizer tap coefficient, with a total of $K_1 + K_2 + 1$ tap coefficients, $K_1 + 1$ for the feedforward part and K_2 for the feedback part. After adding the output of the feedforward filter and the output of the feedback filter, symbol-wise decisions are made, and the symbol decision result is used as the output and input of the feedback filter.

If the tap coefficient is ideal, the combination of the two can cancel the intersymbol interference between symbols in the channel, eliminate the interference of previous symbols on the current symbol vector, and theoretically eliminate all intersymbol interference, thus equalizing the channel [34].

Maximum-Likelihood Criterion

The maximum-likelihood symbol detector and maximum-likelihood sequence estimator are both nonlinear equalizers that can, to some extent, suppress the noise interference generated in the channel at the receiving end of the communication system. Their principle is based on the maximum-likelihood criterion, which selects the transmission signal that is most likely to generate the received signal under the given conditions.

Maximum-likelihood estimation (MLE) was proposed by British statistician Ronald Fisher in 1922 [67]. The basic idea is to estimate the parameter using known observations without any prior knowledge of the parameter so that the selected sample is most likely to appear in the selected population.

Let a represent N observations of $x_1, \ldots, x_k$ random variables, and $\{f(x_1, \cdots, x_N| \theta), \theta \in \theta\}$ represent a given parameter θ. Assume that the joint conditional probability density function exists and is bounded, and consider

unknown parameters θ. When considering the joint conditional distribution density function c as a true parameter, θ, it is often called a likelihood function. Maximum-likelihood estimation is recorded as follows:

$$\widehat{\theta}_{\mathrm{ML}} = \arg\max_{\theta\in\theta} f(x_1, \cdots, x_N|\theta). \tag{17.15}$$

The equilibrium structure of the maximum-likelihood symbol detector is usually a decision-maker used to map the received signal to the most likely sending symbol. The formula can be expressed as

$$\widehat{s} = \arg\max_{s_i} P(r|s_i), \tag{17.16}$$

where $\widehat{s}$ represents the estimated transmission symbol; r represents the received signal; s_i represents the actual sent symbol; and $P(r \mid s_i)$ represents the probability of receiving r when sending symbol s_i.

The equilibrium structure of a maximum-likelihood sequence estimator is typically a filter used to estimate the transmitted symbol sequence. The formula can be expressed as

$$\widehat{\mathbf{s}} = \arg\max_{\mathbf{s}} P(\mathbf{r}|\mathbf{s}), \tag{17.17}$$

where $\widehat{\mathbf{s}}$ represents the estimated sequence of transmission symbols; $\mathbf{r}$ represents the received signal sequence; $\mathbf{s}$ represents the actual sequence of sent symbols; and $P(\mathbf{r} \mid \mathbf{s})$ represents the probability of receiving $\mathbf{r}$ when sending symbol sequence $\mathbf{s}$.

Both the maximum-likelihood symbol detector and maximum-likelihood sequence estimator are nonlinear equalizers designed using statistical principles, which can further improve the performance of optical wireless communication systems.

Channel Equalization Algorithms Based on Neural Networks

Channels are modeled and predicted using neural network models to equalize the channels. Neural networks exhibit strong nonlinear characteristics and play important roles in signal analysis and processing. Compared with the equalization effect of traditional linear equalizers, a system that uses neural networks to equalize channels has a lower bit-error rate.

For example, the channel equalization of a support vector machine (SVM) utilizes the SVM network model to model and equalize the channel. Particle swarm optimization (PSO) channel equalization optimizes the channel parameters through PSO. Genetic algorithm (GA) channel equalization optimizes the channel parameters through genetic algorithms. These nonlinear channel equalization methods are widely used in optical wireless communication.

Compared with linear channel equalization methods, nonlinear channel equalization methods can better adapt to more complex channel characteristics and improve the performance of optical wireless communication. However, their computational complexity is relatively high, requiring additional computational resources and time.

Appropriate methods must be selected according to specific application scenarios and channel characteristics.

Summary

This chapter provided a brief overview of the foreign and domestic research status of channel equalization technology in optical wireless communication. It provided a brief introduction to typical channel equalization technologies in two categories—nonlinear and linear—and analyzed the advantages and disadvantages of linear and nonlinear equalization methods, as shown in Table 17.1.

It was found that, in the case of low channel noise and a narrow signal spectrum, the performance of linear channel equalization was better than that of nonlinear channel equalization, whereas in the case of high channel noise and a wide signal spectrum, the performance of nonlinear channel equalization was better than that of linear channel equalization.

The prospects of channel equalization are very broad, and future research will likely include the following:

1. Research should dig deeper into blind equalization algorithms. Currently, many algorithms require knowledge of the training sequence to determine the tap coefficients, resulting in low equalization efficiency. To avoid this issue, blind equalization algorithms use the transmitted signal characteristics to determine the equalizer tap coefficients.
2. Research should focus on the cross integration of multiple technologies, design new generalized activation functions to improve the ability of neural networks, realize neuro fuzzy systems, develop algorithms and neural network structures, and balance complex time-varying channels with faster convergence and simpler, more efficient architectures.
3. Researchers should study new metaheuristic algorithms, note the importance of swarm intelligence, find inspiration from natural communities, flocks, herds, and

Table 17.1 Advantages and disadvantages of linear and nonlinear equalization methods

	Advantages	Disadvantages
Linear equalization	1. Simple implementation and fast calculation speed 2. Better effect on low channel noise 3. Suitable for narrow spectrum widths	1. Unsuitable for high channel noise 2. Channel characteristics must be known, which is difficult with complex channels 3. Cannot handle nonlinear distortion issues
Nonlinear equalization	1. Can handle nonlinear distortion issues, with good results for large nonlinear channel distortion 2. Can adaptively handle channel characteristics and equalize complex channels	1. Complex implementation and slow calculation speed 2. Poor effect on high channel noise 3. Only suitable for situations with wide spectra

schools, and study new metaheuristic algorithms based on a single problem, such as a slow convergence rate or based on groups.

4. Research should focus on addressing the shortcomings of short transmission distances and narrow coverage, identify transmission wavelengths with stronger penetration, and enable them to overcome obstacles and achieve longer transmission distances. Technology should be selected and optimized, based on specific application scenarios.
5. In terms of hardware, more attention should be paid to reducing the complexity of hardware devices, amount of system computation, and power consumption, and improving the convergence rate of signal errors, thus compensating for system performance.

Abstract

The channel environment of the optical wireless communication is complicated, susceptible to various natural phenomena such as rain, snow, and fog. The channel code is usually used to correct the error caused by the channel noise. Common channel codes are Reed–Solomon (RS) code, turbo code, low-density parity-check (LDPC) code, polarization code, and other types. The development of the error-correction code was combed, the research progress of the error-correction code for the optical wireless communication was summarized, and the comparative analysis was made, which introduced the progress of Xi'an University of Technology in this field of theory and experimentation. RS code, turbo code, and LDPC code were comparable to the error correction characteristics in rain, snow, and fog environments. Finally, the future possible research directions and challenges were pointed out, providing references for the future development and research in the relevant fields.

Introduction

The optical wireless communication channel environment is complex and vulnerable to various natural phenomena, such as rain, snow, and fog. Channel coding methods are typically used to correct error codes caused by channel noise. Channel coding includes Reed–Solomon code (RS), turbo code, low-density parity-check code (LDPC), and polarization code.

This chapter presents the development of error-correction codes, summarizes the research progress on the error-correction codes used in optical wireless communication, and presents a comparative analysis. It introduces the theoretical and experimental research progress of Xi'an University of Technology in this field. In addition, it compares and analyzes the error-correction characteristics of RS, turbo, and LDPC codes in rain, snow, and fog. Finally, it lists possible future research directions and challenges in this field, which provides a valuable reference for future development and research in related fields.

In an era of rapid information technology development, cloud computing, artificial intelligence, and multimedia services continue to increase. Massive amounts of data are transmitted and stored in communication networks, and impose higher requirements on their bandwidth, speed, and delay. Optical communication, with wide bandwidth, large capacity, and high speeds, has been extensively developed.

Optical wireless communication transmits voices, images, text, etc., in a optical wireless channel. It has good application prospects in solving the "last mile" access, emergency rescue, disaster relief communication, etc. Natural phenomena in optical wireless channels adversely affect laser communication, such as broadening the communication pulse range, reducing the signal-to-noise ratio, and increasing the bit-error rate [1].

To suppress channel degradation, the anti-interference performance of signals must be improved through error-control coding (i.e., error-correction codes) and increasing the signal redundancy to meet the system index requirements. Introducing error-correction codes into optical wireless communication systems is another new practice in error-correction code applications. The research and development of coding technologies with good anti-interference performance and high speeds have become key topics in the field of optical wireless communication [2].

Research Progress in Error-Correction Codes

Shannon founded information theory in 1948 and published the pioneering document "Mathematical Theory of Communication," marking the birth of information and coding theory and the beginning of error-correction coding theory [3]. Since

then, many scholars have devoted themselves to researching error-correction coding. With improvements in coding methods and computing power, error-correction coding methods that have better error-correction performance and are closer to the Shannon limit have emerged one after another.

In 1950, Hamming proposed a linear block code, called the Hamming code, which could correct an independent error. The Hamming code can indicate the location of a data error and correct a single-bit error in seven bits [4]. In 1954, Muller proposed a structurally rich algebraic coding scheme [5]. In the same year, Reed of the Massachusetts Institute of Technology of the United States proposed an efficient decoding algorithm for the hierarchical structure of the algebraic coding scheme: a large-number logical decoding algorithm. This algebraic coding scheme is called the Reed–Muller (RM) code. The RM code is also a linear block code, but it can correct multiple errors, unlike the Hamming code [6]. It was later applied to Mars exploration.

In 1954, Golay studied the shortcomings of the Hamming code and proposed the Golay code, which can correct any three-bit errors [7], effectively improving the coding efficiency. The abovementioned error-correction codes are all linear block codes.

In 1955, Elias proposed convolutional codes, which are non-block codes. They are more suitable for forward error correction. In many practical applications, their performance is better than that of linear block codes, with a small amount of computation. This coding method makes better use of the correlation between various modules. The coding output at the current time depends on the input at the current time and the input at the previous time; thus, a higher coding gain can be obtained. The emergence of convolutional codes also greatly improved the development of wireless communication [8].

In 1957, Prange proposed the cyclic code, which improves on linear block codes. It not only has the characteristics of general linear block codes but also has the cyclic characteristics of any code word after a cyclic shift [9]. Cyclic codes have strong error detection and correction capabilities, can detect random and some burst errors [10], and the encoding and decoding equipment is relatively simple; however, their ability to correct multiple random errors is limited.

In 1959, Hocquenghem proposed the Bose–Chaudhuri–Hocquenghem (BCH) code, which is a cyclic code that can correct multiple random errors and compensate for the limited correction ability of the cyclic code proposed by Prange. It has been studied extensively [11].

In 1960, Reed and Solomon proposed the Reed–Solomon (RS) code that effectively corrects random-symbol and random-burst errors. This code is a further improvement on the BCH code with strong error-correction ability [12]. It is especially applicable to multi-ary modulation.

Cyclic codes add linear constraints and are the most mature type of codes. Most practical error-correction codes are cyclic (Table 18.1).

The coding efficiencies of several error-correcting coding schemes proposed by scholars were very close to the Shannon limit, which significantly promoted the development of error-correcting codes. The low-density parity-check (LDPC) code

proposed by Gallager in 1962 is a linear error-correction code based on a sparse matrix, with performance very close to the Shannon limit. The advantages of this code are more significant when a code group is extremely long.

At that time, computers were not able to process lengthy code groups; thus, the LDPC code did not receive scholars' attention [13, 14]. Later, with the enhancement of computing ability, it received renewed attention and is now widely used in many fields, such as mobile and optical fiber communication.

In 1993, Berrou and Glavieux proposed the turbo channel coding scheme with a coding efficiency approaching the Shannon limit [15]. The proposed turbo code broke away from the traditional channel coding method, integrated a convolutional encoder and interleaver, effectively reduced the correlation between codes, and rendered the coding sequence highly random. The decoding algorithm used for this code is extremely complex.

The encoding efficiencies of the LDPC and turbo codes are very close to the Shannon limit; however, their decoding delay is high. Therefore, they are more suitable for communication systems with low real-time requirements. Arikan et al. proposed the polar code in 2009; it is a channel coding, error-correcting scheme with relatively low coding and decoding complexities, which has been proven to theoretically approach the Shannon limit. It has been proved theoretically to reach the capacity of any binary input discrete memoryless symmetric channel [16, 17].

We have discussed the emergence, advantages, and disadvantages of various error-correction codes. During the development of error-correction codes, scholars have improved various coding methods and concatenated different error-correction codes, resulting in different combinations of concatenated codes, and thereby improving the coding performance.

In 2006, Li et al. concatenated the BCH and LDPC codes. The error rates of the concatenated and LDPC codes were similar, but the concatenated code's signal-to-noise ratio performance was better [18]. In 2007, Kang et al. used concatenated RS and BCH codes to correct random and burst errors, which effectively reduced the error rate in a Poisson channel [19].

In 2009, Zhang et al. found that the performance of concatenated RS and turbo codes as an error-correction code was at least 1 dB higher than that of the concatenated RS and convolutional codes. A bit-error rate of 10^{-6} resulted in a 2-dB coding gain [20].

In 2010, Yuan et al. proved through simulation that when the bit-error rate was the same, concatenated RS and BCH codes achieved a greater coding gain, compared to using the RS code alone, and the system error-correction performance was greatly improved [21]. In 2017, Dong et al. investigated the optimal allocation of sub-channel rates and the construction of irregular quasi-cyclic low-density parity-check (QC-LDPC) codes, focusing on the optimization of multilevel coding and modulation schemes [22].

The above results show that concatenated codes can effectively improve the error-correction performance and coding efficiency, and combinations of different coding methods are better than single codes. The emergence of various concatenated codes has further promoted the development of error-correction coding. The development of error-correction coding is presented in Table 13.1.

Applying Error-Correction Codes to Optical Wireless Communication

Optical wireless communication uses an atmospheric channel, and the communication link is extremely vulnerable to atmospheric effects. A poor channel environment reduces the communication quality. Channel coding suppresses the interference of an optical signal in a channel. Channel coding can improve the signal anti-interference ability and the system's communication performance.

Forward error-correction codes are generally applied to optical wireless communication systems. In 1993, Ohtsuki et al. applied the RS code to an optical wireless communication system and analyzed the results [23]. In 2003, Josephm et al. combined turbo codes with an optical wireless communication system and conducted theoretical calculations and simulations for this scheme [24]. In 2005, Jaime et al. analyzed the atmospheric channel capacity of an optical wireless communication system from the perspective of information theory, introduced an LDPC code to suppress the channel noise, and obtained a large net coding gain [25].

The application of RS, turbo, and LDPC codes to optical wireless communication systems can improve the system performance and increase the coding gain. Scholars have compared several coding methods from different perspectives. In 2008, He et al. deduced the average bit-error rate (BER) of an optical wireless communication system when the channel information was known and compared the system performance of two schemes using RS and turbo coding. The results showed that the turbo coding scheme effectively reduced the required reception power.

In weak turbulence, the BER of turbo codes slowly deteriorates with an increase in turbulence intensity, making them more suitable for optical wireless communication systems than the RS code. Later, scholars began applying concatenated codes to optical wireless communication systems [26].

In 2010, Wen et al. studied channel coding in satellite communications. The fountain code and nonbinary LDPC codes were introduced, including their encoding and decoding algorithms. Cascade and nonbinary LDPC fountain codes were proposed based on characteristics similar to those of sparse graphic codes. Simulation results demonstrated the good performance of the cascade codes [27].

In 2011, Jiang et al. optimized the performance of interleaved RS codes. The optimal coding efficiency was calculated when the interleaving depth was fixed. Simulation results showed that interleaved RS codes significantly improved the performance of communication systems in fading channels. They have the maximum anti-interference ability when the coding efficiency is 0.5 [28].

The excellent performance of polarization codes has attracted the attention of many researchers. In 2013, Habif et al. combined a polarization code with pulse-position modulation and adopted direct detection to achieve a photon information efficiency of 4.8 bits per received photon in a weakly coherent state [29]. In 2015, Wu et al. applied polarization codes to an optical communication system and studied the transmission performance of a 7% redundant polarity code in a coherent ultra-dense wavelength-division multiplexing (WDM) optical access network scheme. They obtained a performance gain of 1.4 dB when the bit-error rate was 10^{-3} [30].

In 2018, Fang et al. analyzed the performance of polar codes in turbulent atmospheric channels [31]. The results showed that the polar code could effectively suppress the signal fading caused by atmospheric turbulence in medium- and strong-turbulence channels, and its coding complexity was low.

In 2019, Iqbal et al. proposed a coherent-optical polarity-coding transmission system with orthogonal amplitude modulation and an adjustable data rate. An implicit hole–hole polar-coded modulation system was designed, based on a many-to-one constellation-shaping method. The scheme was experimentally evaluated in a WDM system, and a new hole polarity code was proposed. Compared with the traditional hole polarity code, the shaping gain was 1.2 dB, and the maximum communication distance was increased by 200–400 km [32].

To improve the transmission efficiency in weak atmospheric turbulence channels, Zhang et al. designed an adaptive-rate polarization code in 2021. Under different turbulence intensities, when the frame error rate was 10^{-8}, the adaptive-rate polarization code obtained a performance gain of 1.7–2.3 dB [33]. The above conclusions were mostly based on theoretical calculations and simulations.

In 2019, Ao et al. used the Raptor10 code to combine optical wireless and radio frequency (RF) channels. Optical wireless communication was demonstrated on a 1.87-km urban link, and the Raptor code was applied to the actual channel coding, which proved that it could maximize the link utilization [34].

A multiple-input multiple-output (MIMO) transmission and reception method was proposed to suppress the impact of atmospheric turbulence on communication systems. In 2021, Wen et al. proposed a MIMO polarization-coding scheme suitable for optical wireless communication to address the problem of communication links being vulnerable to atmospheric turbulence. It maintained low complexity while achieving better system performance [35].

Scholars have also improved the methods for decoding polarization codes. In 2021, Wenhao et al. proposed a segmented polarization code–cyclic redundancy check–serial cancellation list decoding method based on relaxed polar codes. This method significantly improved the error rate of free-space optical (FSO) communication systems and the signal-to-noise ratio [36].

In the same year, Lu et al. analyzed channel combination and decomposition in channel polarization, further studied the polarization code encoding and decoding process, and discussed the polarization calculation method in different channels and the impact of coding parameters on the bit-error rate [37].

The optimization and improvement of other coding schemes have continued. Research on LDPC codes in optical wireless communication systems is becoming increasingly mature. In 2021, Cao et al. proposed a dynamically adjusted log-likelihood ratio (LLR) as the input of an LDPC decoder to obtain better communication performance. Compared to the traditional LLR input, the simulation results showed that the LDPC code based on the dynamically adjusted LLR had strong turbulence resistance and better error performance under different atmospheric turbulence conditions [38].

In 2021, Sonali et al. proposed an analysis model verified by simulation to evaluate the performance of LDPC codes in optical wireless communication links under various channel conditions. They analyzed and formulated a backpropagation (BP) algorithm using LDPC codes in fast-fading and spatial-multiplexing optical wireless communication channels. The maximum coding gains were 13.95 dB and 19.83 dB, respectively [39].

Some applications of error-correction codes in optical wireless communication are listed in Table 18.2.

Error-Correction Coding Simulations in an Optical Wireless Communication System

The performance of an optical wireless communication system is affected by several factors. Alignment errors can cause spot drift, reduce the signal-to-noise ratio, and cause the optical signal to randomly fluctuate. Atmospheric absorption can cause the power to attenuate and reduce the average signal-to-noise ratio. Scattering can cause optical power attenuation and optical pulse broadening, resulting in intersymbol

2021	Sonali	Analyzed and developed a backpropagation algorithm for LDPC code

crosstalk and a lower signal-to-noise ratio. Atmospheric turbulence can cause light intensity fluctuation, beam drift, angle-of-arrival fluctuation, and beam expansion. It also distorts the optical signal wavefront, reduces the average signal-to-noise ratio, and generates random fluctuations in the received signal.

This chapter only analyzes the impact on the BER performance. Since 2002, Xi'an University of Technology has studied error-control coding in optical wireless communication systems. RS, turbo, LDPC, fountain, and polarization codes have been used in optical wireless communication systems, and the performance of various codes in optical wireless communication systems has been simulated and experimentally studied.

Error-Correction Control Based on RS Codes

An RS code groups the original information and adds a certain number of supervision symbols to each information group. Every nine symbols are divided into a group with six bits of supervision symbols added. The RS decoder adopts a pipeline decoding algorithm. We simulated the performance of the RS (30, 10) code used in optical wireless communication systems under various weather conditions [40] (Figs. 18.1, 18.2, 18.3, and 18.4).

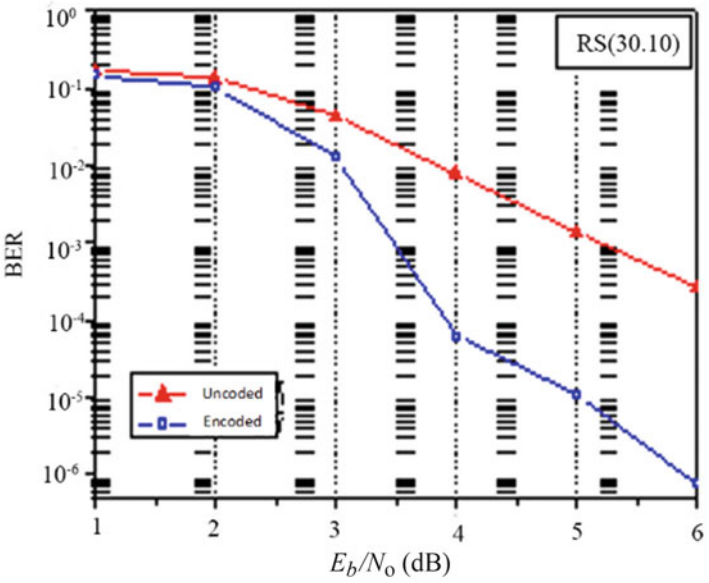

Fig. 18.1 Error rate before and after error correction with RS (30, 10) code on sunny days [40]

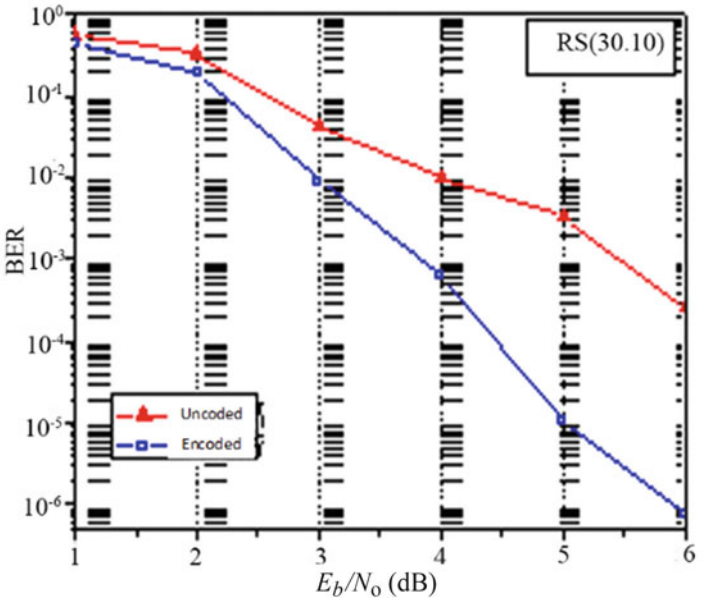

Fig. 18.2 Error rate before and after error correction with RS (30, 10) code on cloudy days [40]

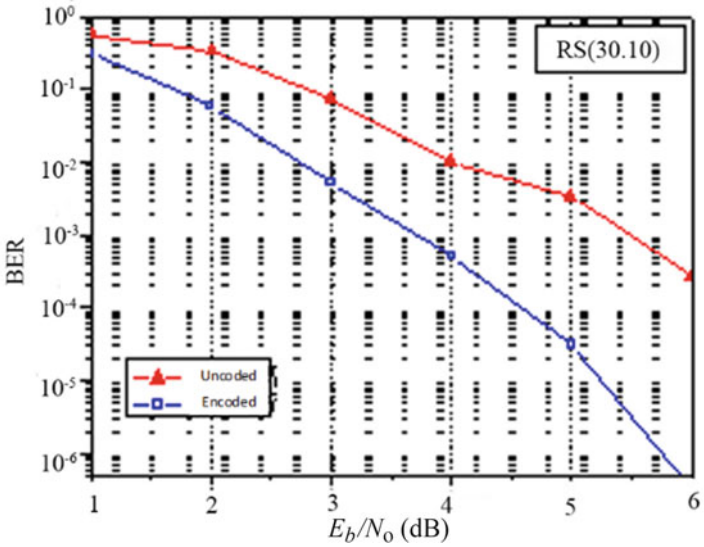

Fig. 18.3 Error rate before and after error correction with RS (30, 10) code on rainy days [40]

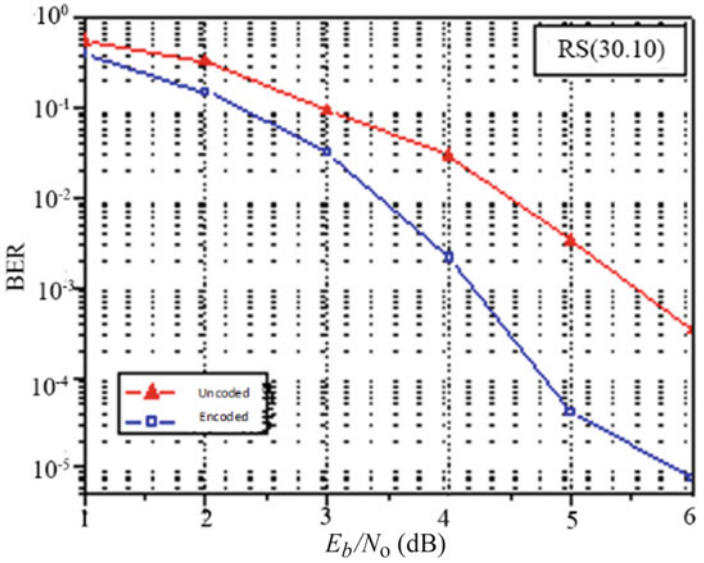

Fig. 18.4 Error rate before and after error correction with RS (30, 10) code on snowy days [40]

Error Control Based on LDPC Codes

The LDPC code is a linear error-correction code with excellent performance that comes very close to the Shannon limit. Figures 18.5, 18.6, 18.7, and 18.8 show the error-correction performance of LDPC codes under different weather conditions [41].

Error Control Based on Turbo Codes

Figures 18.9, 18.10, 18.11, and 18.12 compare the performance of the bit-error rate before and after turbo code error correction under four different weather conditions: sunny, cloudy, rainy, and foggy [43].

Figures 18.9, 18.10, 18.11, and 18.12 show that the error rate with the turbo codes in different weather conditions improved to different degrees. Although the system was complicated by error-correction coding, its performance was greatly improved [43].

Error Control Based on Fountain Codes

Fountain codes are error-correction codes that generate multiple coded packets from one original data packet. All the original data packets can be recovered by receiving any coded packet. Luby transform (LT) codes and Raptor codes are specific implementations of fountain code [45].

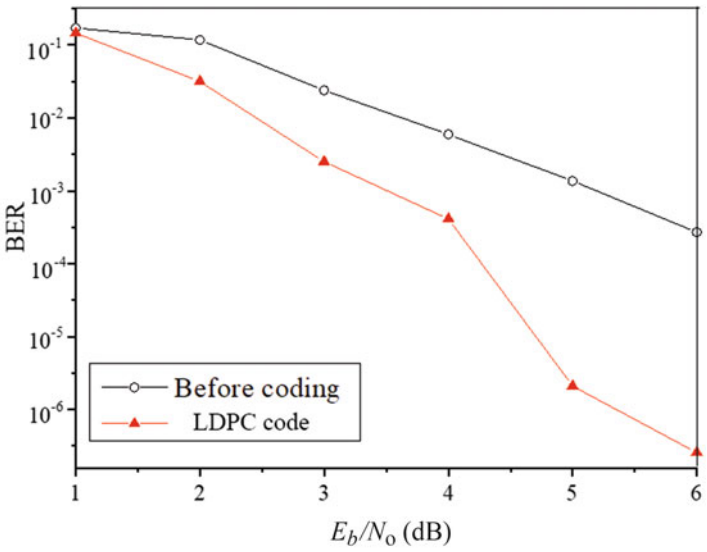

Fig. 18.5 Error rate before and after LDPC code error correction on sunny days [42]

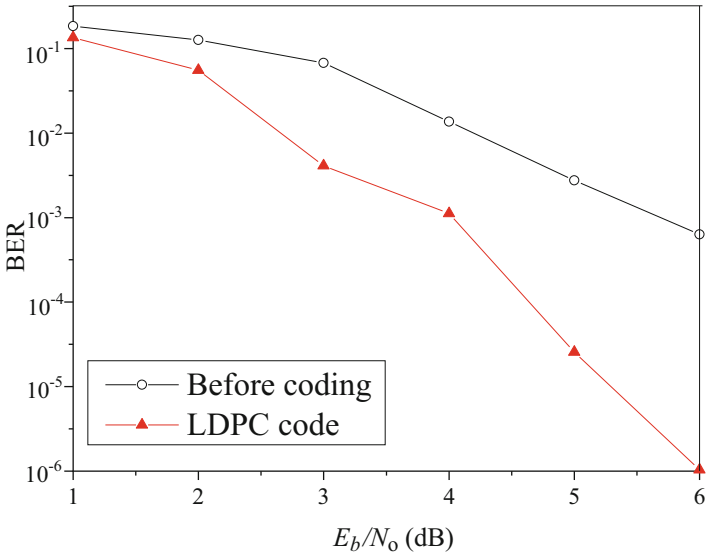

Fig. 18.6 Error rate before and after LDPC code error correction on cloudy days [42]

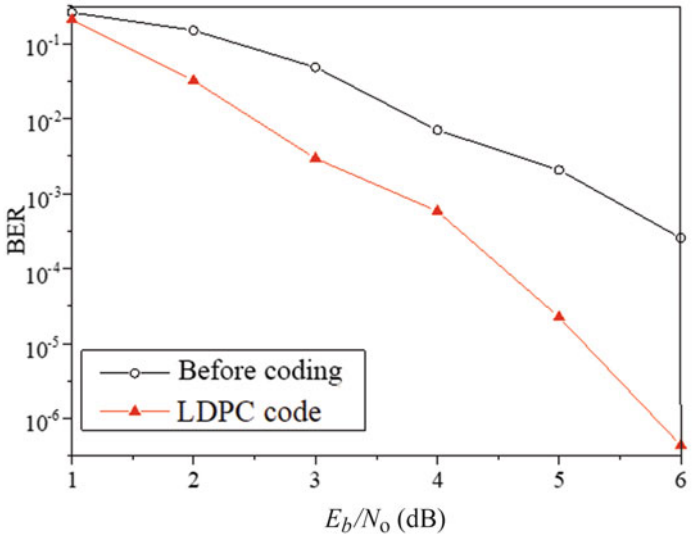

Fig. 18.7 Error rate before and after LDPC code error correction on rainy days [42]

LT Codes

The decoding success probability of LT codes is closely related to the degree distribution. Luby provides two practical degree distributions: ideal soliton and robust soliton. Because the number of verification units with an ideal soliton

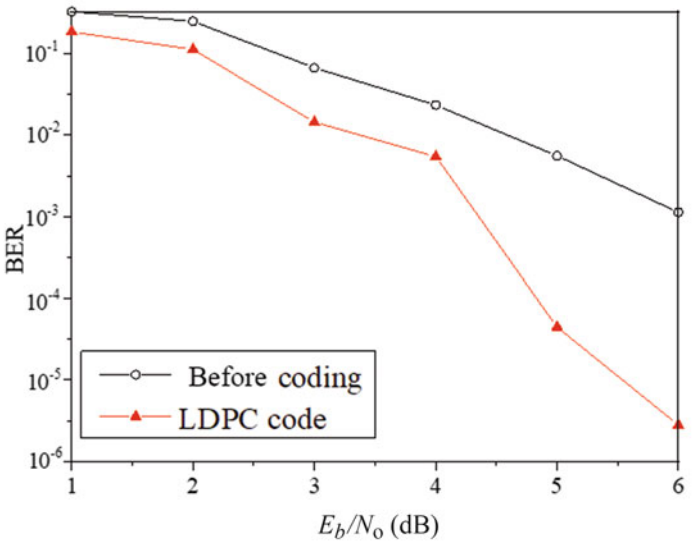

Fig. 18.8 Error rate before and after LDPC code error correction on snowy days [42]

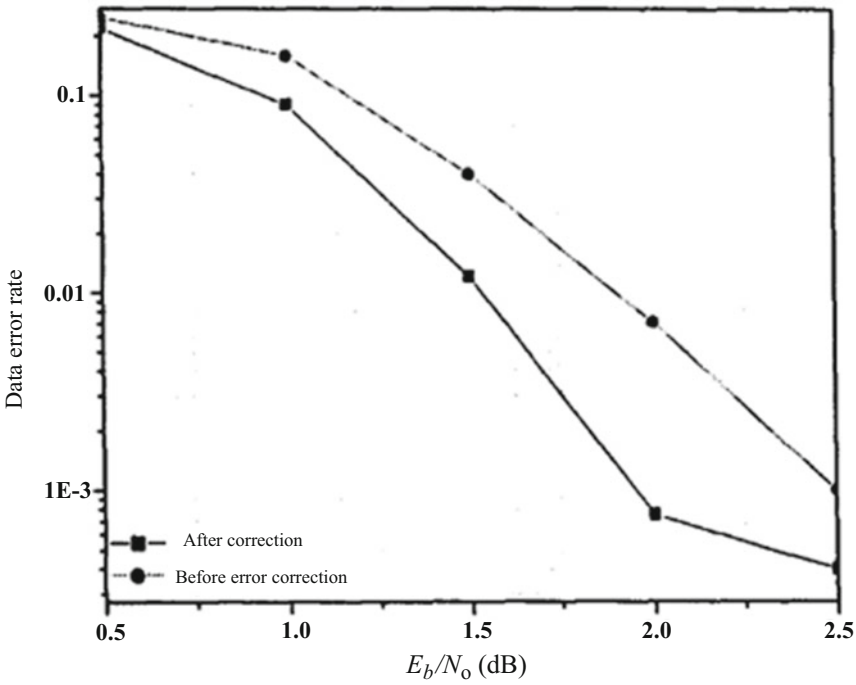

Fig. 18.9 Error rate before and after error correction using turbo codes on sunny days [44]

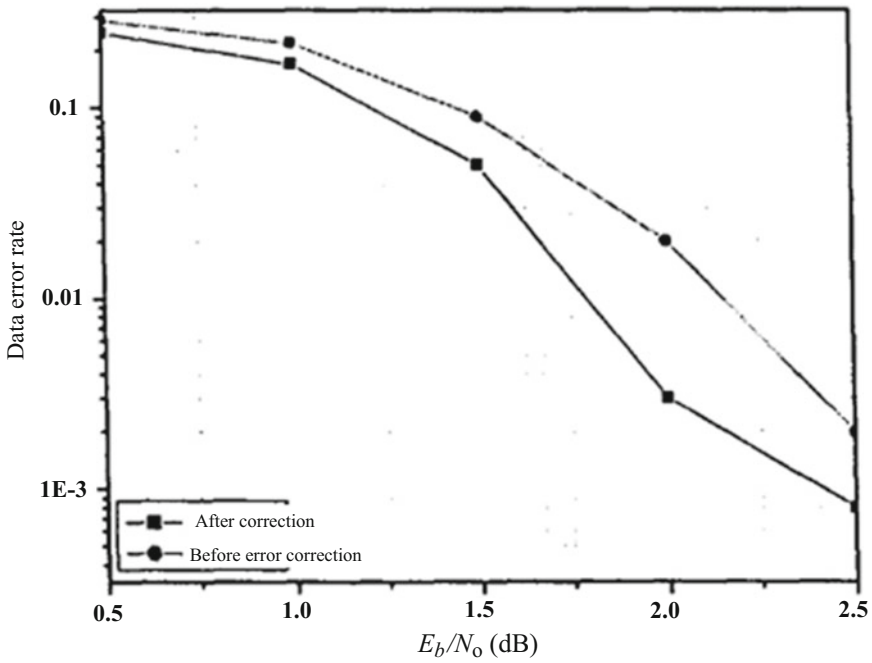

Fig. 18.10 Error rate before and after error correction using turbo codes on cloudy days [44]

distribution degree of one only accounts for the total number of verification units, the number is small and the fluctuation is large. Sometimes, there are no nodes with a degree of one, and some original packets have no verification nodes connected to them at all. As a result, the original information cannot be recovered correctly from the received information. This chapter adopts an improved robust soliton distribution that adds two parameters, which can achieve better results than the ideal soliton distribution [45].

Figure 18.13 compares the performance of LT codes with two different degree distributions: ideal and robust solitons. The abscissa represents the coding overhead, defined as $\varepsilon = \frac{k}{n} - 1$, and the ordinate represents the decoding failure probability, defined as $k = 155$, $c = 0.8$, $\delta = 0.05$. As shown in Fig. 18.14, when $n = 1.6k$, the decoding failure rate under the ideal soliton distribution is approximately 0.15, while the failure rate using the robust soliton distribution is 0.1; thus, the decoding failure probability is significantly reduced [45].

Raptor Codes

After decoding the LT code, $k' < k$ original input symbols are recovered, and the recovery failure rate is defined as $\eta = (k - k')/k$. As long as η is less than the error-correction ability of the RS code, the code can recover incorrect symbols. Figure 18.15 compares the performance of the LT and Raptor codes under the same conditions, where $k = 155$, $c = 0.8$ and $\delta = 0.05$ [45].

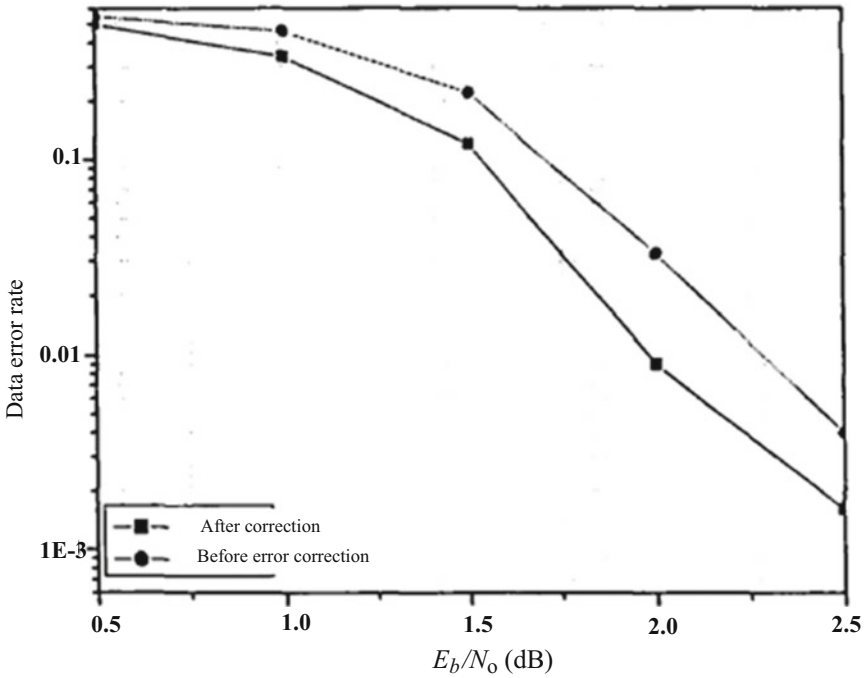

Fig. 18.11 Error rate before and after error correction with turbo codes on rainy days [44]

After adopting the Raptor code, the RS code can correct errors that cannot be recovered by the LT code, which significantly reduces the error rate. When receiving a coded packet with $n = 1.6k$, the decoding failure probability is approximately 0.12 when using the LT coding method, and approximately 0.08 when using the Raptor code. Therefore, the Raptor code is greatly optimized [45].

The higher the value of the fountain code, the lower the probability of decoding failure, which is suitable for transmission of larger data volumes. Figure 18.16 compares the decoding failure probability $c = 0.8$, $\delta = 0.05$ [45] under the same reception redundancy as $k = 100$, $k = 1000$.

As shown in Fig. 18.16, the decoding failure probability when $k = 1000$ is lower than that when $k = 100$. When the received coding packet $n = k$ is received, the decoding failure probability of the longer data packet is 0.98 and the decoding failure probability of the shorter data packet is 1. When the data are grouped as $n \geq 1.1k$, the decoding failure rate decreases rapidly. When encoding the packet $n = 1.55k$, the longer data packet is recovered, whereas the decoding failure probability of the shorter data packet is approximately 0.1 [45].

When the distribution is certain, the more the original input data are grouped, the more the BER changes with increasing overhead, which has a significant advantage compared to small data volumes. When the received data packet n is

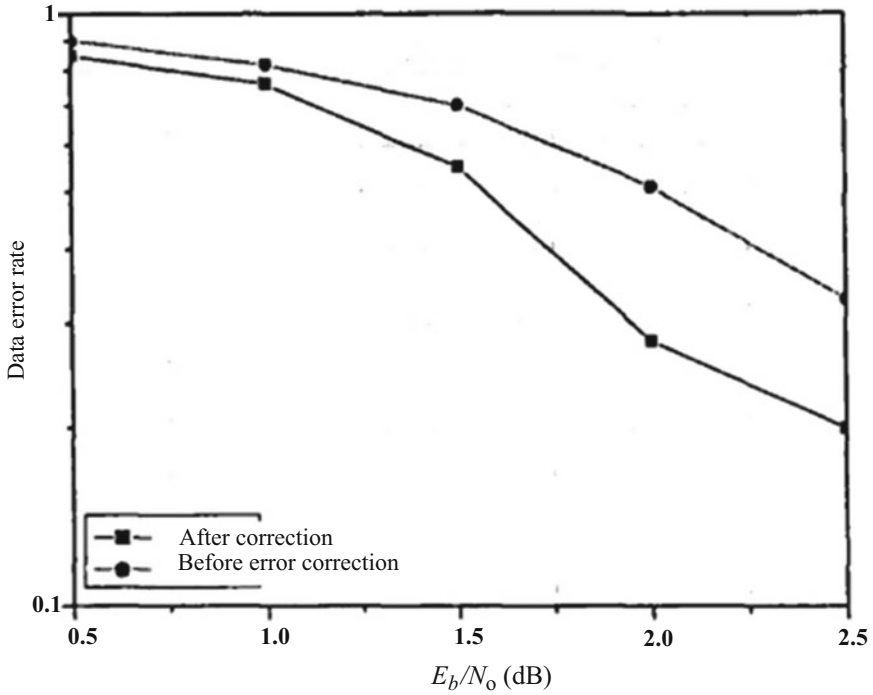

Fig. 18.12 Error rate before and after error correction with turbo codes on foggy days [44]

slightly larger than $k(n > 1.1k)$, the probability of a decoding failure decreases rapidly. However, when n is large, the change of bit-error rate is relatively slow. With an increase in the received coded packets, the decoding success probability also increases and is related to the number of original data packets [45].

Error Control Based on Polarization Codes

The polarization code has low coding complexity and is the only error-correction code that can be proven to approach the Shannon limit. This section analyzes the performance of the serial-cancellation (SC) decoding algorithm and the impact of pulse-position modulation (PPM) on the performance of polarization codes in an atmospheric laser channel. Experimental results demonstrated the error-correction performance of the polarization code under subcarrier modulation [46, 47].

Polarization codes can reach the channel capacity and fulfill the requirements of 5G channel coding schemes. Therefore, achieving an efficient coding design with limited code length, and developing high-efficiency and high-spectral-efficiency

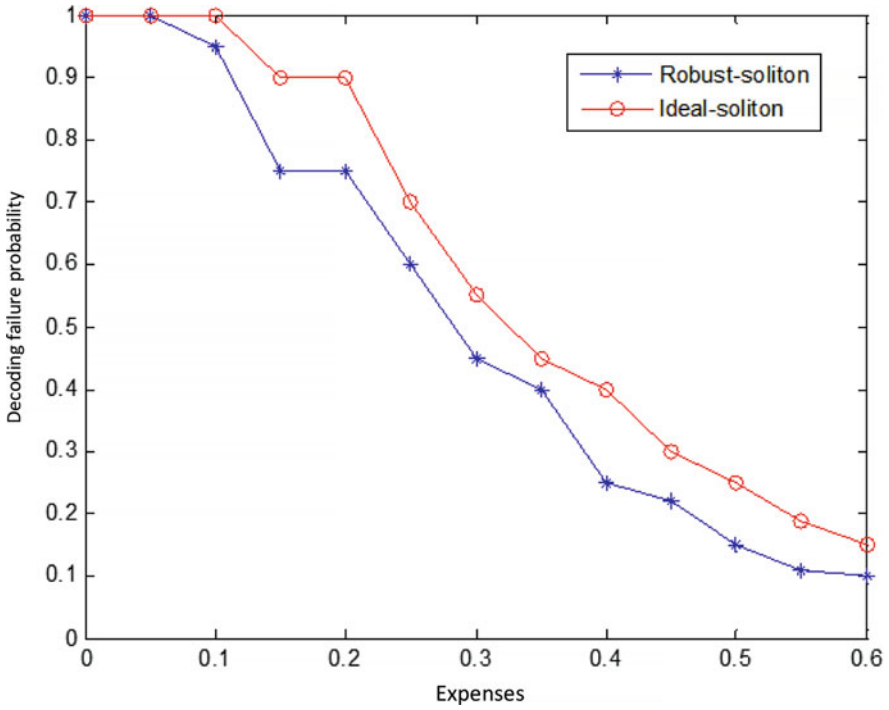

Fig. 18.13 Comparison of LT code performance under two degree distributions [45]

data-transmission technology combined with MIMO and non-orthogonal multiple access have become important research directions for improving future 6G wireless-transmission performance [48].

SC Decoding Algorithm Performance Simulation

Figure 18.16 shows the decoding simulation results of the serial-cancellation (SC) polarization code algorithm in a weak-turbulence channel constructed using a Gaussian approximation. It shows the bit-error rate of the polarization code in a weak turbulence channel when the signal-to-noise ratio is large (10^{-6}). Figure 18.16a compares the bit-error rate performance when $R = 0.5$ and $N = 512$, 1024 and 2048.

Under the same bit rate, the performance of the polarization code tends to improve with an increase in code length. The ratio of the 1024 code length to the 512 code length has a 0.8-dB coding gain, while the ratio of the 2048 code length to the 1024 code length has a 1.5-dB coding gain. It can be seen that increasing the code length can improve the coding gain of the polarization code. However, it increases the cost and delay of the encoder and decoder; the progressive complexity of coding and decoding is $O(N \log N)$.

Figure 18.16b shows the impact of different code rates on the polarization code when the code length is the same. It can be seen from the figure that the code rate has

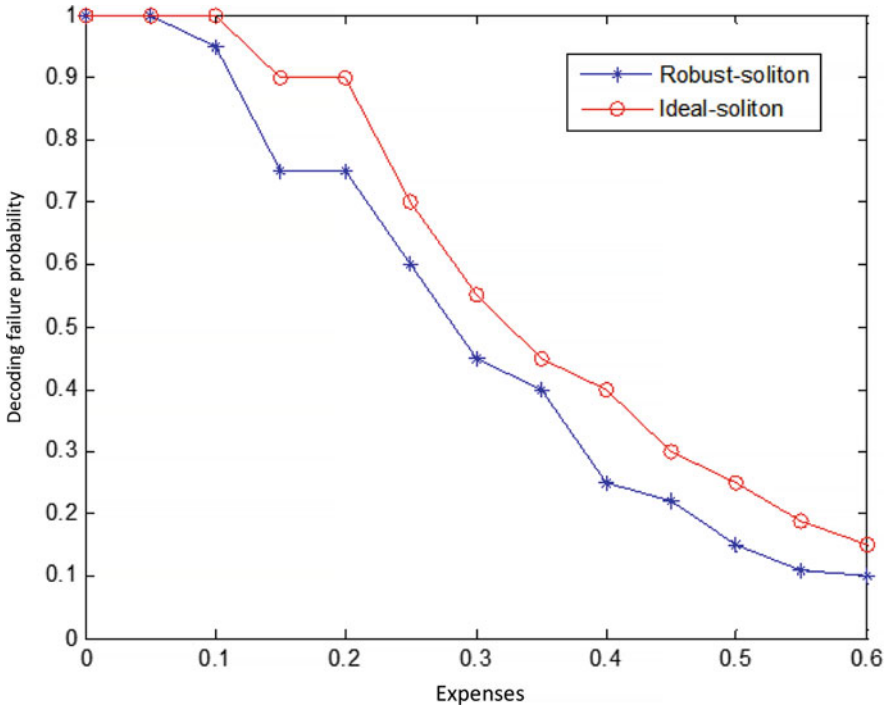

Fig. 18.14 Comparison of LT code and Raptor code performance [45]

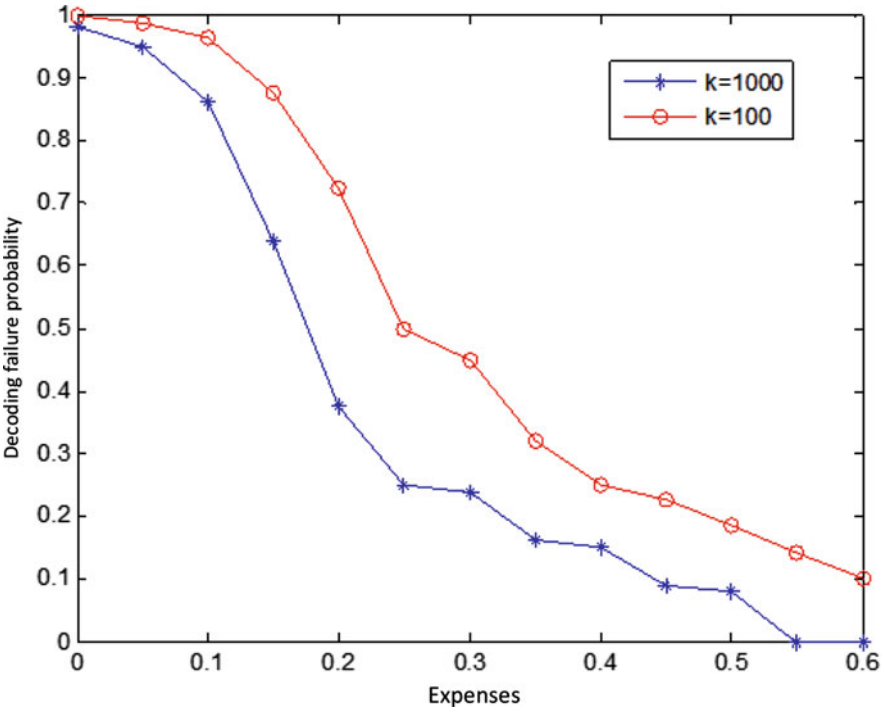
a very large impact on the polarization code. This is because, with an increase in the bit rate, more channels are not fully polarized for information transmission. The impact of noise on this part of the channel is more evident with an increase in the bit rate, which increases the bit-error rate and reduces the decoding performance [46, 47].

We consider the impact of weak turbulent noise on the communication system when the code length is $N = 1024$ and the code rate is $R = 0.5$. Figure 18.17 shows the BER simulation curve of the SC algorithm decoding under different turbulence intensities. It can be observed that the system performance is reduced by atmospheric turbulence, and the reduction is more evident with an increase in turbulence intensity. For the same code rate and code length, the stronger the turbulence, the fewer channels are fully polarized, and the greater the bit-error rate [47].

Polarization Code Performance Under PPM Modulation

The bit-error rate performance simulation diagram of binary on-off keying (OOK) modulation and 2-PPM modulation is shown in Fig. 18.18, and the bit rate is 0.5. As shown in Fig. 18.18, the performance of the 2-PPM modulation is significantly improved, compared with that of OOK modulation. Under the same code-length and



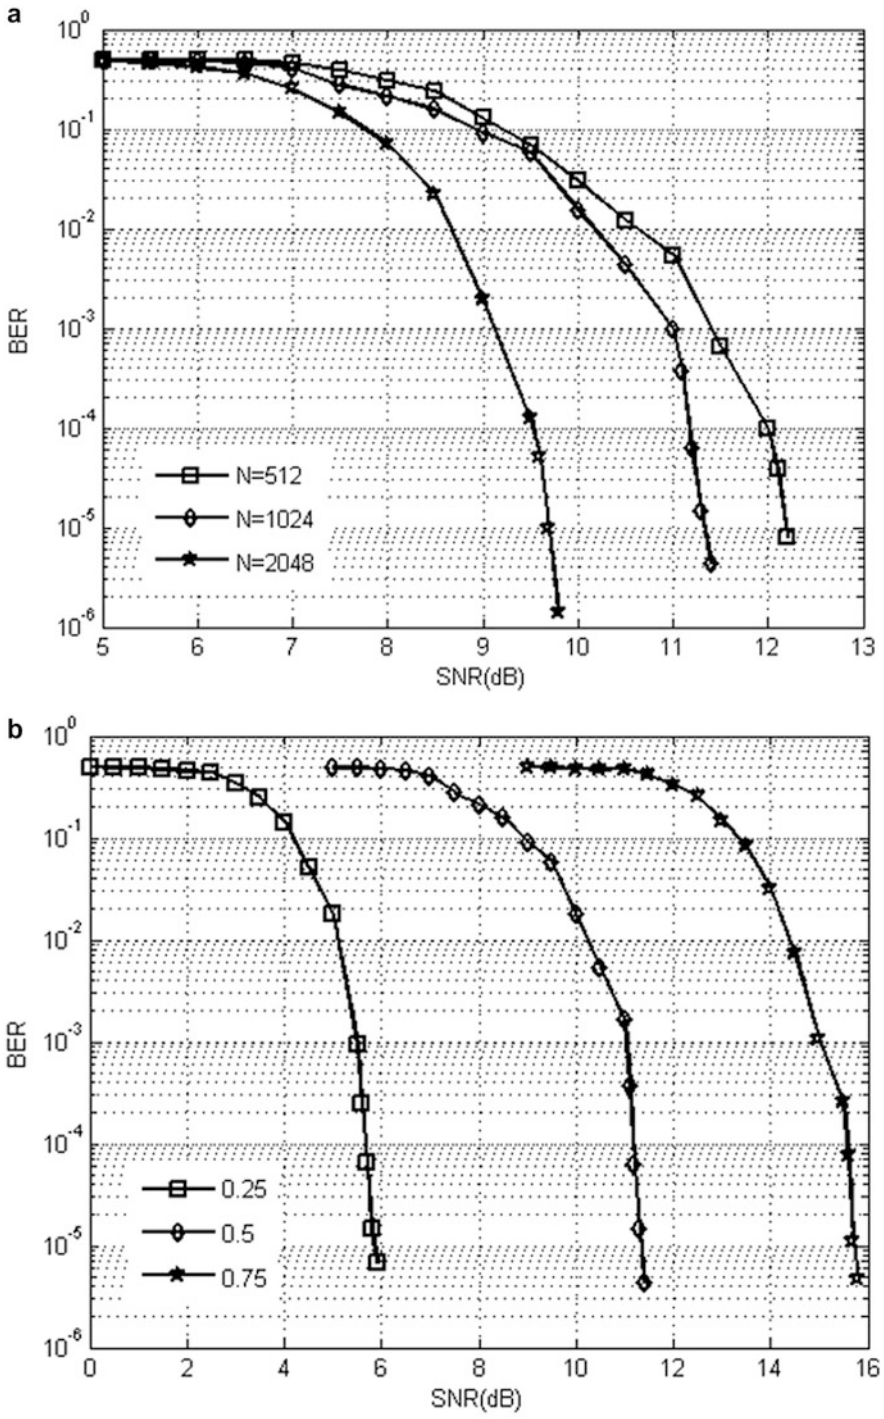


Fig. 18.15 Decoding failure rate at $k = 100$, $k = 1000$ [45]

code-rate parameters, 2-PPM modulation can obtain a 3.5 dB–3.8 dB coding gain compared to OOK modulation [47].

Figure 18.19 shows the performance of polarization codes in an atmospheric turbulence channel with an increase in M-ary PPM. As can be seen from the curve in Fig. 18.19, when the number of slots is small, the bit-error rate decreases with an increase in M, and the signal-to-noise ratio gain also increases.

However, as the modulation order M continues to increase, the modulation performance decreases; for example, the performance of 16-PPM is worse than that of OOK. This is because, the error probability of each frame demodulation increases with an increase in the modulation order M, which also increases the influence of turbulence and Gaussian noise, and thereby reduces its demodulation and decoding performance.

However, the average laser power required by the transmitter decreases with an increase in the number of time slots. The use of higher-order PPM results in a higher power utilization rate, which can improve the effective communication distance for optical wireless communication. Therefore, a reasonable compromise must be made in actual application scenarios [47, 49].

Simulation and Experiment of Polarization Code Performance Under Subcarrier-Modulation Technology

The SC decoding algorithm was used in the experiment and simulation in this section, with a code length of 512 and code rate of 0.5. Figure 18.20 shows the BER simulation curve of uncoded subcarrier binary phase-shift keying (BPSK) and quadrature phase-shift keying (QPSK) modulations under different turbulence intensity channels ($\sigma_0 = 0.1$, $\sigma_0 = 0.2$, and $\sigma_0 = 0.3$) and different signal-to-noise ratios (SNRs) [47].

Figures 18.21 and 18.22 show the bit-error rates of subcarrier BPSK and QPSK modulations in different turbulence intensity channels, respectively. Comparing Figs. 18.21 and 18.22, it can be seen that the BPSK system using polarization coding is superior to QPSK and obtained a 4.8-dB coding gain [42].

Table 18.3 shows the bit-error rate characteristics of coded and uncoded data on sunny, cloudy, and rainy days. Using a polarization code can improve the bit-error

Fig. 18.16 Polarization code performance curve under a weak-turbulence channel [42]. (**a**) Constant code rate R = 0.5; different code lengths N = 512, 1024, and 2048 [47]. (**b**) Constant code length N = 1024; different code rates R = 0.25, 0.5, and 0.75 [47]

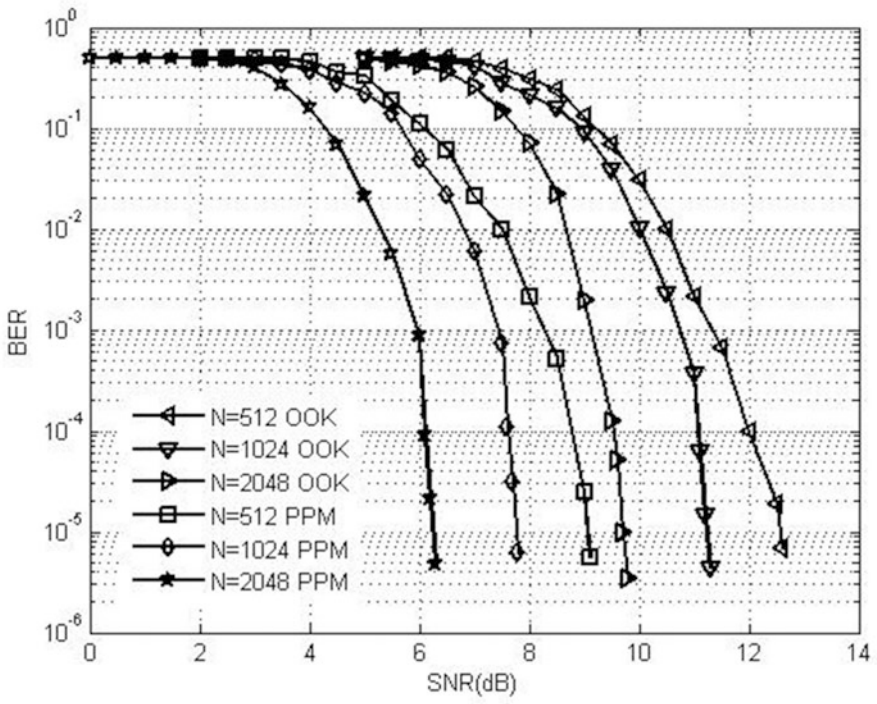

Fig. 18.18 PPM modulation with different code lengths [47]

rate characteristics by an order of magnitude and can effectively improve the bit-error rate performance of optical wireless systems [47].

Experimental Measurements

Experimental measurements were taken between September 2006 and January 2008. The experiment was conducted between two buildings in oblique transmission mode. The RS error-correction code adopted the RS (15, 9) code and the cyclic shortening RS (30, 10) code. The LDPC code rate is one-half and the code length is 128; the turbo code has a one-third bit rate and the interleaving length is 64.

Table 18.4 presents the system error rate before and after error correction on foggy, sunny, and cloudy days. Because of the low system error rate on sunny and cloudy days, no error rate was found after error correction. The bit-error rate measurement results of some rainy days are shown in Table 18.5, and the partial measurement results of a system in snowy weather are shown in Table 18.6.

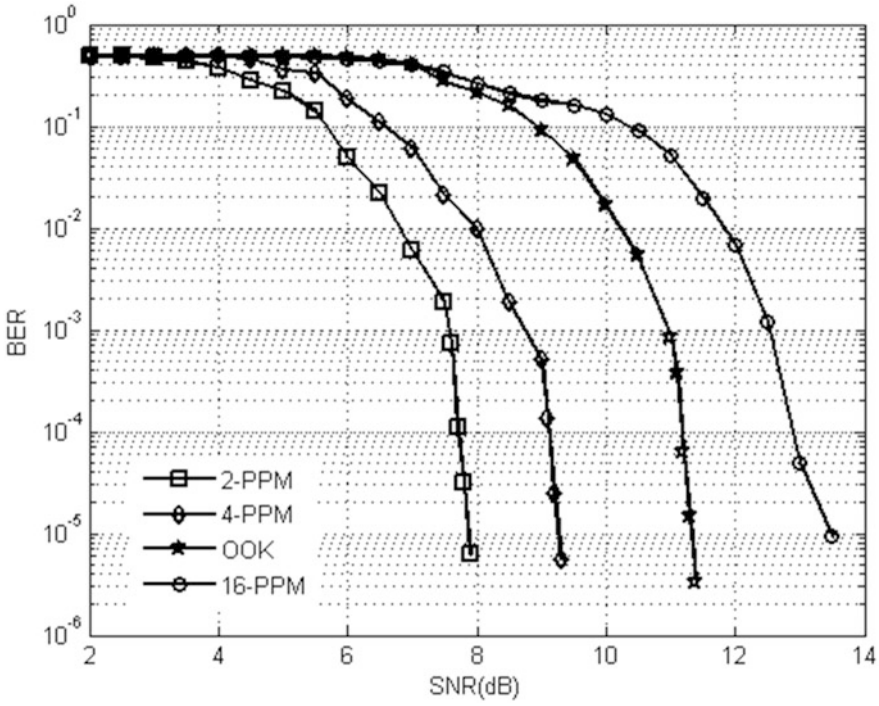

Fig. 18.19 Effect of the PPM timeslot number on the bit-error rate [47]

The experimental results show that, although the error-correction code can partially improve the performance of the optical wireless communication system, it is generally less effective in foggy and snowy weather, which leads to a significant increase in the error rate in snowy and foggy weather. In bad weather, the bit-error rate can reach 10^{-3} or even 10^{-2}. Most errors can be improved by using error-correction coding, e.g., 10^{-5}.

The error rate of turbo code and RS (30, 10) after error correction was below 10^{-5}. The bit-error rate was approximately 10^{-4} in light rain. After error correction using RS (15, 9) and the LDPC code, it was maintained at 10^{-6}. The average bit-error rate on sunny and cloudy days was 10^{-7}, but after error correction, the bit-error rate was better than 10^{-9} [50].

RS Codes

Figures 18.23 and 18.24 show the changes in the error rate before and after error correction using the two RS codes measured under different weather conditions. It can be seen from the figures that under light and moderate rain, the error rate of

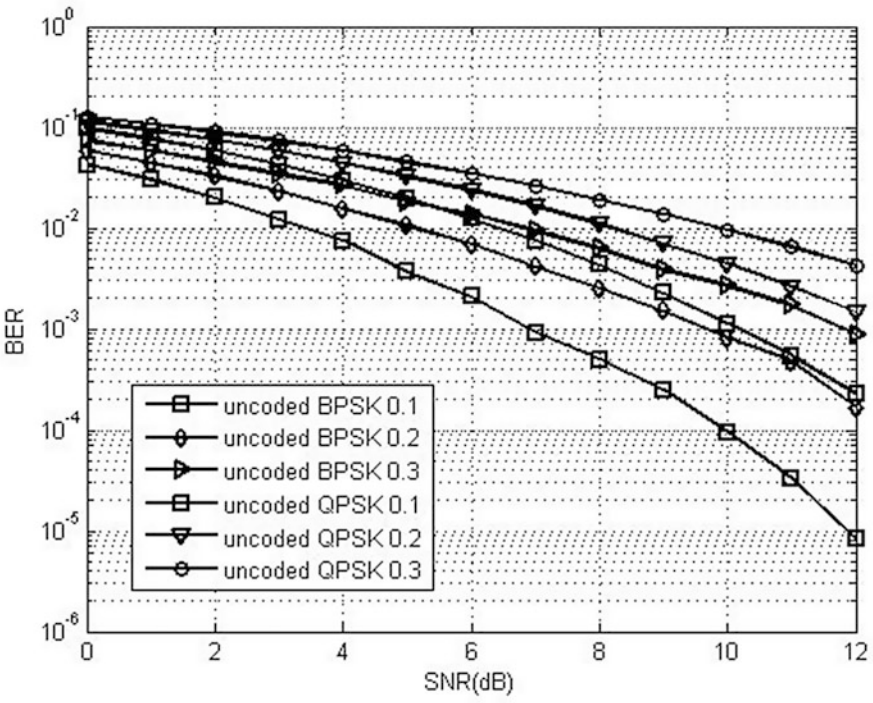

Fig. 18.20 Bit-error rate of an uncoded subcarrier system [42]

the RS (15, 9) code was significantly improved, from 10^{-4} to approximately 10^{-6}. However, for a high bit-error rate, the improvement was poor. In light to heavy rain, the error rate of the RS (30, 10) coding was reduced from 10^{-4} to 10^{-7}. Therefore, it can generally be used in rainy weather. In rough weather conditions, the bit-error rate of the system is generally between 10^{-3} and 10^{-2}. After error correction, the bit-error rate was effectively reduced and remained between 10^{-6} and 10^{-5} [50].

Turbo Codes

To further verify the improvement of the turbo code on the bit-error rate of optical wireless communication systems [51], we experimentally measured the bit-error rate in moderate rain, heavy rain, and rainstorm weather, and the results are shown in Fig. 18.25.

From Fig. 18.25, it can be seen that the turbo code improves the system, with a bit-error rate of about 10^{-4}; however, its correction ability is average for the system, with a bit-error rate of about 10^{-3}. Turbo codes are applicable to moderate rainfall and misty weather [50].

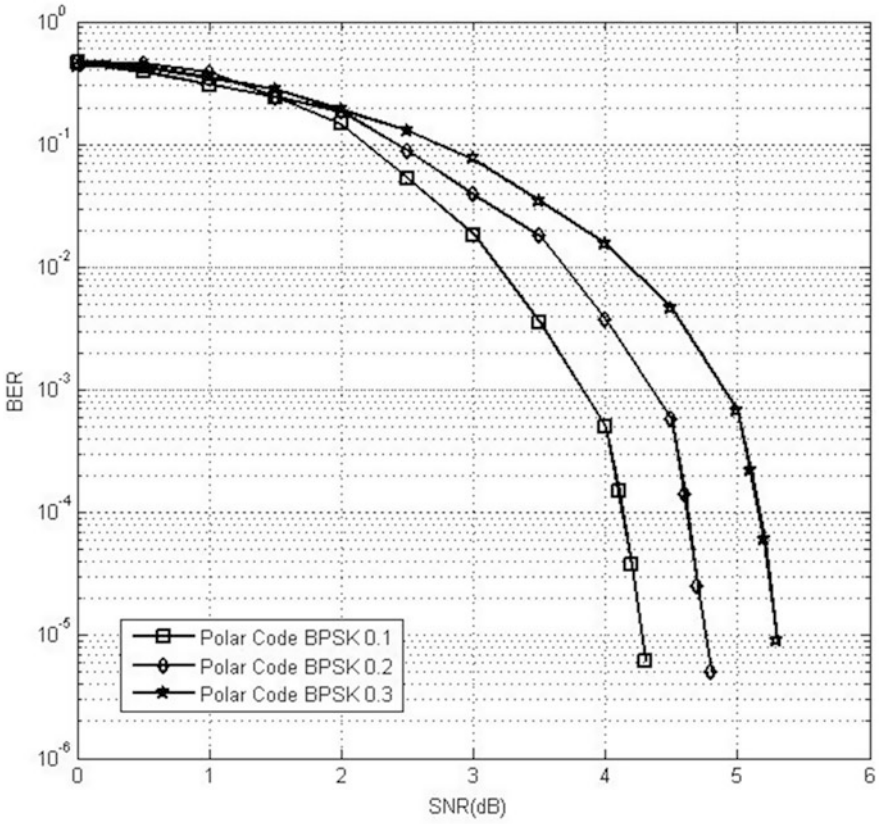

Fig. 18.21 Bit-error rate of the BPSK subcarrier system [47]

LDPC Codes

An LDPC code with a code length of 128 and code rate of 0.5 was adopted, and the measurement results are shown in Fig. 18.26 [50].

As shown in Fig. 18.26, when the error rate was between 10^{-4} and 10^{-3} under light and moderate rain conditions, the error rate after error correction was between 10^{-6} and 10^{-5}. In the case of a rainstorm, the error rate was between 10^{-3} and 10^{-2}, and the system error rate after error correction was still greater than 10^{-5}. LDPC coding is suitable for cases with a low bit-error rate. The system bit-error rate does not obviously improve in bad weather conditions [50].

Summary

This chapter systematically summarized the application of error-correction control coding in the field of optical wireless communication and introduced the work of Xi'an University of Technology in related fields [52], including the simulated and

Number of decoding errors	12	0	18
Demodulation error rate	0.0119	0.0000977	0.0106
Decoding error rate	0.00234	0	0.00261

experimental error-correction performance of RS codes, turbo codes, LDPC codes, and polarization codes under different modulation modes. These systems showed excellent performance in simulations and experimental measurements and effectively reduced the bit-error rate of optical wireless communication systems [51]. The development trends of error-correction coding in optical wireless communication systems can be summarized as follows [51, 52].

Table 18.4 Bit-error rate under foggy weather conditions [50]

Time	Weather	Visibility	Uncorrected BER	Error-correction method			
				LDPC	Turbo	RS (15, 9)	RS (30, 10)
2006-10-26	Dense fog	200 m	3.41×10^{-3}	5.74×10^{-5}		5.10×10^{-5}	
2006-10-27	Dense fog	200 m	3.35×10^{-3}	2.96×10^{-5}		2.72×10^{-5}	
2007-12-8	Rain and fog	150 m	7.3×10^{-3}		5.4×10^{-5}		3.2×10^{-5}
2007-12-9	Dense fog	200 m	2.6×10^{-3}	4.4×10^{-5}			7.6×10^{-6}
2007-12-10	Dense fog	400 m	1.3×10^{-3}			8.4×10^{-6}	2.5×10^{-6}
2006.9–2006-10	Sunny	15 km	$\leq10^{-7}$	$<10^{-9}$			
	Overcast	3 km	$\leq10^{-6}$	$<10^{-9}$			

Table 18.5 Bit-error rate under rainy weather conditions [50]

Time	Weather	Rainfall (mm)	Uncorrected BER	Error-correction method			
				LDPC	Turbo	RS (15, 9)	RS (30, 10)
2007-4-23	Light rain	0.2	2.2×10^{-4}	3.3×10^{-6}		3.0×10^{-6}	
2007-7-4	Heavy rain	21.8	6.8×10^{-4}		4.0×10^{-6}		2.4×10^{-6}
2007-6-17	Moderate rain	31.5	3.5×10^{-4}		8.4×10^{-7}		6.8×10^{-7}
2007-7-5	Rainstorm	34.1	2.4×10^{-3}	4.2×10^{-5}	8.8×10^{-6}	3.2×10^{-5}

2007-7-4	Moderate to heavy rain	21.8	6.2×10^{-4}	8.4×10^{-6}		8.2×10^{-6}	
2007-5-23	Moderate rain	12.2	4.5×10^{-4}	5.4×10^{-6}	7.3×10^{-6}		

Table 18.6 Bit-error rate under snowy weather conditions [50]

Time	Weather	Snowfall (mm)	Uncorrected BER	Error-correction method			
				LDPC	Turbo	RS (15, 9)	RS (30, 10)
2007-1-3	Moderate snow	1.9	4.6×10^{-3}	7.8×10^{-5}		8.4×10^{-5}	
2008-1-11	Moderate snow	2.5	3.4×10^{-4}		2.1×10^{-6}		1.2×10^{-6}
2008-1-12	Major snow	5.6	6.2×10^{-3}	8.8×10^{-5}			3.6×10^{-5}
2008-1-18	Major snow	6.4	5.5×10^{-3}		3.8×10^{-5}		2.5×10^{-5}
2008-1-20	Major snow	6.0	4.4×10^{-3}		1.6×10^{-5}		9.2×10^{-6}
2008-1-21	Major snow	4.8	4.5×10^{-3}	6.3×10^{-5}		5.7×10^{-5}	

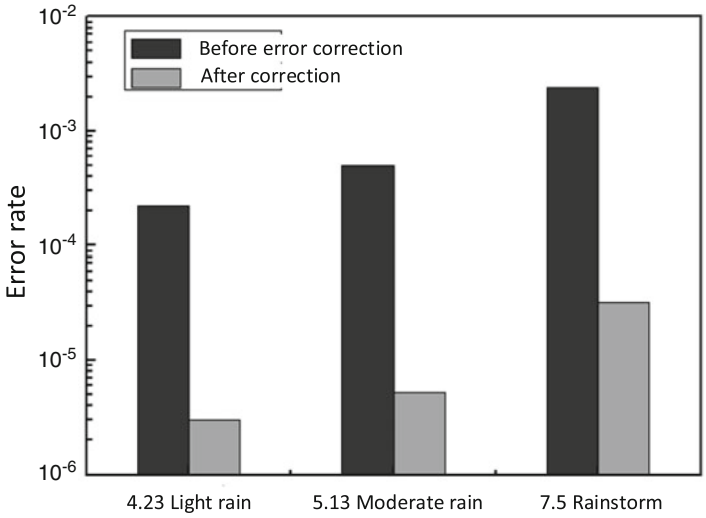

Fig. 18.23 RS (15, 9) code [50]

1. Adopt forward error correction to simplify system implementations. The effectiveness of a communication system is important; however, accurately transmitting information to the receiver is also an objective. Forward error correction can effectively improve the signal credibility and can correct error codes in the transmission process. Simplifying the system implementation is an important prerequisite for applying error-correction coding technology to optical wireless communication systems.
2. Explore codes that approach the Shannon limit and reduce the complexity of coding and decoding. To address the problems of coding efficiency and

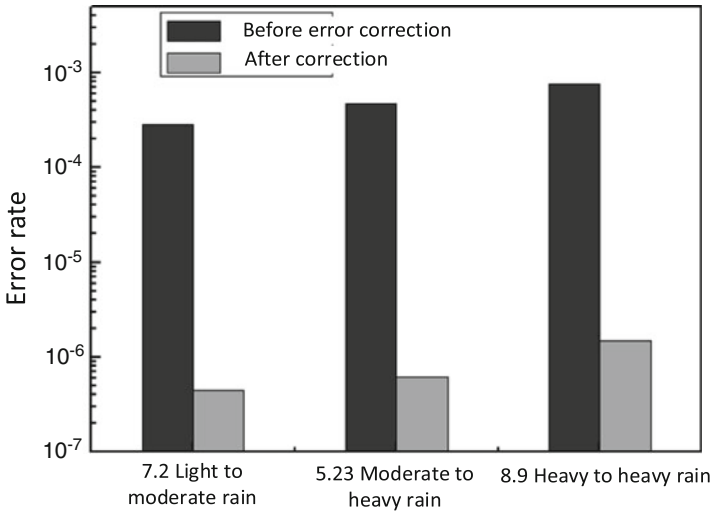

Fig. 18.24 RS (30, 10) code [50]

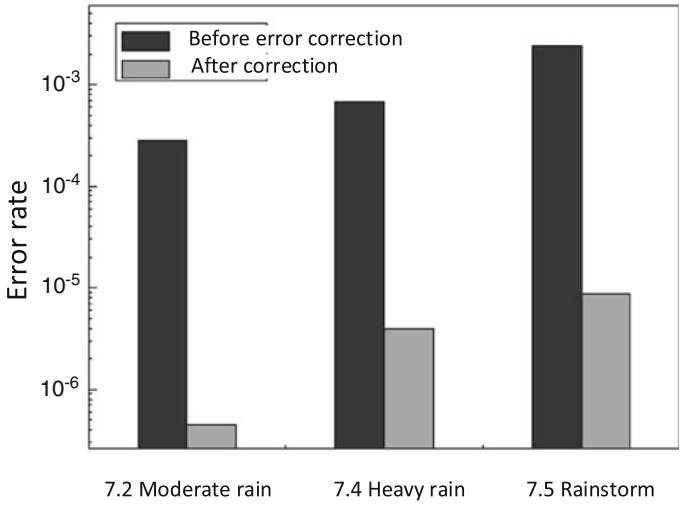

Fig. 18.25 Histogram of turbo code performance improvement [45]

computational complexity in current error-correction coding methods, a code with better performance was proposed. Polarization codes appeared late, and other error-correction codes have been applied to various fields. Therefore, problems have been encountered in practical applications. Polarization codes should be actively applied to practical communication systems. The coding and decoding algorithms of error-correction codes should be constantly optimized, their computational complexity reduced, and their implementation simplified.

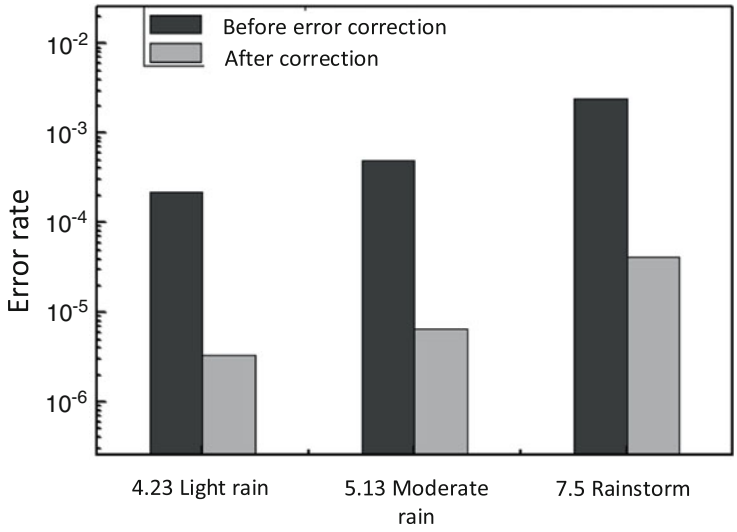

Fig. 18.26 Histogram of LDPC code performance improvement [44]

3. Make a reasonable compromise between coding complexity and error-correction performance and select the source modulation method that best matches the error-correction coding to improve efficiency.
4. Explore the effect of various error-correction codes on the performance of an actual experimental optical wireless system and make improvements.

Currently, research on the application of error-correction codes to optical wireless communication systems is mostly based on theoretical calculations and simulations. Although the performance of different error-correction codes applied to the system can be obtained, a combination of theory and practice can find the most suitable coding method for different communication systems, help reduce the deterioration of system performance encountered in the process of practical applications, and effectively improve the ability of optical wireless communication systems to suppress atmospheric turbulence.

The development of error-correction coding supports the suppression of the impact of turbulent channels on communication system performance and helps the promotion and application of optical wireless communication technology.

Abstract

The work of the previous authors is reproduced and summarized, including the authors' own views. Multiple-Input Multiple-Output (MIMO) technology makes full use of spatial resources and can suppress the influence of channel characteristics on optical-signal transmission. The evolution and development of optical wireless MIMO at home and abroad are described in detail from the perspective of improving the channel capacity and spectrum utilization of optical wireless communication. The principle of space–time coding is introduced. Finally, the key technical problems faced by optical wireless MIMO systems are summarized.

Introduction

In recent years, interest has increased in using multiple-input multiple-output (MIMO) technology and its associated space–time coding techniques, through multicarrier modulation technology, smart antennas, and adaptive coding, to improve spectrum utilization [1–4]. MIMO utilizes spatial resources to increase the capacity and spectrum utilization of optical wireless systems [5–11].

Research Status of Optical MIMO Technology

Foreign Development Status

Optical wireless communication has been extensively studied since 1960 [5–9]. Institutions engaged in optical wireless communication research include the European Space Agency (ESA), United States Optical Communications Telescope Laboratory (CTL) [10–14], Japanese National Space Development Agency (NASDA) [15–19], and the United States National Aeronautics and Space Administration (NASA).

In 1980, high-bit-rate satellite communication experiments were conducted at the MIT Lincoln Laboratory [20–24]. In 1985, the United States Air Force conducted half-duplex optical-link communications between a ground station and the laser intersatellite transmission experiment (LITE) system [25–30]. Astro Terra developed a full-duplex optical wireless communication system, and the ESA verified the relevant unit technology of satellite optical communication [31–34]. In the 1990s, with the maturing of wavelength-division multiple access (WDMA), erbium-doped fiber amplifiers (EDFA), and other technologies, optical wireless communication improved greatly in terms of channel capacity and communication distance. In 1995, Japan conducted a satellite–ground optical communication experiment.

In 1984, Divsalar et al. [35] introduced coding and modulation technologies to the optical-communication field. Later, Reed–Solomon (RS) codes [36], trellis-coded modulation (TCM) codes [37], Bose–Chaudhuri–Hocquenghem (BCH) codes [38], turbo codes [39, 40], low-density parity-check (LDPC) codes [17], interleaving technology [41], and cascaded codes [42, 43] were applied to optical wireless communication.

In 1997, Wilson et al. [44] introduced the concept of multibeam transmissions to the field of optical wireless communication. The U.S. Jet Propulsion Laboratory (JPL) conducted several experiments on multibeam transmissions [45–48]. In October 1995, the effectiveness of multibeam transmissions in suppressing the atmospheric-turbulence effect was verified jointly by the United States and Japan [49]. Kim et al. [45] conducted an atmospheric-scintillation measurement experiment.

Theoretical models for beam transmissions in atmospheric turbulence have been presented in the literature [50, 51], but their practical application is still difficult. In 1996, Ibrahim [52] studied the performance of optical wireless communication using

receiver-diversity technology. In 2000, Bell Laboratories developed its prototype system [53]. In 2002, the JPL conducted a 46.8-km multibeam optical transmission experiment [54] and, using spatial-diversity reception, conducted an outfield test [55–57].

In 2001, the JPL and the laser-communication research group of Stanford University conducted an in-depth study on diversity reception and optical-signal detection and achieved good results [58]. Haas et al. [59] proposed a space–time coding criterion for atmospheric laser communication, based on a log-normal attenuation atmospheric-channel (weak undulating turbulence) model and deduced its bit-error rate (BER) performance limit.

Coherent detection requires a very stable frequency for the receiver's local oscillation light and the transmitted light, which affects its practical application [60, 61]. Reference [62] provides the space–time coding criterion and BER performance limit, which are not suitable for optical communication systems with direct detection.

In 2002, Zhu et al. [63, 64] applied a diversity-reception technique in radio-frequency (RF) communication to optical wireless communication. In 2003, Simon et al. [65] modified and improved the Alamouti code. Alqudah et al. [66] proposed orthogonal space–time coding for indoor optical wireless channels. In 2004, Pan et al. [67] found that multibeam transmissions could effectively suppress the light-intensity fluctuations caused by atmospheric turbulence.

Wilson et al. [68] studied the BER performance of a quantized pulse-position modulation system (QPPM) with modulated MIMO optical communication. Brandt-Pearce et al. [69] analyzed the BER performance limit using PPM modulation under the same conditions. In 2005, Simon et al. [70] proposed a space–time coding scheme based on direct detection (intensity-modulation direct detection, IM/DD). In 2006, Angulta et al. [71] found that multibeam modes could achieve a higher signal-to-noise gain than single-beam transmissions. In 2007, Angulta et al. [72] analyzed the effects of the transmission distance, turbulence conditions, transmitter spacing, and receiver aperture on the performance of a communication system.

Navidpour et al. [73] derived a formula for calculating the BER when the transceiver simultaneously used diversity technology. Cao et al. [74] designed a PPM optical MIMO system. García-Zambrana analyzed the BER performance of Simon's space–time block code in strongly turbulent channels [75], and found that the space–time block code could suppress atmospheric turbulence at the cost of reduced multiplexing gain.

In 2008, Cvijetic et al. [76] derived performance bounds for optical communication links with multibeam transmit–multidetection receive. Reference [77] analyzed the interruption capacity of MIMO systems with IM/DD in Poisson fading channels, but did not consider their optical wireless communication performance with thermal-noise IM/DD modulation [74]. References [77, 78] investigated the performance of the system in different cases, but did not investigate how to achieve the maximum channel capacity for MIMO transmissions using the optimal transmission mechanism.

Safari et al. [79] studied the performance of on–off keying (OOK) modulated repetition codes and space–time codes. The BER performance of the two was very close in strong turbulence; in weak turbulence, the former outperformed the latter. Zaidi et al. [80] proposed a cross-coding scheme that combined a medium access control (MAC) layer and orthogonal space–time coding.

In 2009, Ntogari et al. [81] studied the performance of space–time coding in an indoor environment and found that space–time block codes improved the channel capacity. In 2010, Bayaki et al. [82] used two lasers and arbitrary-detector reception to obtain a closed expression of the pairwise error probability of space–time coding. García-Zambrana et al. [83] proposed a space–time trellis code and analyzed the BER performance in a strong turbulent channel.

Domestic Development Status

In 1999, the Northwest Institute of Nuclear Technology found that the light intensity of a multibeam transmission was twice as high as that of a single-beam transmission [84]. In 2003, the University of Electronic Science and Technology of China studied and verified the characteristics of multibeam transmissions to suppress the atmospheric-turbulence effect [85, 86]. In 2004, the National University of Defense Technology [87–89] studied the channel model and space–time coding of multibeam transmissions, and the Shanghai Institute of Optics and Fine Mechanics implemented a communication system based on multiple transmitters [90]. The system adopted transmitting diversity instead of receiving diversity and space–time coding.

In 2005, the Huazhong Institute of Optoelectronic Technology [91] and Yanshan University [92] studied diversity technology. Similar studies were reported by Anhui University [93] and Beihang University [94]. In 2006, Wuhan University verified the performance of optical wireless space–time coding through simulation [95]. Since 2007, the team of Professor Ke Xizheng from Xi'an University of Technology has investigated space–time coding, and in 2019, they conducted a 100-kilometer multibeam-transmission experiment. Subsequently, Huazhong University of Science and Technology [96, 97] and Changchun University of Science and Technology [98, 99] also researched space–time coding.

Optical MIMO Systems

Owing to the differences between radio-frequency communication and wireless laser communication, the theory and model of the original MIMO technology significantly differ from those of wireless laser-communication systems [14]. Optical MIMO can effectively suppress the atmospheric-turbulence effect and improve the channel capacity.

Composition of Optical MIMO Systems

An optical MIMO system is an organic fusion of coding, modulation, and diversity, as shown in Fig. 19.1.

Optical MIMO divides the source data into groups according to certain rules, and obtains multiple modulation symbols after constellation mapping. Then, the corresponding coding matrix is obtained using space–time coding. At the receiving end, the optical signal is converted into the corresponding electrical signal. After decoding, it is converted into a multichannel sub-stream to improve the channel capacity and antifading ability of the system [100].

Classification of Optical MIMO Technologies

Diversity Technology

Diversity is a basic technology for suppressing fading in wireless communication systems [14]. It suppresses channel fading and improves the system reliability [101]. Diversity technology receives multiple signal sequences from many different channels and its fading usually shows some independence. Spatial diversity [14] is realized using multiple antennas, and its performance is better than that of time and frequency diversity.

The anti-jamming ability of receiving diversity is limited, and must be supplemented by other anti-jamming methods [102]. Time diversity [14] combines time interweaving with channel coding; it has a limited effect on slow fading, but is very effective for fast fading. Time diversity contains a large number of redundant signals caused by error-correcting codes in the signals at the receiving end [102]. In spatial diversity [14], multiple antennas are staggered at a certain distance in space such that the signals received by each antenna are not correlated [103].

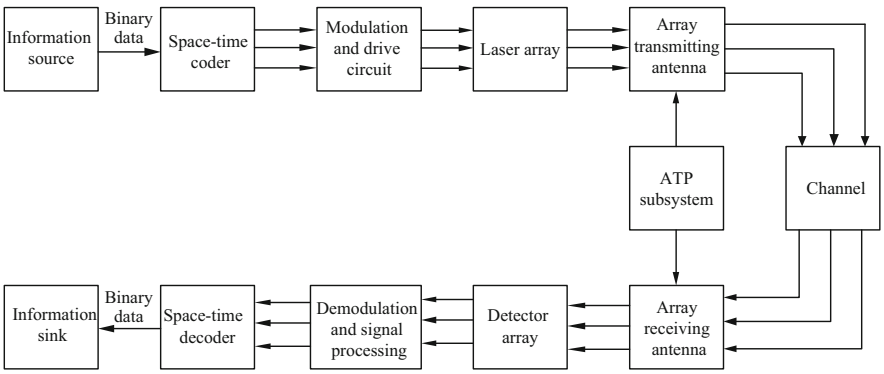

Fig. 19.1 Composition of an optical MIMO communication system

Diversity Combining Technology

Introducing diversity technology into optical wireless communication can effectively suppress the fading caused by atmospheric turbulence [104]. Diversity technology can multiplex the same signal to prevent all signals from being simultaneously affected by atmospheric fading [105].

Equal-Gain Combining-Receiving Diversity

As shown in Fig. 19.2, assuming that the number of receiving antennas is $N \geq 2$, the total receiving aperture area of the N receiving antennas is SR, the aperture area of each receiving antenna is SR/N, and it is an equal-gain combination. It is assumed that the receiving aperture area is equal to that of a nondiversity single-input single-output (SISO) system.

Equal-Gain Combining of Transmit and Receive Diversity

As shown in Fig. 19.3, we assume that the number of transmitting antennas $M \geq 2$, number of receiving antennas $N \geq 2$, area of each transmitting aperture is AT/M, transmitting power is $1/M$ of the transmitting power of a single-ended receiving system without diversity, and the area of each receiving antenna is AR/N.

Reference [106] proves that the single-transmit receive diversity in Fig. 19.2 is equivalent in effect to the spatial diversity in Fig. 19.3, which uses $M \times N$ receiving antennas, and the power gain is the same.

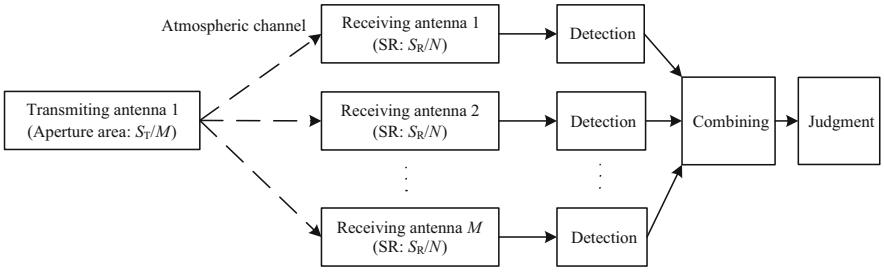

Fig. 19.2 Equal-gain combining-receiving diversity block diagram [105]

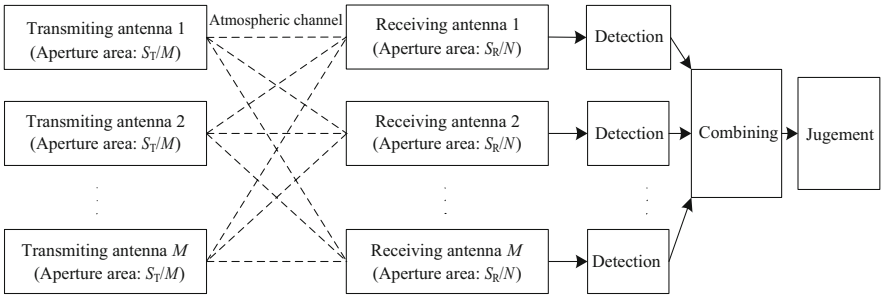

Fig. 19.3 Equal-gain combining transmit and receive diversity block diagram [105]

Spatial Multiplexing Technology in MIMO Systems

A schematic diagram of spatial multiplexing is shown in Fig. 19.4. Various layered space–time codes use spatial multiplexing to improve the channel capacity. The main receiver-side decoding algorithms for spatial multiplexing include the zero-forcing algorithm (ZF), minimum mean-squared-error algorithm (MMSE), and maximum-likelihood algorithm (ML) [107].

Spatial multiplexing means each sub-stream is sent from a different antenna, which is similar to diversity transmission, except that the full ergodic capacity can be obtained on the independent and identically distributed Rayleigh channels [108]. However, it cannot provide the same diversity gain as MIMO diversity and requires a reasonable compromise between rate and reliability. The essence of MIMO systems is the compromise between the system error probability and the system data-transmission rate [14]. Increasing the spatial-diversity gain results in a lower spatial multiplexing gain.

The Bell Laboratories layered space–time (BLAST) algorithm [14] is divided into the diagonal BLAST (D-BLAST) and vertical BLAST (V-BLAST) algorithms. V-BLAST encodes, maps, and interleaves M bit streams, and then transmits them independently to M antennas, which maximize diversity; all information streams are detected independently [109–112].

D-BLAST is basically the same as V-BLAST in terms of coding and modulation methods and sequences, except that the signal is divided into different signal blocks after processing. These signal blocks are assigned to different antennas for simultaneous transmission; thus, the effect of the entire signal transmission is not significantly affected when the transmission is not too ideal on one line. However, the system complexity correspondingly increases [113, 114]. BLAST can make full use of scarce spectrum resources; however, it is less feasible for downlinks because the number of transmitting antennas must be less than or equal to the number of receiving antennas. Moreover, because all antennas transmit different signals, the information in each link is unique, and when a link is broken, the signal integrity is not guaranteed [115, 116].

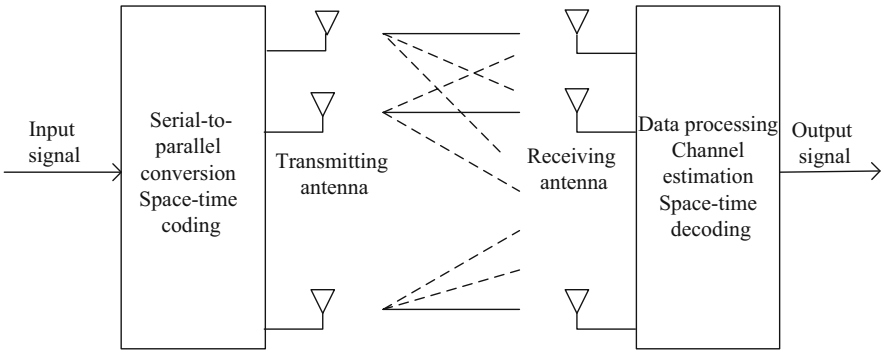

Fig. 19.4 Spatial multiplexing diagram

Evolution from SISO to MIMO Channels

The SISO wireless channel model is the basis for all derivative channels and rarely involves the study of spatial characteristics. The key point that distinguishes the MIMO channel model from SISO is the spatial characteristics of the wireless channel [117]. The vector model of the MIMO system is derived according to the spatial characteristics, and based on the SISO-channel vector model [118].

The SISO wireless channel system is a single transmitting and receiving antenna-communication system; its channel impulse response is

$$h(t,\tau) = \sum_{i=1}^{L} \alpha(t,\tau) e^{j\varphi_i(t,\tau)} \delta[\tau - \tau_i(t)], \tag{19.1}$$

where $\varphi(t, \tau)$ denotes the sum of the phase shifts of the multipath propagation channels.

The channel model of a system with one antenna at the transmitter and M receiving antennas at the receiver is called SIMO. According to reference [1], a SIMO channel can be combined as M SISO scalar channels, and its channel impulse response is

$$\boldsymbol{h}(t,\tau) = h_1(t,\tau), h_2(t,\tau), \ldots, h_M(t,\tau)^{\mathbf{T}}, \tag{19.2}$$

where $h_i(t, \tau)$ is the impulse response of the ith SISO channel. Then, the impulse response of the SIMO channel is

$$\boldsymbol{h}(t,\tau) = \sum_{i=0}^{l-1} \alpha(\theta_i,\varphi_i) \beta_i^{j(2\pi f_i \tau_i + \varphi_i)} \delta[\tau - \tau_i(t)]. \tag{19.3}$$

Here, β_i denotes the path gain of the ith subchannel, τ_i denotes the path delay of the ith subchannel, $\alpha(\theta_i, \varphi_i)$ denotes the direction of arrival of the ith subchannel, f_i denotes the Doppler frequency shift, φ_i denotes the additional phase shift, and $\alpha(\theta, \varphi)$ denotes the array steering vector. The expressions are as follows:

$$\boldsymbol{a}(\theta,\varphi) = 1, \alpha_1(\theta,\varphi), \ldots, \alpha_{M-1}(\theta,\varphi)^{\mathrm{T}}, \tag{19.4}$$

where the ith component is

$$\alpha(\theta_i,\varphi_i) = e^{j2\pi(x_i \sin\theta\cos\varphi + y_i \sin\theta\sin\varphi + z_i\cos\theta)}. \tag{19.5}$$

Comparing the SIMO and SISO channels, the scalar channel expands to the vector channel, thus showing the spatial channel characteristics of the system.

The MISO channel employs N transmit antennas and a single receive antenna. Considering the channel as a vector channel formed by the combination of N SISO scalar channels [120], the MISO channel impulse response can be obtained as

$$\boldsymbol{h}(t,\tau) = h_1(t,\tau), h_2(t,\tau), \ldots, h_N(t,\tau)^{\mathrm{T}}, \tag{19.6}$$

where $h_i(t, \tau)$ is the impulse response of the ith subchannel. The impulse response of the MISO channel is

$$\boldsymbol{h}(t,\tau) = \sum_{i=0}^{l-1} \alpha(\theta_i, \varphi_i)\beta_i^{j(2\pi f_i \tau_i + \varphi_i)} \delta\left[\tau - \tau_i(t)\right], \tag{19.7}$$

where $\alpha(\theta_i, \varphi_i)$ denotes the wave direction.

According to the formation ideas of SIMO and MISO, a MIMO channel with N and M respective transmit and receive antennas can be regarded as a matrix channel composed of $N \times M$ SISO scalar channels.

$$\boldsymbol{h}(t,\tau) = \begin{pmatrix} h_{11}(t,\tau) & h_{12}(t,\tau) & \cdots & h_{1n}(t,\tau) \\ h_{21}(t,\tau) & h_{22}(t,\tau) & \cdots & h_{2n}(t,\tau) \\ \vdots & \vdots & \ddots & \vdots \\ h_{m1}(t,\tau) & h_{m2}(t,\tau) & \cdots & h_{mn}(t,\tau) \end{pmatrix}, \tag{19.8}$$

where, $\boldsymbol{h}_{ij}(t, \tau)$ is the impulse response of the subchannel (SISO scalar channel) between the ith transmitting antenna and the jth receiving antenna.

Urgent FSO-OFDM Problems

Owing to the difference between radio-frequency orthogonal frequency-division multiplexing (RF-OFDM) and free-space optical orthogonal frequency-division multiplexing (FSO-OFDM), as well as the shortcomings of FSO technology, many problems can be solved by combining them.

1. RF-OFDM and optical OFDM have the same principle [119]; however, there are essential differences, and the RF-OFDM system model cannot simply be applied to optical OFDM.
2. Source and channel coding [120–123] can significantly improve the antiinterference capability of communication systems. Because FSO cannot directly transmit signals in a complex manner [124], the coding method needs to be improved.
3. The FSO-OFDM system has carrier, symbol, and sample synchronization. Because the OFDM signal is composed of multiple mutually orthogonal subcarrier signals, ensuring this orthogonality is crucial for OFDM systems [125 –128].
4. Because the FSO-OFDM channel is affected by the scattering of particles, such as dust, raindrops, and fog, a cyclic-protection interval is introduced in OFDM. Simple frequency-domain equalization can be used at the receiving end to eliminate multipath interference caused by atmospheric scattering. However, the exact channel frequency response on each subcarrier must be known before frequency-domain equalization.

OFDM technology has just appeared in the field of optical wireless research, and its theory and technology are imperfect. In-depth research is urgently needed to better exploit the potential of their respective technologies.

Abstract

Multiple-input multiple-output (MIMO) technology uses multiple antennas at the sending and receiving ends, which can suppress channel fading, reduce the bit-error rate, and improve spectrum utilization. It makes space a resource that can be used to improve communication performance. In wireless laser communication, space–time coding combines the advantages of space and time diversity

Optical wireless communication · Hierarchical space–time code · Space–time code · Cascade code

Introduction

Space–time coding is a signal coding technique that can obtain high data transmission rate, which is a two-dimensional processing method that combines spatial and temporal transmission signals. With the continuous development of wireless communication technology, space–time coding has been studied by more and more scholars due to its ability to use multiple antennas at both the transmitter and receiver ends to effectively counteract channel fading, reduce the bit error rate, improve spectrum utilization [1–4], and improve system performance.

Overview of Space–Time Coding Research

Rise of Optical Wireless MIMO

Since 1960, extensive research has been conducted on wireless laser communication [5–9]. International organizations engaged in optical wireless communication research mainly include the European Space Agency (ESA), Communications Research Office (CTL) of the Ministry of Posts of Japan, Japan's National Space Development Agency (NASDA), United States National Aeronautics and Space Administration (NASA), and United States Air Force.

In 1980, the Massachusetts Institute of Technology (MIT) Lincoln Laboratory conducted an end-to-end satellite-communication demonstration experiment with a high bit rate using the heterodyne method [9]. In 1985, the US Air Force developed a half-duplex optical-link connection experiment between a ground station and the laser intersatellite transmission experiment (LITE) system [7]. In the late 1980s, the European Space Agency established a laser communication link between two satellites and verified the technology of an intersatellite laser communication unit [5, 8].

In 1982, Nakai studied coding and modulation technology in an optical channel, laying the foundation for the development of optical communication [10]. Later, Reed–Solomon (RS) codes [11], trellis-coded modulation (TCM) codes [12], Bose–Chaudhuri–Hocquenghem (BCH) codes [13], turbo codes [14, 15], low-density parity-check (LDPC) codes [16], interleaving technology [17], and concatenated codes [18, 19] were applied to wireless laser communication.

However, it is still difficult to meet the requirements of large-capacity, high-speed, and long-distance communication.

In 1995, Japan successfully conducted a satellite–ground optical-link communication experiment between a ground station and Engineering Test Satellite VI (ETS-VI). In the same year, the US Strategic Missile Defense Organization developed an all-weather tracking and scanning test system. In December 1996, Thermo Trex conducted an optical communication experiment between a ground station and an aircraft. Foreign manufacturers engaged in atmospheric laser communication include Air Fiber, Light Pointe, Terabeam, and Canon.

In 1997, Lesh and Wilson et al. of Caltech first proposed the concept of multibeam emission [20] to suppress turbulence effects in atmospheric laser transmissions and effectively compensate atmospheric channels.

Since the concept of multibeam emission was proposed, the MIT Lincoln Laboratory and the Jet Propulsion Laboratory (JPL) of the United States have experimented with multibeam atmospheric transmissions and obtained numerous experimental results [21–24]. From October 1995 to May 1996, the United States and Japan successfully verified the effectiveness of multibeam emission technology in suppressing atmospheric-turbulence effects [25]. Kim et al. conducted an atmospheric-scintillation measurement experiment [21] and found that the fluctuation in the received light intensity caused by atmospheric turbulence decreased with an increase in the number of transmitted beams. A theoretical model of multibeam propagation in a turbulent atmosphere was presented in [26, 27].

In 1996, assuming that the input-signal fading of each small-aperture receiver was independent, Ibrahim [28] studied the performance of wireless laser communication using reception-diversity technology. In 2000, Bell Labs successfully developed a prototype system for atmospheric laser communication using multibeam transmission technology [29]. In 2002, the JPL conducted an optical-transmission experiment at a distance of 46.8 km using multiple beams [30].

The JPL has studied a combination of output signals and conducted field experiments [31–33]. In 2001, the JPL's Communication Engineering Research Office and Stanford University's Laser-Communication Research Group conducted in-depth research on diversity reception and optical-signal detection [34].

In the same year, Haas et al. [35] of the Massachusetts Institute of Technology proposed space–time coding criteria for atmospheric laser communication and provided their error-code performance limits. However, this theory is only suitable for heterodyne detection. Heterodyne detection requires that the frequencies of the receiver's local oscillation laser and the emission laser be very stable, and that the frequency stability must be at least 10–11 orders of magnitude, which affects the practicality of the process [36]. Reference [37] also provides space–time coding criteria and error-code performance limits; however, it remains difficult to apply this method to direct-detection atmospheric laser communication systems.

In 2002, Zhu et al. [38–41] applied the time-domain detection technology, likelihood-ratio detection theory, and diversity-reception technology in radio-frequency (RF) communication to atmospheric laser communication, and studied their effectiveness in suppressing turbulence effects. In 2003, Simon et al. improved

the traditional Alamouti code [40] and proposed a method to realize space–time coding in atmospheric laser communication using intensity modulation/direct detection (IM/DD).

In the same year, Alqudah et al. proposed orthogonal space–time coding for indoor optical wireless channels [41]. In 2004, Feng et al. [42] analyzed the light-intensity fluctuation characteristics of a satellite–ground multibeam transmission link, and Wilson et al. analyzed the bit-error performance of MIMO optical communication using quantized pulse-position modulation (QPPM) technology [43]. Under the same conditions, Brandt-Pearce et al. [44] designed a coding scheme with equal Hamming weights using PPM modulation technology and analyzed the error-code performance limit.

In 2005, Simon et al. proposed a space–time coding scheme suitable for IM/DD [45]; however, this scheme was only applicable to on–off keying (OOK) modulation and 2-PPM modulation. In 2006, Angulta et al. [46] analyzed the space–time coding mode for communication systems using multibeam transmissions.

In 2007, Angulta et al. [47] found that the ability to reduce fluctuations in light intensity was related to the spatial correlation of the beams, transmission distance, turbulence conditions, transmitter spacing, and receiver aperture. Navidpour et al. [48] of Pennsylvania State University found that the spatial-diversity performance was seriously affected by the spatial correlation of each subchannel. In the same year, Cao et al. [49] proposed a MIMO system for atmospheric laser communication suitable for PPM modulation. In the same year, García-Zambrana analyzed the bit-error performance of the space–time block codes proposed by Simon in strong turbulence channels [50].

In 2008, Neda et al. [51] analyzed a ground optical communication link during multibeam transmissions and multiple avalanche-photodiode (APD) detection and reception. For IM/DD optical communication, reference [52] analyzed the MIMO interrupt capacity in a Poisson fading channel with thermal noise and limited transmission power. Letzepis et al. used PPM modulation to study the performance of MIMO systems in free-space optical (FSO) communication under a Gaussian mechanism [53].

Safari et al. [54] studied the performance of repetitive codes and space–time block codes using OOK modulation, while Raza et al. [55] proposed a cross-coding scheme by combining the media access control (MAC)-layer and physical-layer coding (orthogonal space–time coding), and used training sequences to estimate the channel parameters.

In 2009, Ntogari et al. [56] studied the performance of space–time coding in a scattering-rich indoor environment, in combination with IM/DD technology. In 2010, Bayaki et al. [57] introduced a closed type with the probability of pairing errors in the space–time coding of free-space optical communication, when receiving two lasers and any detector for IM/DD. In the same year, García-Zambrana et al. [58] proposed a space–time trellis code for a strong turbulence channel and analyzed its bit-error performance.

It is necessary to further study the structure, design, performance, and scope of space–time coding applications in IM/DD atmospheric laser communication.

Domestic Research on Optical Wireless MIMO

Research on multibeam transmitting and receiving technologies has been gradually conducted in China. In 1999, the Northwest Nuclear Technology Research Institute studied the transmission of a multibeam laser in the atmosphere. The results showed that the received light intensity of a multibeam transmission was twice as high as that of a single-beam transmission [59]. In 2003–2004, the University of Electronic Science and Technology of China studied the theory of multibeam transmissions and showed that multiple beams could effectively suppress the atmospheric-turbulence effect [60, 61].

In 2004, the National University of Defense Technology [62–64] studied a multibeam-transmission channel model, space–time coding, and the temperature field of multibeam light sources. The Shanghai Institute of Optics and Precision Machinery, Chinese Academy of Sciences, implemented a 155/622 Mbit/s multi-transmitter laser communication system [65].

In 2005, the Huazhong Optoelectronic Technology Research Institute [66], Yanshan University [67], and others studied diversity technology in atmospheric laser communication and analyzed the system performance. Anhui University [68], Beijing University of Aeronautics and Astronautics [69], and other organizations have published relevant reports.

In 2006, Wuhan University used quadrature amplitude modulation (QAM) to apply the space–time coding in RF communication to optical wireless communication, and verified the performance of space–time block coding through simulation experiments [70]. Since 2007, Xi'an University of Technology has investigated space–time coding technology in atmospheric laser communication and conducted optical MIMO communication experiments. Huazhong University of Science and Technology [71, 72] and Changchun University of Technology [73, 74] have also studied space diversity, time diversity, optical MIMO technology, and space–time coding in optical wireless communication.

Multi-Aperture Transmitting/Receiving Experiment

Multibeam-Emission System Composition and Experiment

Figure 20.1 shows the composition of an experimental multibeam emission system. The system consists of two parts: transmitting and receiving. In this experiment, the transmitting end uses two lasers with the same wavelength. The laser uses 532-nm green light. The receiving end uses a single aperture. The receiving lens has a 0.1-m diameter. The laser is transmitted through a Cassegrain telescope into the atmosphere.

At the receiving end, the signal is gathered into a beam of light through the receiving lens, and a detector is used for detection. The detector is connected to a data-acquisition card on a computer. The measured data were used to calculate the light-intensity variance. The experiment was conducted at 9:00 p.m. on November

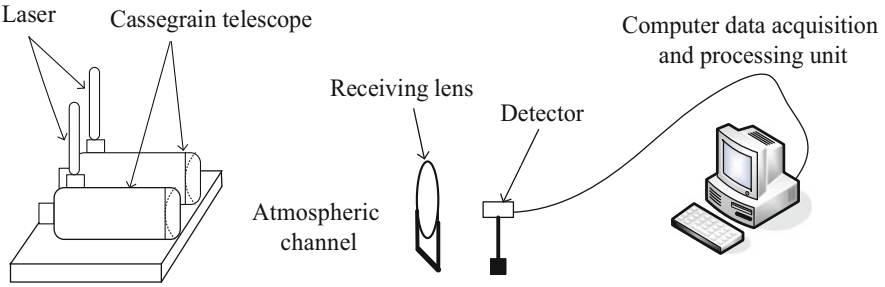

Fig. 20.1 Composition of the multibeam-emission experimental system

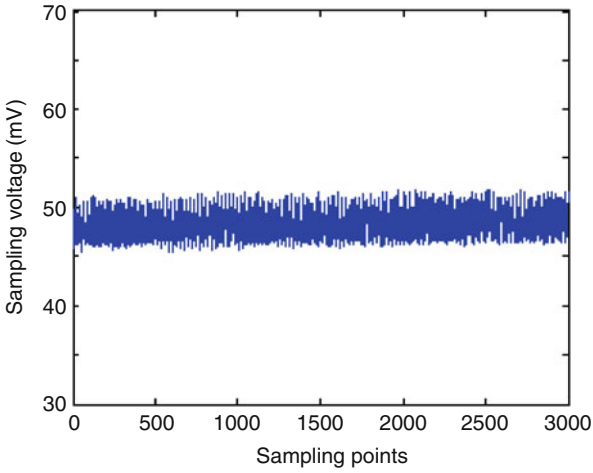

Fig. 20.2 Measured voltage values of a single transmitter and single receiver

24, 2011, between the sixth and fifth floors of Xi'an University of Technology. It was sunny and breezy during the experiment.

The light-intensity data of single-beam and dual-beam emissions were collected in the experiment to compare the performance of single-emission and multiple-emission systems. Figure 20.2 shows the sampling voltages measured when transmitting a single beam and receiving with a single aperture. The sampling frequency was set at 2 MHz. Three-thousand data points were used in the experiment. The figure shows the discrete points. It can be seen from the figure that most of the data were concentrated near 47, and a small number of data points were slightly off-center, which was caused by light-intensity flickering.

Figure 20.3 shows the sampling voltage when transmitting with two light beams and receiving with a single lens. It can be seen from the figure that, compared with a single-beam transmission, the voltage fluctuation when transmitting with two light beams is reduced and relatively stable.

According to the theoretical calculations, the variance values of the light intensity of a single transmitter with a single receiver and a double transmitter with a single

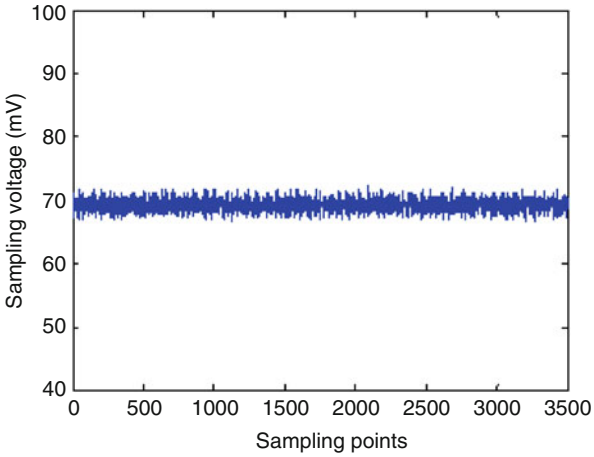

Fig. 20.3 Measured voltage values of double-beam transmitting and single-aperture receiving

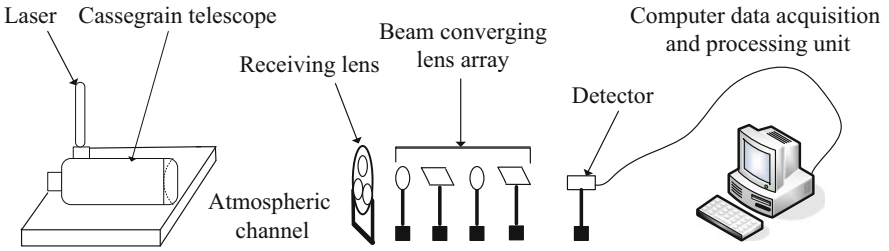
receiver were 3.4001 and 2.3800, respectively, and the variance values of the data measured in the experiment were 1.8815 and 0.8852, respectively. Theoretical and experimental measurement data show that the variance of the light intensity of the double-beam emission is smaller than that of the single-beam emission. Thus, a multibeam emission system can reduce the light-intensity fluctuation and improve the communication-system performance.

Multi-aperture Receiving-System Composition and Related Experiments

Figure 20.4 shows the structural diagram of the multi-aperture receiving system. The transmitting end is mainly composed of a Cassegrain telescope and a laser, and the receiving end is composed of a receiving lens with three apertures, beam-convergence lens array, detector, and computer data-acquisition and processing unit. The spacing between the three lenses is 0.1 m, and the diameter of the lens is 0.1 m.

When the laser beam at the transmitting end reaches the surface of the receiving lens and passes through it, three beams of light appear. It is necessary to use a lens and a reflector array that converge the light beam to combine the three beams into one beam. However, the optical path is relatively complex. The key point is to maintain the stability of the transmitting beam; otherwise, the beams are difficult to combine.

The experiment was conducted at 9:00 p.m. on October 25, 2011, when the weather was cloudy. The laser used in the experiment was a green light with a 532-nm wavelength. The data-acquisition card at the receiver had a 40-MHz sampling frequency. When the beam passed through the three-aperture receiving lens, it was received by the detector and collected using a computer. During the experiment,



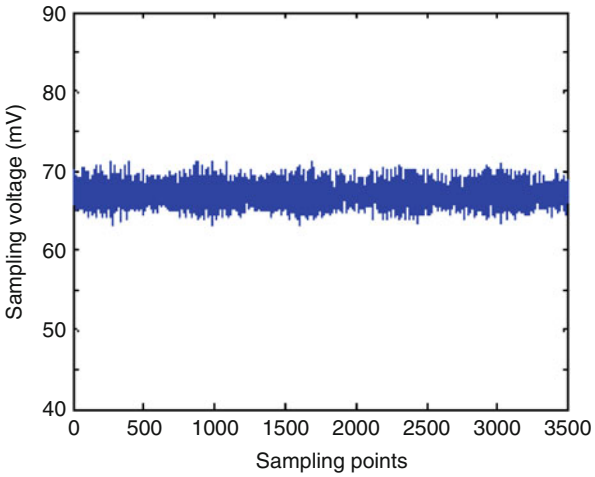


Fig. 20.4 Structural diagram of a multi-aperture receiving system

Fig. 20.5 Sampling voltage for single-aperture reception

two groups of data received by one, two, and three apertures were measured. Figures 20.5, 20.6, and 20.7 show sample voltage values when single-aperture, dual-aperture, and triple-aperture reception were adopted, respectively.

Comparing the single-, dual-, and triple-aperture reception, it can be seen that with an increase in the number of apertures, the measured data jitter decreases, and the overall signal is relatively stable. The variance was calculated based on the data measured in this experiment.

Two groups of data were calculated in each case. The measured variances of the single-aperture reception were 5.9763 and 5.717, respectively, and the theoretically calculated variance was 4.8638. The variances of the experimental data for dual-aperture reception were 2.8183 and 2.8181, respectively, and the theoretical data was 2.0372. When the triple-aperture receiver was used, the two groups of variances calculated from the experimental data were 0.1042 and 0.1050, respectively, while the variance calculated from the theoretical data was 0.5998.

In general, it can be concluded that the light-intensity variance decreases with an increase in the number of apertures, indicating that multi-aperture reception can more

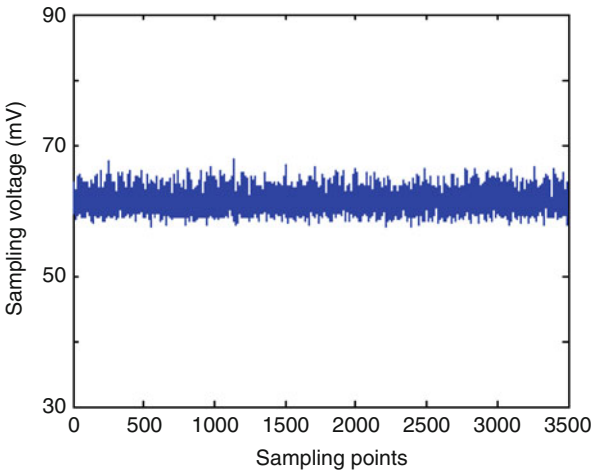

Fig. 20.6 Sampling voltage for dual-aperture reception

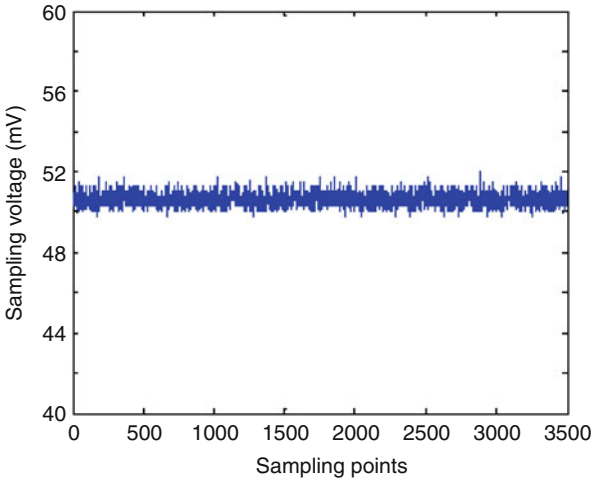

Fig. 20.7 Sampling voltage for triple-aperture reception

effectively suppress the impact of turbulence and improve the laser-transmission performance.

We conducted experiments on multibeam transmission and multi-aperture reception, and calculated the light-intensity variance of the data measured in the experiment. By comparing the light-intensity fluctuation variance of different numbers of beams when transmitting and the light-intensity variance of different numbers of receiving apertures when receiving, we can conclude that the multibeam-transmission system and multi-aperture reception system could suppress the impact of turbulence on laser transmissions more effectively than single-beam transmission and single-aperture reception systems.

Layered Space–Time Codes

Layered space–time codes (LSTCs) [1, 75] are based on the multiple-input multiple-output (MIMO) transmission mode proposed by Bell Laboratories. It is mainly based on space-division multiplexing to improve the spectral efficiency of the system. The Bell Laboratories layered space–time (BLAST) code [72] can be coded in both spatial and temporal dimensions. It decomposes the input information bitstream into several bitstreams, and independently encodes, modulates, and maps them to multiple transmission antennas.

At the receiving end, special processing technology is used to separate the signals that arrive at the receiving antenna and send them to the corresponding decoder [77]. This technology combines a one-dimensional coding method with spatial dimension transmission. Thus, the computational complexity of the decoding end only increases linearly with an increase in the number of antennas, unlike the exponential growth of the two-dimensional space–time code.

Layered space–time coding requires that the number of receiving antennas should not be less than the number of transmitting antennas, which means that multiple antennas should be installed at the receiving end. However, it is relatively difficult for RF communication systems to install multiple antennas on mobile terminals, which will undoubtedly limit the application of this technology in RF communication. Multiple receiving antennas are no longer difficult in optical wireless communication.

Layered Space–Time Coding Models

Layered space–time codes include horizontal (H-BLAST), diagonal (D-BLAST), vertical (V-BLAST), and spiral layered space–time codes (S-BLAST).

We combined the OOK and PPM intensity-modulation methods to construct a layered space–time coding scheme [78] in a optical wireless channel. The transmission model is illustrated in Fig. 20.8. The basic idea is to divide high-speed data services into several low-speed data services, which are sent to M identical channel encoders for coding. The channel coding is either block or convolutional. After channel coding, it is layered space–time coded and then transmitted by M antennas after modulation.

The receiving model is illustrated in Fig. 20.9. At the receiving end, N antennas are used for diversity reception. The layered feedback interference is eliminated by the linear decision-feedback equalizer and sent to the channel decoder after layered space–time decoding. The channel must be estimated because the channel-transmission characteristics are used in the decoding process.

The reception model of the layered space–time coding shows that the received signal at each receiving aperture is the superposition of signals from different transmitting apertures. In a layered space–time structure, multiple transmit antennas are used to achieve high data rates, and multiple receive antennas are used to cancel the interference of multiple spatial signals.

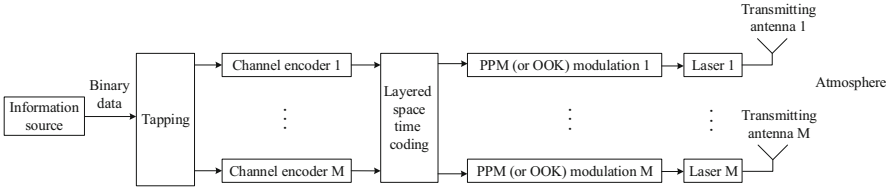

Fig. 20.8 Transmission model of layered space–time coding in atmospheric laser communication

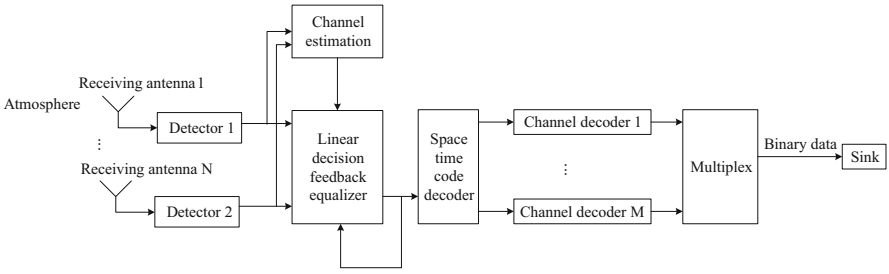

Fig. 20.9 Reception model of layered space–time coding in atmospheric laser communication

Layered Space–Time Codes

We used the horizontal-layered, spiral-layered, and diagonal-layered space–time codes as examples to analyze the performance of layered space–time codes. The simulation conditions are as follows:

1. Assuming that the total power E_s is unchanged, the value is 1 (normalized).
2. We assume that the channel characteristics and noise can be accurately estimated by the receiver.
3. The photoelectric-conversion efficiency is 0.6.
4. In weak turbulence, the atmospheric channel obeys a logarithmic normal distribution, and the scintillation index SI is 0.6. The atmospheric channel follows a gamma–gamma distribution in moderate–strong and strong turbulence; the scintillation indexes SI are 1 and 3, respectively.
5. The system adopts pulse-position modulation, taking 4-PPM modulation as an example.
6. 2×2, 2×4, 4×4, and 4×6 antennas are used as examples.

Zero-forcing (ZF) detection, minimum mean-squared error (MMSE) detection, maximum-likelihood (ML) detection, sequential interference-cancellation (SIC), and ordered sequential interference-cancellation (OSIC) algorithms were used to analyze the performance of the layered space–time codes.

Horizontal Layered Space–Time Coding

Figures 20.10 and 20.11 show the error-rate curves under the zero-forcing detection, minimum mean-squared error detection, and maximum-likelihood detection algorithms when SI = 0.6. The weak-turbulence atmospheric channel follows a lognormal distribution. The following results can be observed:

1. The detection algorithm with the best performance is the maximum-likelihood detection algorithm, followed by the minimum mean-squared error detection algorithm, and finally the zero-forcing detection algorithm. The simulation results were consistent with the theoretical analysis results.
2. The diversity gain is related to the number of detectors, as shown in Fig. 20.11.

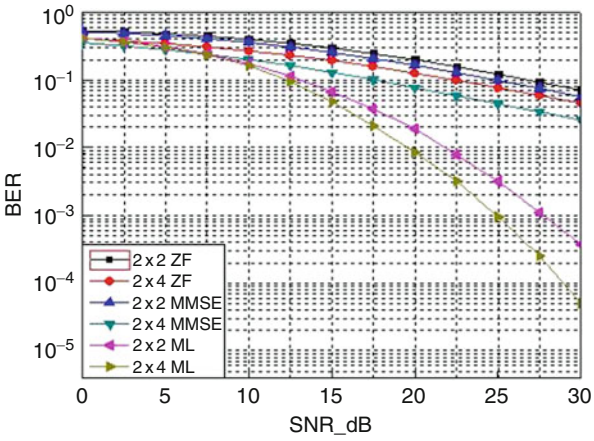

Fig. 20.10 Simulation diagram of 2 × 2 and 2 × 4 (SI = 0.6)

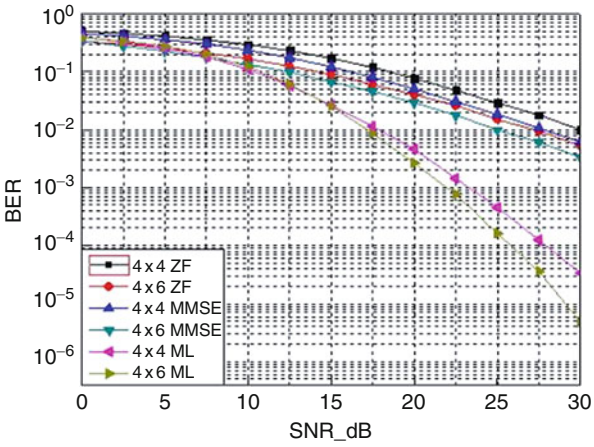

Fig. 20.11 Simulation diagram of 4 × 4 and 4 × 6 (SI = 0.6)

Figures 20.12 and 20.13 show the error-rate curves of the zero-forcing detection, minimum mean-squared error detection, and maximum-likelihood detection algorithms when SI = 1. The atmospheric channel follows a strong-turbulence gamma–gamma distribution. It can be seen that atmospheric turbulence affects the system performance to a certain extent; however, the bit-error rate (BER) characteristics, similar to those in weak turbulence, can still be obtained when the number of antennas is increased.

Figures 20.14 and 20.15 show the bit-error rate characteristics of the system under strong turbulence when SI = 3. It can be observed that the bit-error rate of the system is affected by strong turbulence in the case of two-transmitter–multiple receivers and four-transmitter–multiple receivers. However, the bit-error rate of the system with

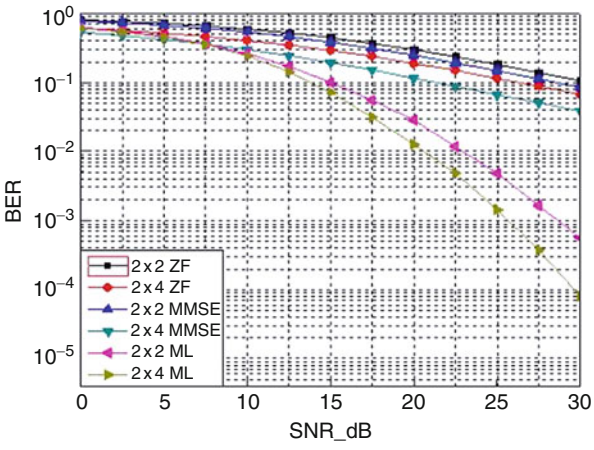

Fig. 20.12 Simulation diagram of 2 × 2 and 2 × 4 (SI = 1)

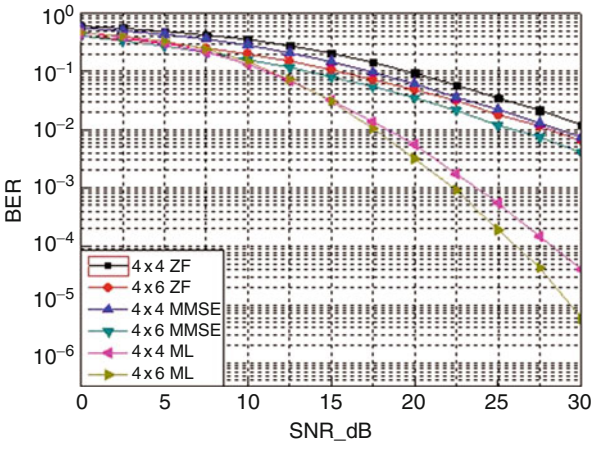

Fig. 20.13 Simulation diagram of 4 × 4 and 4 × 6 (SI = 1)

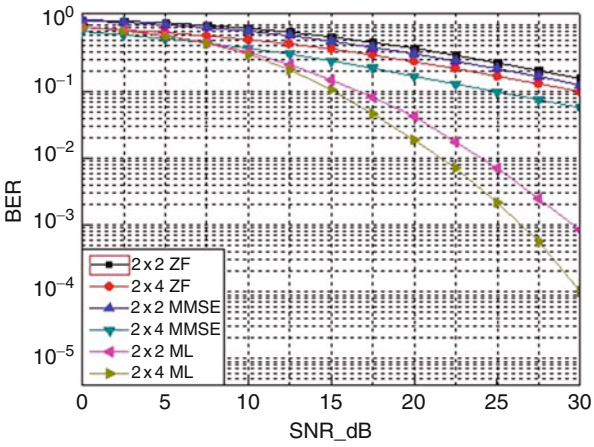

Fig. 20.14 Simulation diagram of 2×2 and 2×4 (SI = 3)

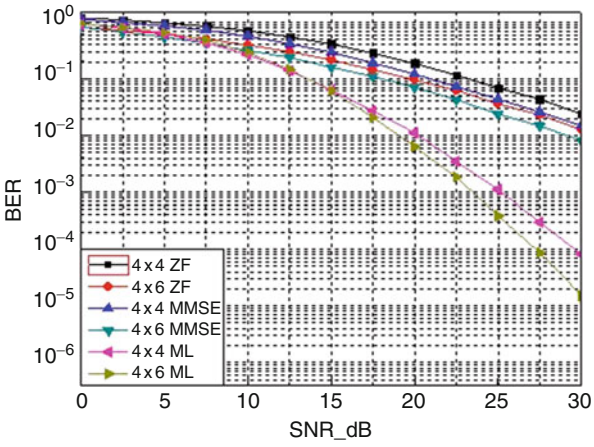

Fig. 20.15 Simulation diagram of 4×4 and 4×6 (SI = 3)

two transmitters and multiple receivers greatly increased, from nearly 10^{-6} to 10^{-4} at 30 dB, and the bit-error rate of the system with four transmitters and multiple receivers rose to 10^{-5}.

Horizontal layered space–time coding cannot effectively suppress the impact of atmospheric turbulence on the system, owing to its poor coding characteristics. Figure 20.16 compares the ZF, SIC-ZF, and OSIC-ZF detection algorithms in a horizontal layered space–time coding system. It can be seen that SIC-ZF and OSIC-ZF perform better than the ZF algorithm, which improves the performance of the horizontal layered space–time coding system to a certain extent.

Figure 20.17 compares the results of three detection algorithms, MMSE, SIC-MMSE, and OSIC-MMSE, in a horizontal layered space–time coding system.

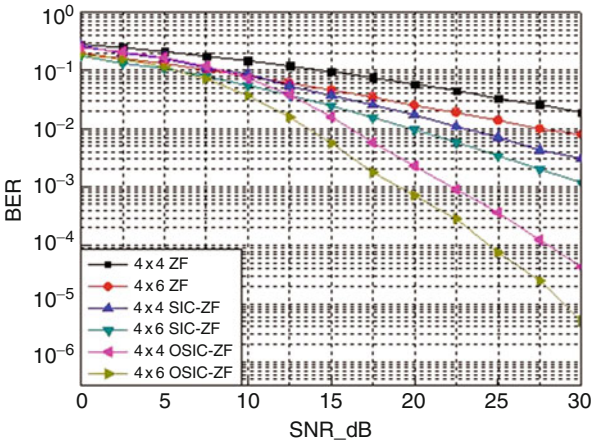

Fig. 20.16 Simulation of ZF, SIC-ZF, and OSIC-ZF algorithms

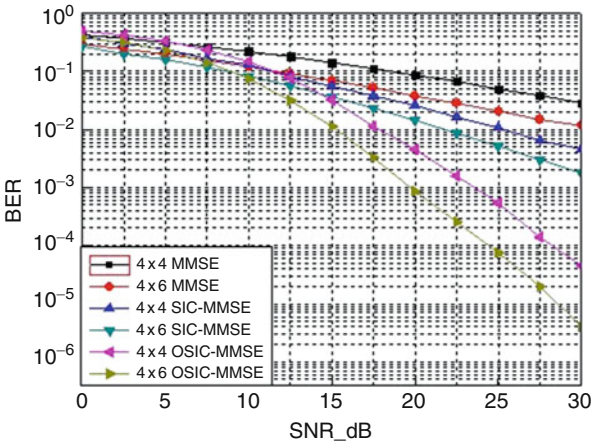

Fig. 20.17 Simulation of MMSE, SIC-MMSE, and OSIC-MMSE algorithms

It can be seen that the ordered successive interference-cancellation (OSIC) algorithm improves the performance of the MMSE detection algorithm, and the improvement extent is greater than that of the serial detection algorithm.

Diagonal Layered Space–Time Codes

Considering different receiving and transmitting antennas, noise levels, and atmospheric scintillation-factor parameters, the impact of diagonal layered space–time coding on the system bit-error rate is analyzed.

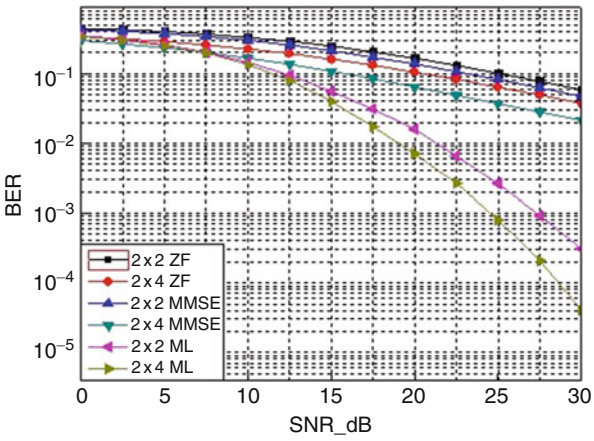

Fig. 20.18 Simulation diagram of 2 × 2 and 2 × 4 (SI = 0.6)

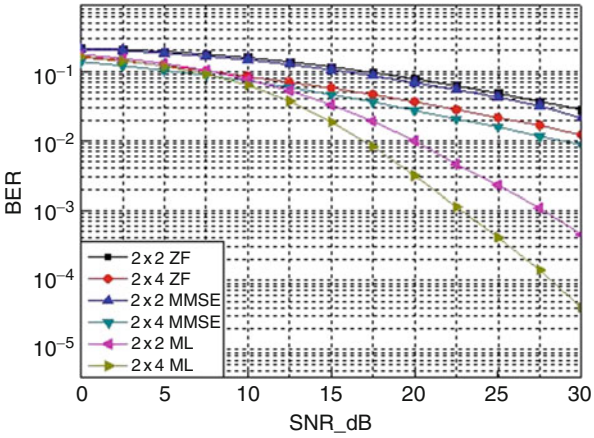

Fig. 20.19 Simulation diagram of 2 × 2 and 2 × 4 (SI = 1)

Comparing Figs. 20.18 and 20.19, when the scintillation factors SI are 0.6 and 1, respectively, in the case of two transmitters and multiple receivers, the bit-error rate of the system slightly increases in the case of medium turbulence with an increase in the scintillation factor. This indicates that the system cannot effectively suppress the impact of atmospheric turbulence in this case.

Comparing Figs. 20.20 and 20.21, in the case of four transmitters and multiple receivers, enhancing the turbulence intensity does not affect the bit-error rate of the system. Increasing the number of antennas under moderate and strong turbulence enhances the system's ability to suppress atmospheric turbulence. It can be seen that the D-BLAST system has a certain ability to suppress the scintillation effect caused by atmospheric turbulence.

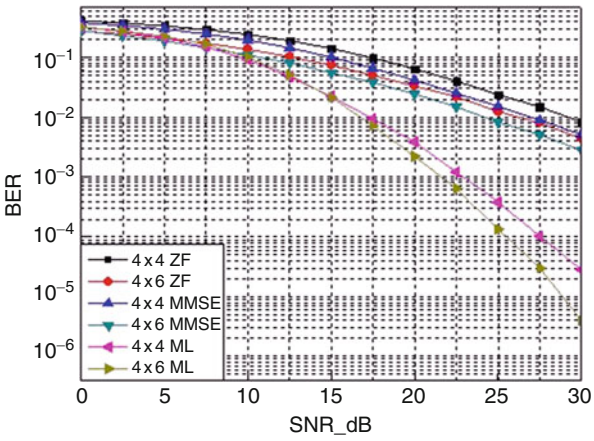

Fig. 20.20 Simulation diagram of 4 × 4 and 4 × 6 (SI = 0.6)

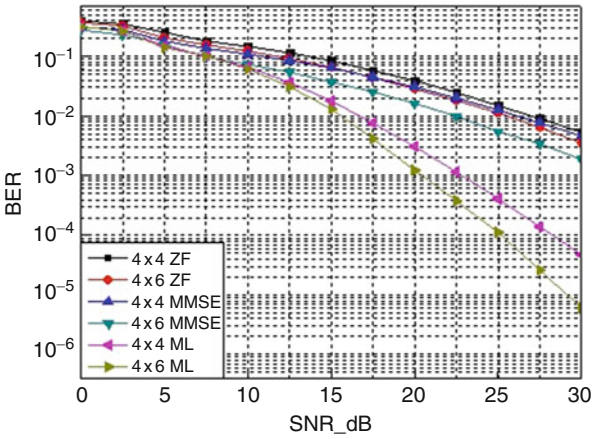

Fig. 20.21 Simulation diagram of 4 × 4 and 4 × 6 (SI = 1)

The performance of the D-BLAST coding system is also greatly affected by different detection algorithms. As shown in Fig. 20.21, when the scintillation index was SI = 1 and the signal-to-noise ratio (SNR) was approximately 30 dB, the numbers of antennas were 4 × 4 and 4 × 6. The ZF bit-error rates were 3×10^{-2} and 1×10^{-2}, respectively. The bit-error rates obtained using MMSE were 8×10^{-2} and 5×10^{-3}, respectively. The ML error rates were 1×10^{-4} and 4×10^{-6}. The performance of ML in the D-BLAST coding system was significantly better than that of MMSE and ZF.

Figures 20.22 and 20.23 show the BER and SNR curves of the system under strong turbulence and the scintillation index SI = 3. In the case of strong turbulence, the BER of the two transmitter–multiple receiver systems increased from nearly 10^{-6} to 10^{-5} at 30 dB. However, in the case of four transmitters and multiple

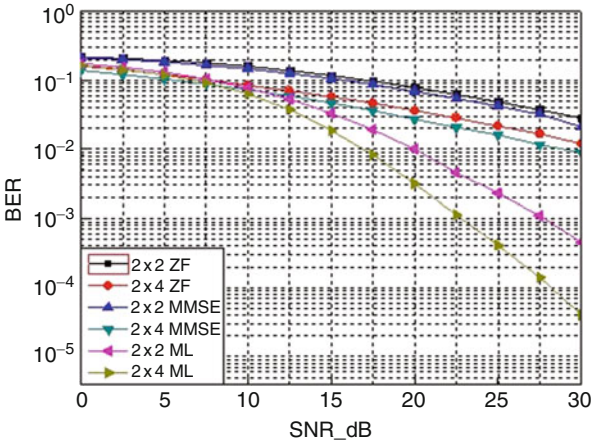

Fig. 20.22 Simulation diagram of 2 × 2 and 2 × 4 (SI = 3)

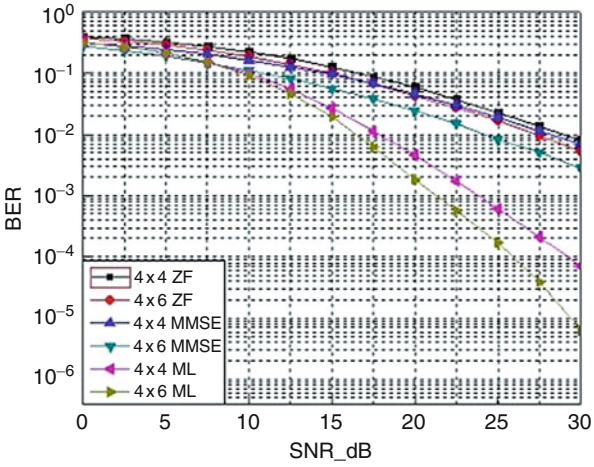

Fig. 20.23 Simulation diagram of 4 × 4 and 4 × 6 (SI = 3)

receivers, the bit-error rate of the system did not change much. Moreover, after increasing the number of antennas, the system restrained the impact of atmospheric turbulence to a certain extent.

As shown in Figs. 20.24 and 20.25, the performances of the SIC-ZF, OSIC-ZF, SIC-MMSE, and OSIC-MMSE detection algorithms were significantly better than those of ZF and MMSE, and the system's bit-error performance was significantly improved. The performance of OSIC was better than that of SIC alone. For example, when the BER is 10^{-2}, the SNR of the system using the OSIC-MMSE algorithm is about 15 dB higher than that of the system using the MMSE algorithm. The signal-to-noise ratio of the system using the SIC-MMSE algorithm improved by about 10 dB.

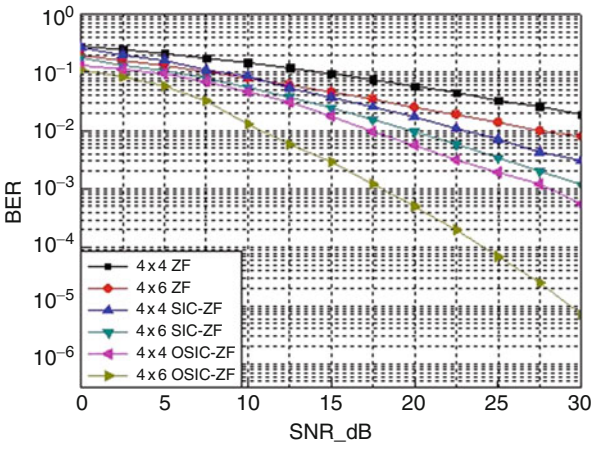

Fig. 20.24 Simulation of ZF, SIC-ZF, and OSIC-ZF

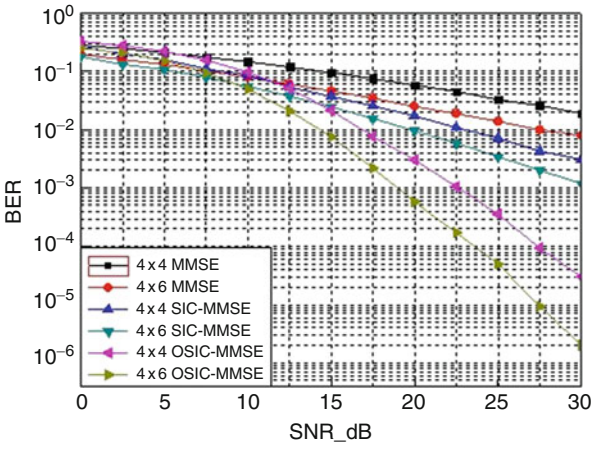

Fig. 20.25 Simulation of MMSE, SIC-MMSE, and OSIC-MMSE

Helical Layered Space–Time Coding

As shown in Fig. 20.26, when the SNR is 30 dB and the detection algorithm is ML, the bit-error rates for 2×2 and 2×4 are respectively 10^{-3} and 10^{-4}. When the signal-to-noise ratio is small, the performance gap between the ZF and MMSE systems is large, and the performance of the MMSE detection algorithm is better when the SNR is low.

As shown in Fig. 20.27, the maximum-likelihood detection algorithm was used in the T-BLAST coded system. When the SNR is 30 dB, the system's bit-error rate drops from 10^{-4} to near 10^{-6}. The performance of the maximum-likelihood detection algorithm was better than those of the MMSE and ZF detection algorithms.

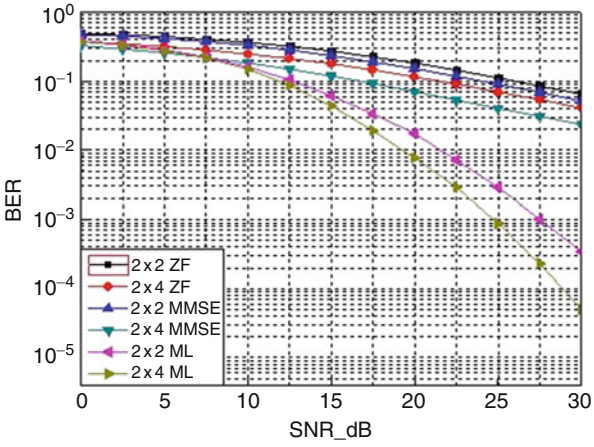

Fig. 20.26 Simulation diagram of 2×2 and 2×4 (SI = 0.6)

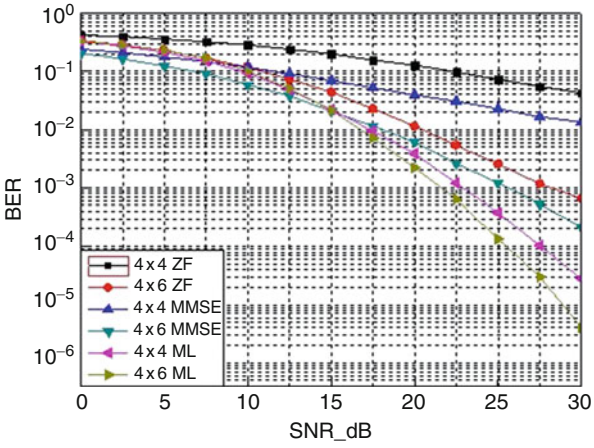

Fig. 20.27 Simulation diagram of 4×4 and 4×6 (SI = 0.6)

Comparing Figs. 20.27 and 20.28, the scintillation index SI is 0.6 and 1, respectively. To reduce the bit-error rate, the T-BLAST system must increase the number of transceiver antennas. The T-BLAST and D-BLAST FSO MIMO systems can well overcome the influence of medium and strong turbulence on the system (Fig. 20.29).

Figures 20.30 and 20.31 show the simulation curves of the bit-error rate and SNR of the system under strong turbulence. The scintillation index SI = 3 indicates that the system will be affected by strong turbulence in the atmosphere. The bit-error rate of the system with two transmitters and multiple receivers increases to a certain extent from nearly 10^{-6} to 10^{-4} at 30 dB. Increasing the number of transmitting and receiving antennas will reduce the influence of turbulence on the system performance to a certain extent.

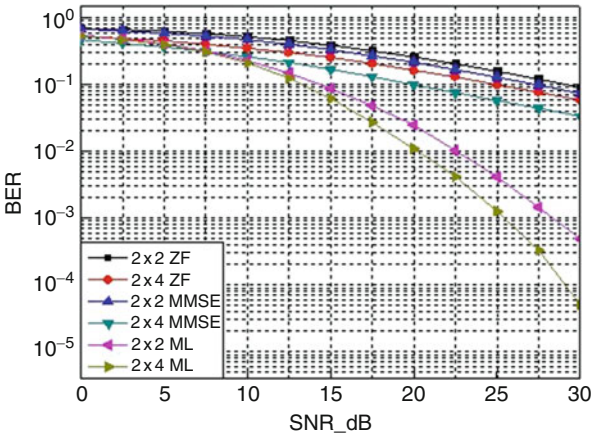

Fig. 20.28 Simulation diagram of 2×2 and 2×4 (SI = 1)

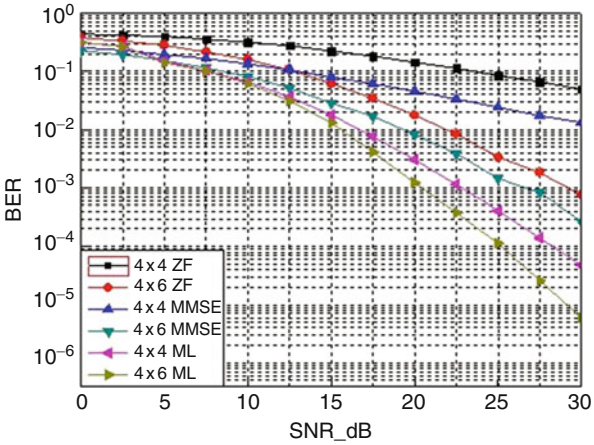

Fig. 20.29 Simulation diagram of 4×4 and 4×6 (SI = 1)

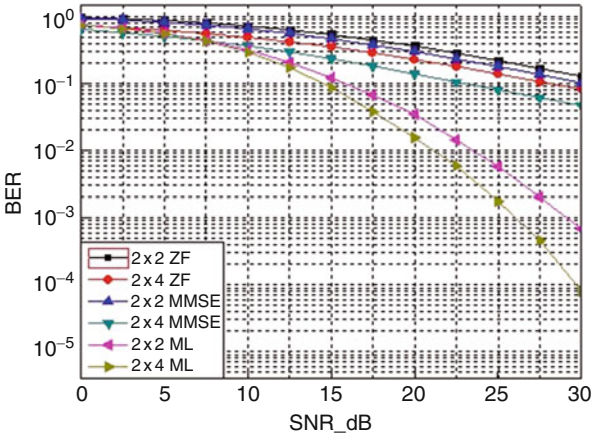

Fig. 20.30 Simulation diagram of 2×2 and 2×4 (SI = 3)

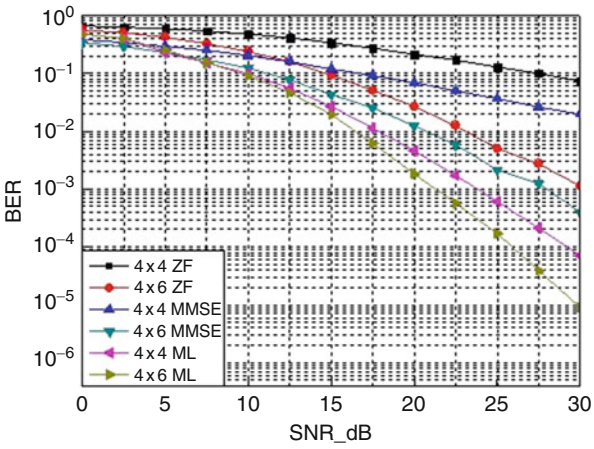

Fig. 20.31 Simulation diagram of 4×4 and 4×6 (SI = 3)

Figures 20.32 and 20.33 show the simulation results of the successive interference-cancellation (SIC) and ordered successive-interference cancellation (OSIC) algorithms using T-BLAST coding. It can be seen that the bit-error rate of the system using spiral layered space–time coding is also close to 10^{-6}. It also shows that the performance of the improved SIC-ZF, OSIC-ZF, SIC-MMSE, and OSIC-MMSE detection algorithms was significantly better than that of the ZF and MMSE detection algorithms, and their bit-error rates were close to that of the maximum-likelihood detection algorithm. The system used T-BLAST and D-BLAST to obtain a lower bit-error rate. Although the bit-error rate was not as low as that of D-BLAST, its coding complexity was much lower.

Vertical Layered Space–Time Coding

To analyze the bit-error performance of different decoding algorithms in atmospheric laser communication after using V-BLAST layered code, the Monte Carlo method was used for system simulation. The effects of the number of receiving and transmitting antennas, noise, and atmospheric flicker on the bit-error rate were analyzed. The performance of the system was compared to that of an uncoded atmospheric (1×1) laser communication system [79–82].

The simulation conditions were as follows:

1. The total transmission power E_S is unchanged and $E_S = 1$ (normalized value).
2. We assume that the channel characteristics and noise can be accurately estimated.
3. The photoelectric-conversion efficiency $\eta = 0.5$.
4. The light-intensity flicker follows a logarithmic normal distribution, and the scintillation index SI = 0.6 and 1.0.
5. The signal is fully synchronized.

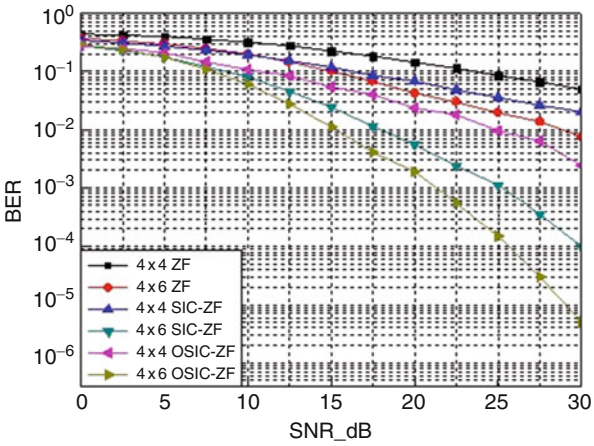

Fig. 20.32 Simulation of ZF, SIC-ZF, and OSIC-ZF

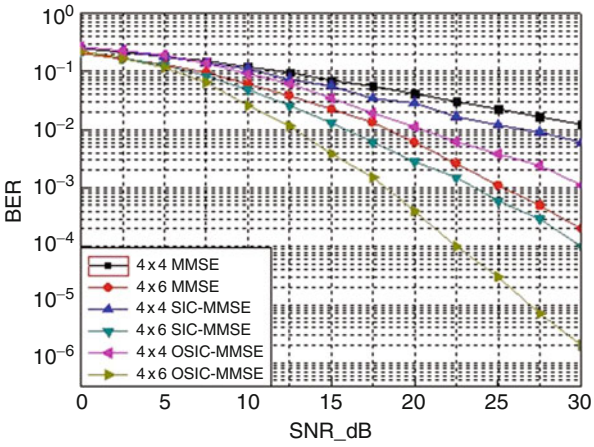

Fig. 20.33 Simulation of MMSE, SIC-MMSE, and OSIC-MMSE

6. The system adopts Q-PPM modulation, where $Q = 4$.
7. The numbers of antennas are 1×1, 1×2, 1×4, 2×2, 2×3, 4×4, and 4×5.

Performance Analysis of the Maximum-Likelihood Decoding Algorithm

Figure 20.34 shows the curves of the bit-error rate and signal-to-noise ratio of the maximum-likelihood decoding algorithm when $SI = 0.6$. The following can be seen from the figure:

1. The values are relative to 1×1. The bit-error performances of the other systems have significantly improved. This shows that layered space–-time coding can effectively overcome the scintillation effect caused by atmospheric turbulence.

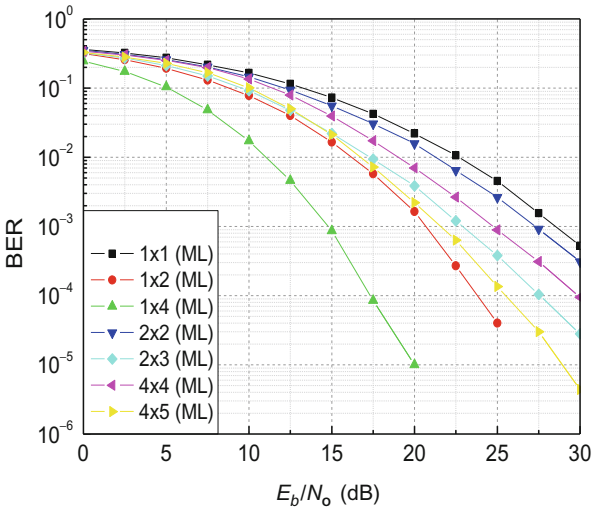

Fig. 20.34 BER and SNR curves of maximum-likelihood decoding algorithm when SI = 0.6

2. The diversity gain is related to the number of detectors. The greater the number of detectors, the greater the diversity gain, and the more obvious the improvement in the bit-error performance. When the bit-error rate is 10^{-3}, relative to the 1×1 system, the signal-to-noise ratios of the 1×2 and 1×4 systems are improved by 6 dB and 14 dB, respectively. When the bit-error rate is 10^{-3}, compared to the 2×3 and 2×2 systems, the signal-to-noise ratio is improved by approximately 4.5 dB.
3. When the number of detectors is the same, the system with more lasers exhibited poorer performance than the system with fewer lasers. This is because vertical layered space–time coding is not based on transmission diversity; thus, it does not obtain transmission-diversity gain, and more importantly, the spatial interference increases.

Figure 20.35 shows the curves of the BER and SNR of the maximum-likelihood decoding algorithm when SI = 1. It can be seen that with the increase in the scintillation index in the 1×1 system, the improvement in the signal-to-noise ratio of the same system is obviously increased. When the bit-error rate is 3×10^{-2}, relative to the 1×1 system, the signal-to-noise ratios of the 1×2 and 1×4 systems improved by approximately 8 dB and 15 dB, respectively. In particular, the 2×2, 2×3, 4×4, 4×5, and other systems have greater diversity gains. This shows that when the scintillation is stronger, the diversity-gain effect of the MIMO system is more evident, resulting in the suppression of the light-intensity fluctuation.

Performance Analysis of Linear-Decoding Algorithms

The linear-decoding algorithms include the zero-forcing and minimum mean-squared error algorithms.

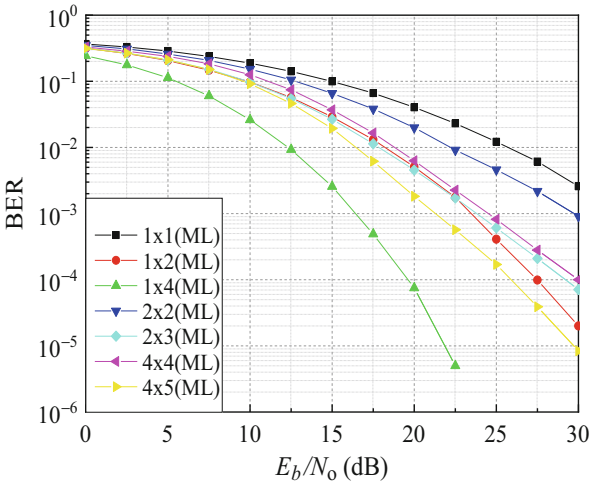

Fig. 20.35 BER and SNR curves of maximum-likelihood decoding algorithm when SI = 1.0

Zero-Forcing Decoding Algorithm

To better describe the bit-error performance of layered space–time coding using the zero-forcing decoding algorithm (ZF), we conducted a simulation analysis. The results are shown in Figs. 20.36 and 20.37. Figure 20.36 shows the error-rate and signal-to-noise ratio curves of the ZF and ML decoding algorithms when SI = 0.6.

It can be seen from the figure that with an increase in the number of lasers and detectors, the bit-error rate of the system decreases gradually with an increase in the signal-to-noise ratio, after using the ZF decoding algorithm. This shows that it is feasible to apply the ZF decoding algorithm to V-BLAST decoding in atmospheric laser communication. However, there are some differences between the rule presented here and the maximum-likelihood decoding algorithm (ML):

1. After using the ZF decoding algorithm, the bit-error performance is obviously improved, owing to the increase in the number of detectors. When the bit-error rate is 6×10^{-2}, relative to the 4×4 and 4×5 systems, the signal-to-noise ratio of the system improves by 7.5 dB. Relative to the 2×2 and 2×3 systems, the signal-to-noise ratio of the system is improved by about 12.5 dB.
2. This is because an increase in the number of detectors is equivalent to an increase in the receiving aperture, indicating that the system can effectively overcome the scintillation effect caused by atmospheric turbulence.
3. After using the ZF decoding algorithm, the BERs of the 4×4 and 4×5 systems are worse than those of the 2×2 and 2×3 systems. This is due to the increase in spatial interference between signals after multiplexing technology is adopted at the transmitter.

Figure 20.37 shows the BER and SNR curves of the ZF and ML decoding algorithms when SI = 1.0. It can be observed from the figure that the law reflected

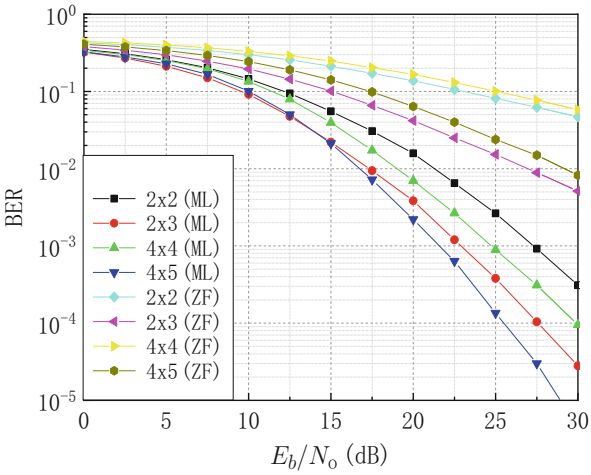

Fig. 20.36 BER curves of ZF and ML decoding algorithms at SI = 0.6

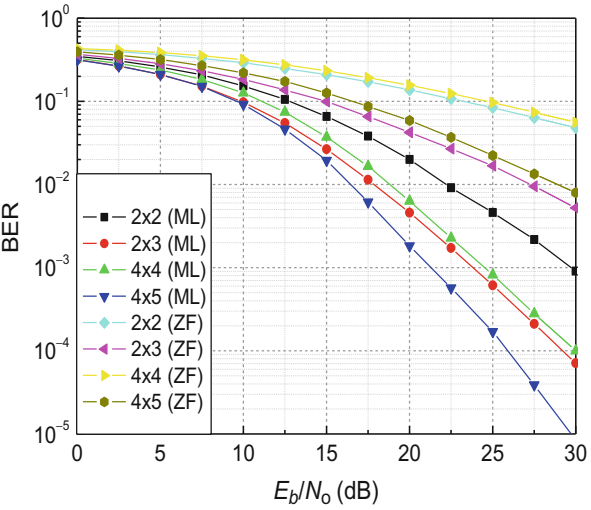

Fig. 20.37 BER curves of ZF and ML decoding algorithms when SI = 1.0

at this time is the same as that in Fig. 20.36; however, the differences are only 2 × 2 and 4 × 4, and 2 × 3 and 4 × 5, respectively. The performance gap between these systems was significantly reduced. This again shows that when the flicker is stronger, the diversity-gain effect of the MIMO system is more evident.

Minimum Mean-Squared Error Decoding Algorithm

Figure 20.38 shows the error-rate curves of the MMSE and ML decoding algorithms when the scintillation index is 0.6. It can be seen from the figure that with an increase in the number of lasers and detectors, the bit-error rate of the system decreases

gradually with an increase in the signal-to-noise ratio after using the MMSE decoding algorithm.

Figure 20.39 shows the BER and SNR curves of the MMSE and ML decoding algorithms when SI = 1.0. The rule reflected in this figure is very similar to that in Fig. 20.53; however, the improvement in the system bit-error rate is different. The improvement in the system bit-error rate is especially greater in the case of a strong scintillation, compared to a classic single-input single-output (SISO) system, when the minimum mean-squared error decoding algorithm is adopted at 2 × 2 and 4 × 4.

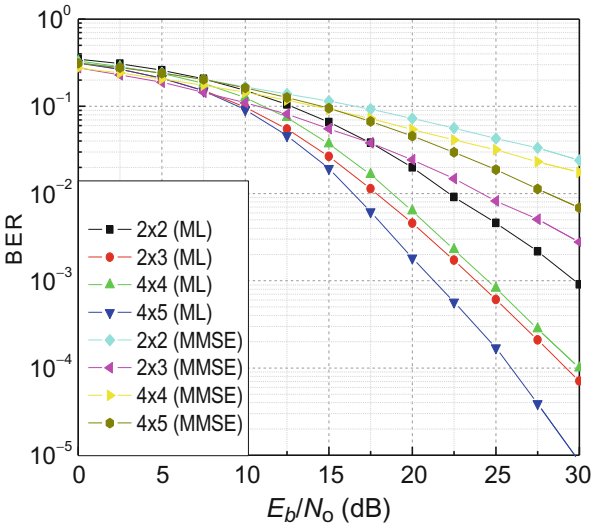

Fig. 20.38 BER and SNR curves of MMSE and ML decoding algorithms when SI = 1.0

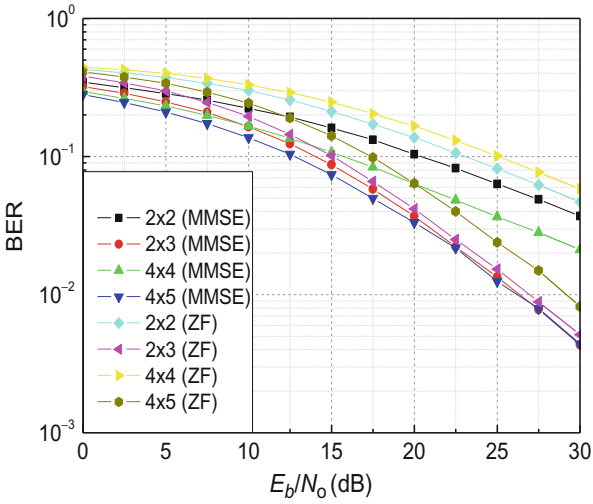

Fig. 20.39 Comparison of ZF and MMSE decoding algorithms when SI = 0.6

The BER characteristics of the different decoding algorithms under different turbulence conditions were compared, and the decoding complexity was analyzed. The results show that the performance of the diagonal layered space–time code is the best of the three codes, followed by the spiral-layered code and horizontal layered space–time code. The bit-error rate of the diagonal layered space–time code does not change significantly when the turbulence is enhanced. The largest change is in the horizontal layered space–time code, which also shows that the diagonal layered space–time coding system can suppress the influence of strong atmospheric turbulence on the system.

Whether in weak or strong turbulence, when the number of transmitting and receiving antennas increases gradually, the best performance of the three-layered space–time codes is the diagonal layered space–time code, followed by the spiral layered space–time code, and finally, the horizontal layered space–time code. The horizontal layered space–time code is not coded in the spatial domain; therefore, its performance is poor. Compared with diagonal layered space–time coding, spiral layered space–time coding has the advantages of lower coding complexity and no redundancy, which makes better use of space and time.

Although the performance of diagonal layered space–time coding is optimal and makes full use of the resources in the space and time domains, because it has $n\ (n-1)/2$ redundancy, the coding increases the redundancy and obtains higher coding performance. Cascaded layered space–time coding is also a direction for space–time code development.

Space–Time Codes

Space–time block codes and space–time trellis codes are based on transmit diversity. To further improve the performance of space–time codes and suppress atmospheric-turbulence effects, we studied differential space–time codes. In this section, we introduce our work on orthogonal space–time codes, space–time trellis codes, hybrid space–time codes, differential space–time codes, and unitary space–time codes [80, 83–87].

Orthogonal Space–Time Coding

The earliest space–time coding (STC) structure was proposed by Alamouti [88], and it has attracted extensive attention. The original form of the space–time block code [89] was also proposed by Alamouti. Trokh extended the two-antenna transmission-diversity scheme proposed by Alamouti [90] to any number of transmit antennas to obtain a full-diversity gain and simple decoding. Simon and Vilnrotter et al. improved the classic Alamouti code [89] and proposed an orthogonal space–time coding scheme suitable for IM/DD optical communication.

Traditional Alamouti codes include negative and complex signals; however, complex conjugations and negative numbers cannot be represented by “on” and “off.” Because optical wireless communication generally adopts intensity modulation, the

traditional Alamouti code [89] has been improved and a space–time coding method suitable for an IM/DD atmospheric turbulence channel has been proposed.

We combined space–time coding with modulation technology, and used the relationship between binary bits (i.e., the complementary relationship between binary bits "0" and "1") to construct the bit-complement orthogonal space–time block code (BCOSTBC), which first performs a bit complement before Q-PPM modulation. When the total power E_s of the system is constant and the channel parameters are known, the Monte Carlo method is used to simulate the bit-error performance of 1×1, 1×2, 2×1, and 2×2. The simulation parameters are $\eta = 0.5$ and $R = 1$. The simulation results are shown in Figs. 20.40, 20.41, 20.42, and 20.43.

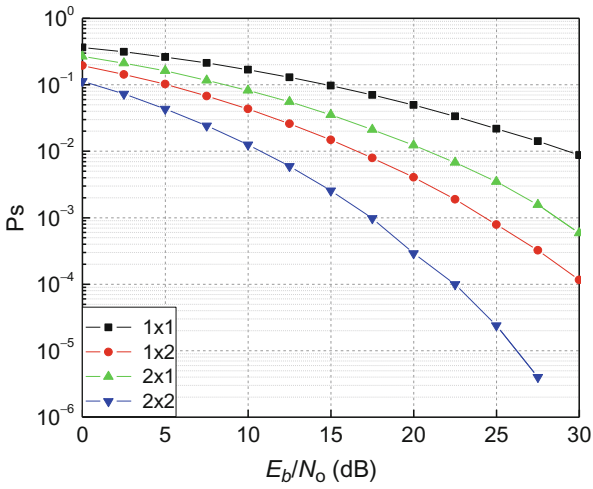

Fig. 20.40 SI = 0.6, word-error rate of BCOSTBC code with 4-PPM

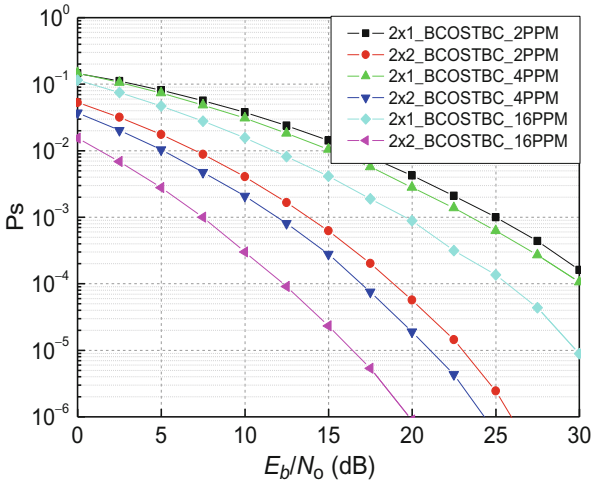

Fig. 20.41 SI = 1.0, word-error rate of BCOSTBC code with different modulation modes

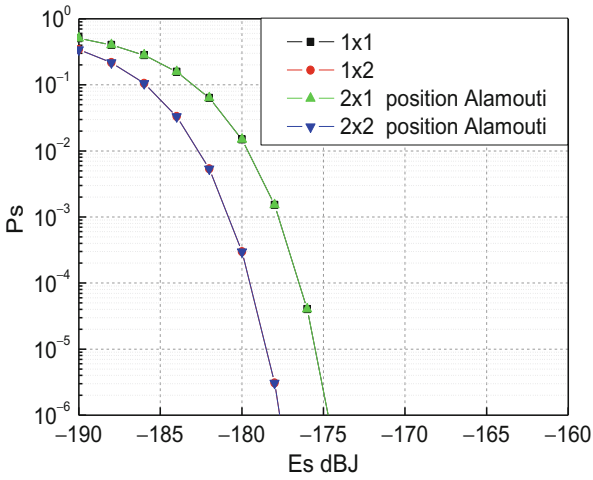

Fig. 20.42 Bit-error rate without background radiation and fading

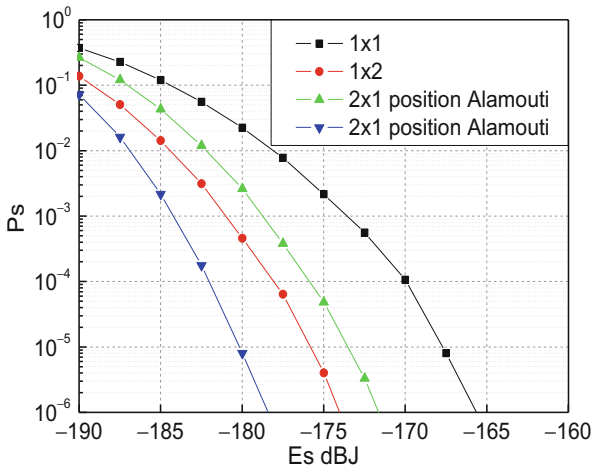

Fig. 20.43 Bit-error rate with fading but without background radiation

Figure 20.40 shows the bit-error rate of the BCOSTBC code modulated by 4-PPM when SI = 0.6. As shown in Fig. 20.40, the error-code performance of the system is significantly better after BCOSTBC coding. When $P_s = 10^{-2}$, relative to 1×1, the BCOSTBC code is adopted after 2×1 and 2×2. Then, the bit-error performance of the system is improved by approximately 8 dB and 18 dB, respectively.

Figure 20.41 shows the error rate of the BCOSTBC code for different modulation modes when SI = 0.6. As shown in Fig. 20.41, under different modulation modes, the error rate of the system decreases with an increase in the signal-to-noise ratio. Moreover, in the same system, the word-error rate of the system decreases with an increase in Q.

Different pulse positions were used to represent the complex conjugate and negative symbols. For example, when $Q = 4$, x [1 0 0 0], x * [0 0 0 1], −x * [0 0 1 0], and −x [0 1 0 0]; the encoding matrix is converted into a real matrix represented by the pulse position. Thus, it can be transmitted using IM/DD-type optical communication.

The Monte Carlo method was used to simulate the bit-error performance of 1 × 1, 1 × 2, 2 × 1, and 2 × 2. While the total power E_s of the system remains unchanged, the simulation parameters are SI = 0.6, wavelength $\lambda = 1550$ nm, $\eta = 0.5$, and $Q = 4$.

Figure 20.42 shows the bit-error performance without background radiation or fading. The following can be seen from Fig. 20.42:

1. The system's bit-error performance in 2 × 2 and 1 × 2 is obviously better than that in 1 × 1. When $P_s = 10^{-6}$, relative to 1 × 1, the bit-error performance of the 2 × 2 and 1 × 2 systems was approximately improved. This shows that increasing the number of detectors is equivalent to increasing the receiving aperture, which is conducive to improving the system performance.
2. The error-rate curves of the 1 × 1 and 2 × 1 systems coincide. This indicates that the bit-error performance of the system does not improve with an increase in the number of lasers when the total power remains unchanged.

Figure 20.43 shows the bit-error performance when there is no background radiation or fading, assuming the scintillation index SI = 0.6. The following can be seen from Fig. 20.43:

1. When the number of lasers remains unchanged, increasing the number of detectors is conducive to improving the bit-error performance of the system.
2. When the number of lasers increases, the bit-error performance of the system does not improve. This is because, when the total power is constant, increasing the number of lasers M means that the power of each laser will be reduced to $1/M$, and the background radiation introduced with each character will be M times that of the system.

Space–Time Trellis Coding

In 1998, Tarokh, Seshadri, and Calderbank [91] proposed the space–time trellis code (STTC) after jointly designing error-control coding, modulation, transmit, and receive diversity technologies. The STTC design criteria were based on flat slow-fading and fast-fading channel assumptions.

We analyzed the change of the bit-error rate with the SNR when two transmitting antennas were used with different numbers of receiving antennas. The simulation conditions were as follows:

1. The channel characteristics and noise at the receiving end can be accurately estimated.

2. The photoelectric-conversion efficiency is set to 0.8, and the scintillation index SI is set to 0.7 and 0.9. (The SI generally ranges from 0.4 to 1.)
3. We assume that the transmitted signals of each antenna arrive at the receiving antenna synchronously and simultaneously.
4. Four-way PPM was adopted for system modulation.
5. When analyzing the bit-error rate, the antenna numbers are 2×2, 2×3, and 2×4.
6. The coding coefficient $g1 = [0\ 2;\ 2\ 0]$; $g2 = [0\ 1;\ 1\ 0]$.

The BER curves for different receiving antennas and scintillation indexes are shown in Figs. 20.44 and 20.45. It can be seen from Figs. 20.45 and 20.46 that with the increase in the number of receiving antennas, the bit-error rate performance is

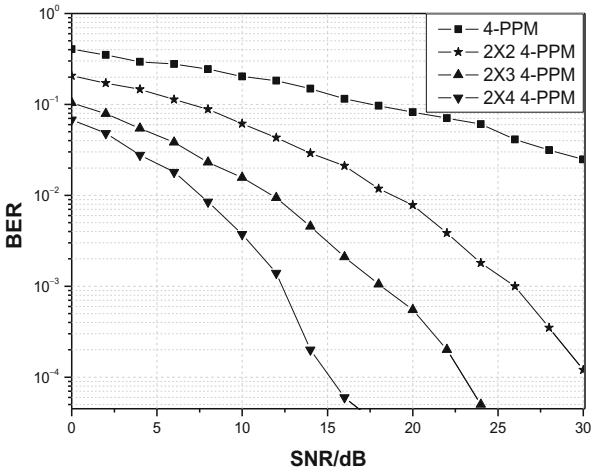

Fig. 20.44 BER and SNR curves when SI = 0.7

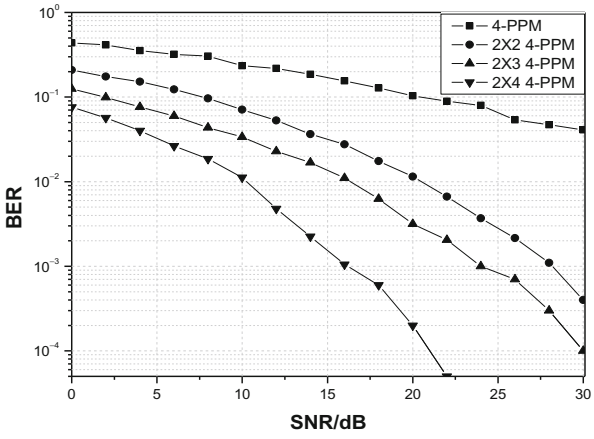

Fig. 20.45 BER and SNR curves when SI = 0.9

significantly improved. Moreover, the STTC 4-PPM system achieves a better BER performance than 4-PPM modulation under the same noise condition. Comparing Figs. 20.45 and 20.47, it can be seen that when SI = 0.9 and SNR = 20 dB with a system ratio of 2 × 3, the bit-error rate of the system is an order of magnitude higher.

In a optical wireless STTC system with three lasers, the influence of the number of receiving antennas under three transmitting antennas on the bit-error rate with the change in the SNR is analyzed. The simulation conditions are as follows:

1. The photoelectric conversion efficiency is set to 0.8, and the scintillation index SI is set to 0.7.
2. We assume that the transmitted signals from each antenna arrive at the receiving antenna synchronously and simultaneously.
3. Four-way PPM is adopted for system modulation.

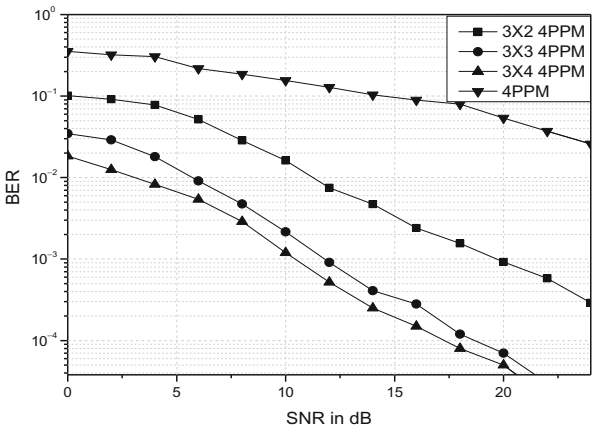

Fig. 20.46 BER and SNR curves when SI = 0.7

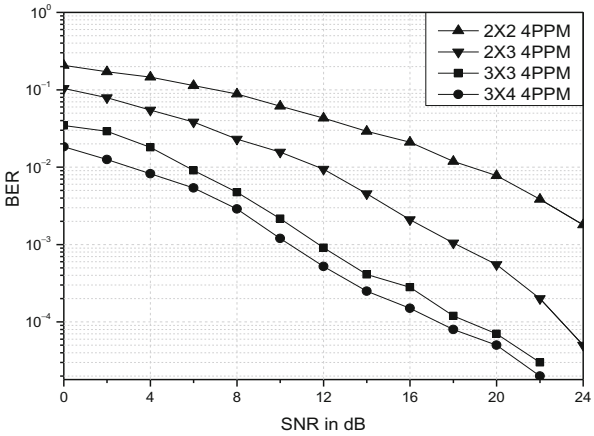

Fig. 20.47 Comparison of BER between a three-antenna system and two-antenna system when SI = 0.7

4. When analyzing the bit-error rate, the number of antennas is 3×2, 3×3, and 3×4.
5. $g1 = [0\ 2\ 2;\ 1\ 2\ 3]$ and $g2 = [2\ 3\ 3;\ 2\ 0\ 2]$.

As shown in Fig. 20.45, the three-antenna system has the same advantages as the two-antenna system. In Fig. 20.46, a direct comparison is made between the two transmitting-antenna system and the three transmitting-antenna system. It can be seen that when the number of receiving antennas is three and SNR = 20 dB, the 3×3 system ratio is improved by two orders of magnitude. The BER decreases with an increase in the number of transmitting antennas.

Differential Space–Time Coding

In 2000, Tarokh and Jafarkhani proposed a two-antenna differential space–time block code based on an orthogonal design [92], which was an improvement on the Alamouti orthogonal space–time block code [93]. Compared to the traditional two antenna space–time block code (Alamouti code), this scheme has a 3-dB performance loss [93] and quadrature phase shift keying (QPSK) modulation has a problem with signal expansion. Tarokh and Jafarkhani generalized the results in [94] such that they could be applied to multiple transmission antennas [94].

In 2000, Hochwald and Hughes successively proposed differential unitary space–time modulation [95] and differential space–time modulation [96]. Differential unitary space–time modulation introduced a type of diagonal matrix, and the symbols on the diagonal of the matrix are phase-shift keying (PSK)-modulated signals. In addition, they proposed a differential space–time modulation scheme for multiple transmit antennas, based on group codes [96].

We define the received energy of each symbol of each detector as $E_S = (\eta I_S)^2 T_S$, when there is no turbulence, where $T_S = T/Q$ is the time-slot length, Q is the modulation order, and T is the character period. It is assumed that the total power of the system is normalized to $E_s = 1.0$.

According to Taylor's frozen turbulent-atmosphere theory, the channel coefficients are assumed to remain unchanged in two adjacent transmission-code matrices. The channel-fading coefficient remains unchanged in two consecutive transmission-matrix blocks; that is, the channel is a slow-fading channel. The BER of the system was simulated using the Monte Carlo method: 1×1, 2×2, 2×3, 4×1, 4×2, 4×3, and 4×4. $\eta = 0.5$. A binary pulse-position modulation (BPPM) mode is adopted, i.e., $Q = 2$, and the binary data stream has one million sample values.

Figure 20.48 shows the bit-error rate of differential space–time coding of two transmitting antennas when the scintillation index SI is 0.4, using the lognormal distribution model. It can be observed from the figure that the system performance gradually improves with an increase in the number of receiving apertures. When the bit-error rate is 10^{-3}, the two receiving apertures are reduced by about 8.5 dB compared with a single one. Compared with one and two receiving apertures, the

bit-error rates of three receiving apertures are reduced by about 13 dB and 4.5 dB, respectively.

Figure 20.49 shows the bit-error rate of the differential space–time coding of two transmitting antennas when the turbulence model adopts the gamma–gamma distribution model and a scintillation index SI = 0.9. It can be seen that when the bit-error rate is 10^{-2}, the two receiving apertures are reduced by about 10 dB compared with a single one. Moreover, the three receiving apertures are reduced by about 15 dB and 5 dB compared with one and two receiving apertures, respectively.

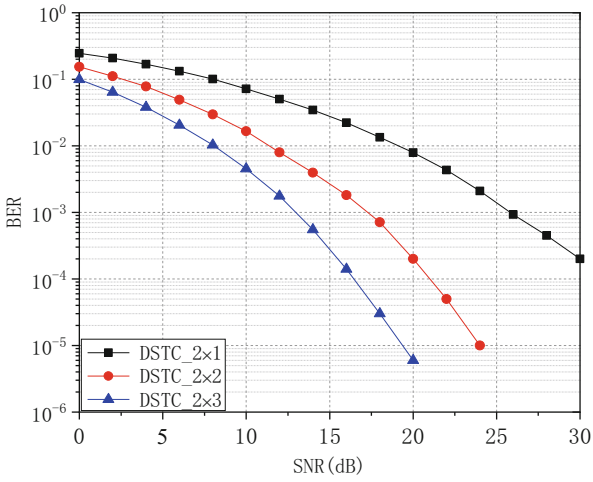

Fig. 20.48 Bit-error rate of differential space–time coding with SI = 0.4 and BPPM modulation

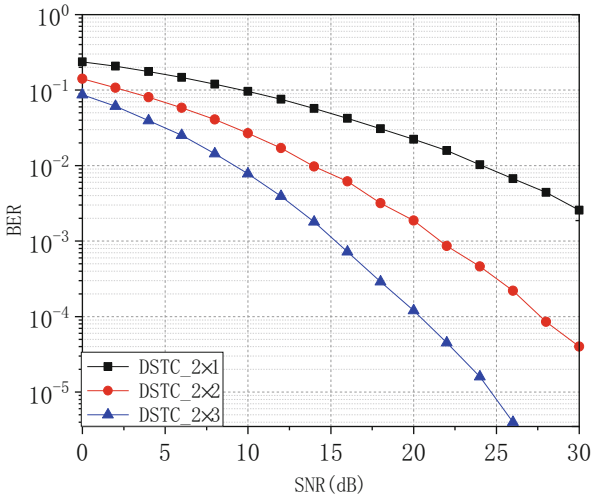

Fig. 20.49 Bit-error rate of differential space–time coding with BPPM modulation at SI = 0.9

Figure 20.50 shows the bit-error rate of differential space–time coding with two transmitting antennas when the scintillation index SI = 1.12 and a gamma–gamma-distribution turbulence model is adopted. When the bit-error rate is close to 10^{-2}, the two receiving apertures are reduced by about 14 dB, compared with a single one. Compared with one and two receiving apertures, three receiving apertures are reduced by about 20 dB and 6 dB, respectively.

Figure 20.51 compares the bit-error rate of differential space–time code with the bit-error rate of Alamouti code [97] improved by Simon and Vilnrotter. A gamma–gamma distribution model is adopted and the scintillation index SI = 0.9.

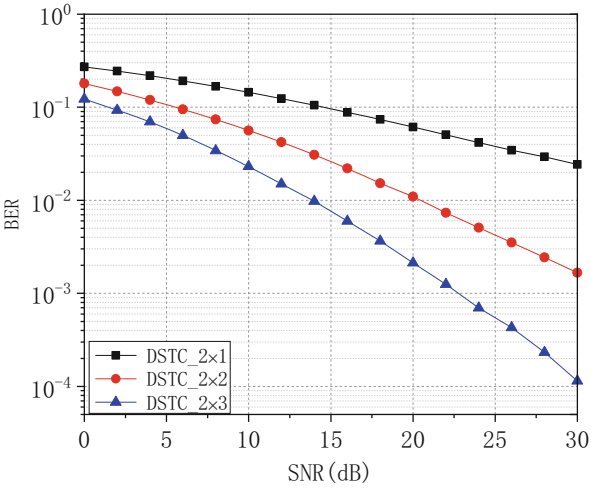

Fig. 20.50 Bit-error rate of differential space–time coding with BPPM modulation at SI = 1.12

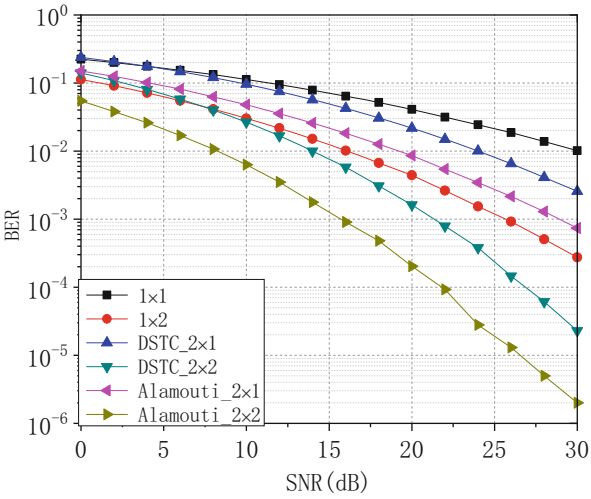

Fig. 20.51 Comparison of bit-error rates of differential space–time code and Alamouti code with BPPM modulation at SI = 0.9

It can be seen from the figure that the performance curves of the differential space–time coding method and the improved Alamouti coding method are parallel, which shows that the differential scheme can achieve complete transmission diversity with the improved Alamouti coding [97]. When the bit-error rate is 10^{-2}, the difference between the differential coding and the improved Alamouti coding [97] is about 5 dB; however, the differential coding scheme in the 2×1 and 2×2 systems is significantly better than the one without coding in the 1×1 and 1×2 systems.

Figure 20.52 compares the bit-error rate of the differential space–time code between two and four transmitting antennas when the scintillation index SI is 0.4 under a lognormal-distribution turbulence model. We can see the following from the figure:

1. When the bit-error rate is 10^{-3}, the bit-error performance of the 4×1 system is improved by about 6 dB, relative to the 2×1 system. When the bit-error rate is 10^{-4}, the bit-error performance of the 4×2 system is improved by about 3.5 dB, relative to that of the 2×2 system.
2. When the bit-error rate is 10^{-3}, the 2×2 system's bit-error performance is improved by about 8 dB over the 4×1 system. When the bit-error rate is 10^{-4}, the bit-error performance of the 4×2 system is improved by approximately 7.5 dB, relative to the 4×1.
3. For two different MIMO systems, when the product MN of the number of transmitting antennas M and the number of receiving antennas N is equal, the bit-error performance of the differential space–time code of the 2×2 system is obviously better than that of the 4×1 system. When the bit-error rate is 10^{-4}, the bit-error performance of the 2×2 system is improved by approximately 3 dB relative to the 4×1 system.

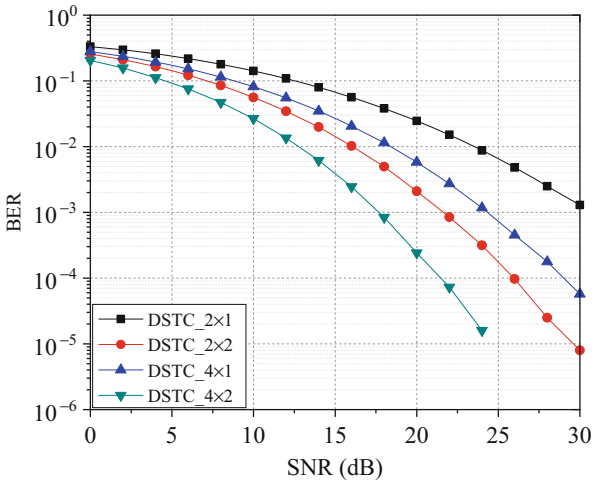

Fig. 20.52 Comparison of bit-error rates of differential space–time codes with two and four transmitting antennas when SI = 0.4

Figure 20.53 shows the bit-error rate for two and four antennas when the scintillation index SI = 0.9 using the gamma–gamma distributed turbulence model. The performance shown in Fig. 20.52 is significantly lower than that shown in Fig. 20.51, owing to the influence of the atmospheric-turbulence intensity.

The performance shown in Fig. 20.54 was significantly worse than that shown in Fig. 20.55 and Fig. 20.53. It can be seen that when the differential space–time code adopts a 4 × 2 system relative to the 2 × 2, 4 × 1, and 2 × 1, the gap increases significantly. When the signal-to-noise ratio is 20 dB, the bit-error rate performance of the 4 × 2 system is improved by one order of magnitude, relative to the 2 × 2

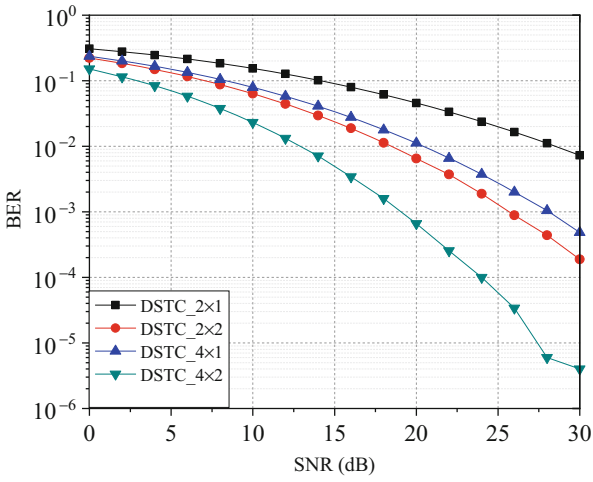

Fig. 20.53 Comparison of bit-error rates of differential space–time codes with two and four transmitting antennas when SI = 0.9

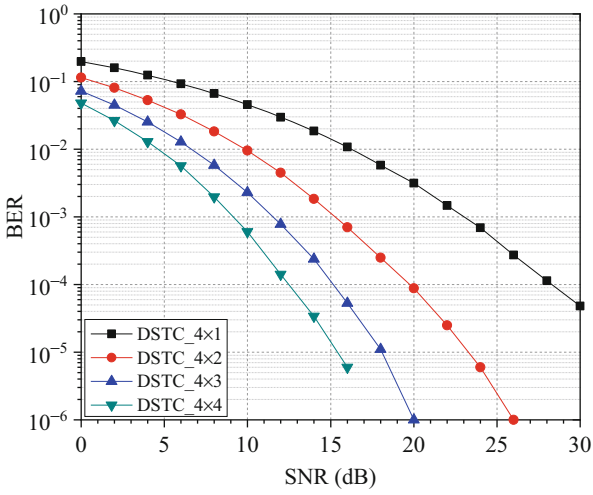

Fig. 20.54 Bit-error rate diagram of differential space–time codes with four transmitting antennas and different receiving antennas

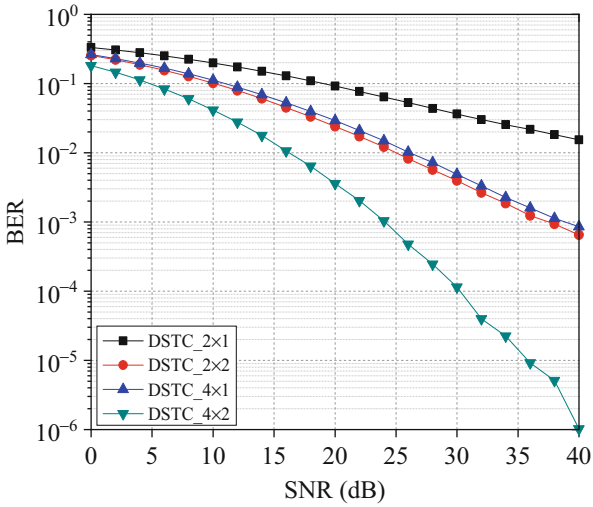

Fig. 20.55 Comparison of bit-error rates of space–time codes with two and four transmitting antennas

system. When the signal-to-noise ratio is 40 dB, the 4 × 2 system is improved, relative to the 2 × 2 system, and the bit-error rate performance of the system is improved by three orders of magnitude.

Figure 20.55 shows the curve of the bit-error rate versus the signal-to-noise ratio of the differential space–time code when the number of transmitting antennas is four and the number of receiving antennas is one, two, three, and four, when a lognormal-distribution turbulence model is adopted and the scintillation index SI = 0.6. It can be seen from the figure that with the increase in the number of receiving antennas, the system performance is better.

When the signal-to-noise ratio is 15 dB, the bit-error rate performance of the 4 × 4 system improved by three orders of magnitude relative to the 4 × 1 system. The bit-error rate performance of the 4 × 4 system improved two orders of magnitude relative to the 4 × 2 system. The bit-error rate performance of the 4 × 4 system improved by one order of magnitude relative to the 4 × 3 system.

Unitary Space–Time Coding

It is difficult, and sometimes even unrealistic, to effectively estimate a channel in a mobile environment with rapidly changing channel characteristics. Therefore, the study of space–time coding without channel estimation at the receiver has great practical value. Hughes, Hochwald, Marzetta, and other scholars [98–100] studied blind space–time block codes without channel-parameter estimation at the receiver.

Hochwald et al. [96] deduced the unitary space–time code (USTC) according to the channel capacity of a Rayleigh fading channel in information theory. If the sending code block is a unitary matrix, the receiver can perform maximum-likelihood decoding without knowing the channel state.

We assume that the total transmission power E_s is unchanged, and the normalized value of E_s is considered. According to Taylor's frozen-field theory, it is assumed that the channel parameters remain unchanged in two consecutive transmission-code matrix blocks. The photoelectric conversion efficiency $\eta = 0.5$ and the number of samples is 100,000. When the scintillation index SI of the channel was 0.4 (weak turbulence) and 0.8 (medium turbulence), the above two methods were used to test the bit-error rate of the 4×2 and 4×1 systems. The simulation results are shown in Figs. 20.56, 20.57, 20.58, and 20.59.

As shown in Fig. 20.58, when SI = 0.4 (weak turbulence) and the bit-error rate is 10^{-3}, the signal-to-noise ratio difference of the 4×2 and 4×1 systems is 5 dB. This shows that the performance of the unitary space–time coding scheme is greatly improved with an increase in the receiver-aperture number.

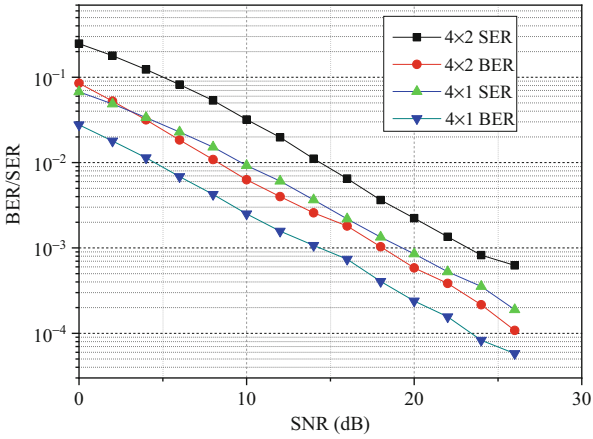

Fig. 20.56 BER performance of unitary space–time coding with channel estimation at SI = 0.4

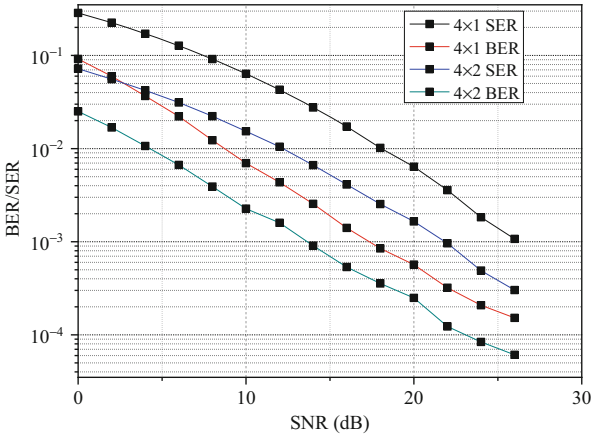

Fig. 20.57 BER performance of unitary space–time coding with channel estimation at SI = 0.8

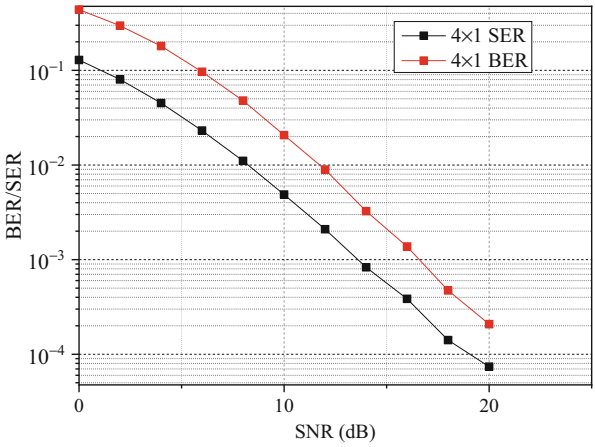

Fig. 20.58 BER performance of unitary space–time coding without channel estimation at SI = 0.4

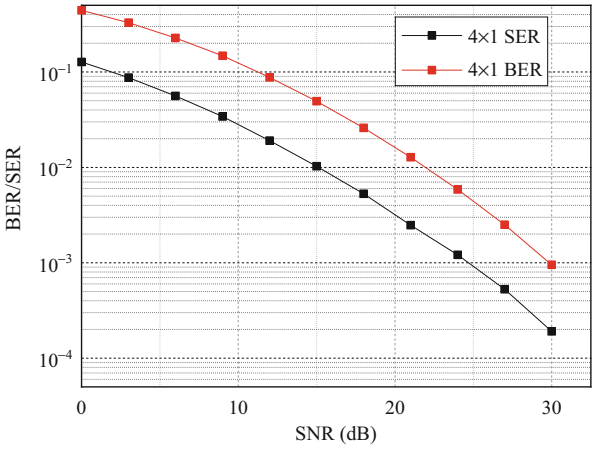

Fig. 20.59 BER performance of unitary space–time coding without channel estimation at SI = 0.8

As shown in Figs. 20.58 and 20.57, when SI = 0.4 and the bit-error rate is 10^{-3}, the 4 × 1 system signal-to-noise ratio remains almost constant at 19 dB, and the 4 × 2 system signal-to-noise ratio is 15 dB. When SI = 0.8 (medium turbulence) and the bit-error rate is 10^{-3}, the 4 × 1 system SNR is 23 dB, which is 4 dB different from that of SI = 0.4. The 4 × 2 system SNR is 14 dB, which is 1 dB different from that of SI = 0.4.

Comparing Figs. 20.58 and 20.59, we can see that when the signal-to-noise ratio is 25 dB, in weak or medium turbulence (SI = 0.4 or 0.8), the 4 × 1 system bit-error rate is 10^{-3} to 10^{-4}, the bit-error rate of the 4 × 2 system is lower, and the bit-error rates of the system under the two turbulence conditions are similar.

By comparing the system-simulation diagrams in Figs. 20.50 and 20.51, which do not require channel estimation, it can be seen that when the signal-to-noise ratio is

20 dB and SI = 0.4 in weak turbulence, the bit-error rate of the 4 × 1 system is low, and when SI = 0.8, the bit-error rate of the 4 × 1 system is between 10^{-3} and 10^{-4}, which is obviously inferior to the bit-error performance that requires channel estimation. This indicates that a system requiring channel estimation has a strong ability to suppress the influence of turbulence.

Hybrid Space–Time Coding

Layered space–time coding (LSTC) [101–103] and space–time block coding (STBC) [104–106] are two important space–time coding methods. Although LSTC has poor bit-error performance, it can achieve high spectrum utilization. Although the STBC code uses orthogonality to achieve transmission diversity in the system, its performance is significantly better than that of the LSTC. However, because of redundant information in the coding matrix, the transmission efficiency is low [107, 108]. Therefore, improving the transmission rate of the STBC code is the first problem to be solved. We make a reasonable compromise between multiplexing gain and diversity gain and propose a hybrid space–time coding scheme suitable for IM/DD optical communication [109].

When the total transmission power remained unchanged and the channel-attenuation coefficient was determined, the Monte Carlo method was used to simulate the bit-error performance of a 4 × 4 system. The simulation parameters are $Q = 4$, SI = 0.6, $\eta = 0.5$, and a 2 × 2 mixed coding scheme is used. The simulation results are shown in Figs. 20.60 and 20.61.

Figure 20.60 shows the bit-error performances of different systems using different coding methods. The following can be seen from Fig. 20.59:

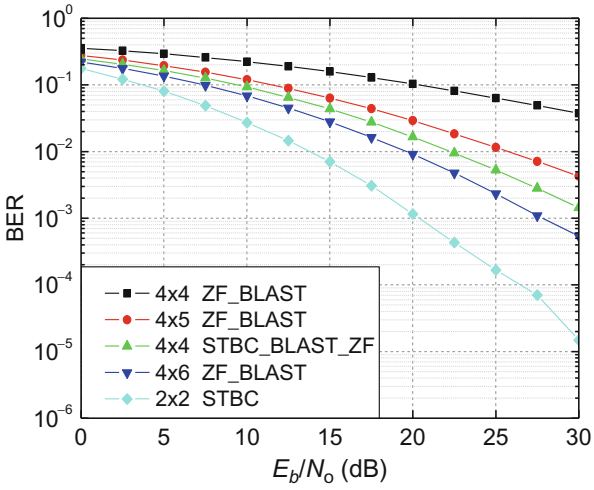

Fig. 20.60 BER performance of different systems with different coding methods

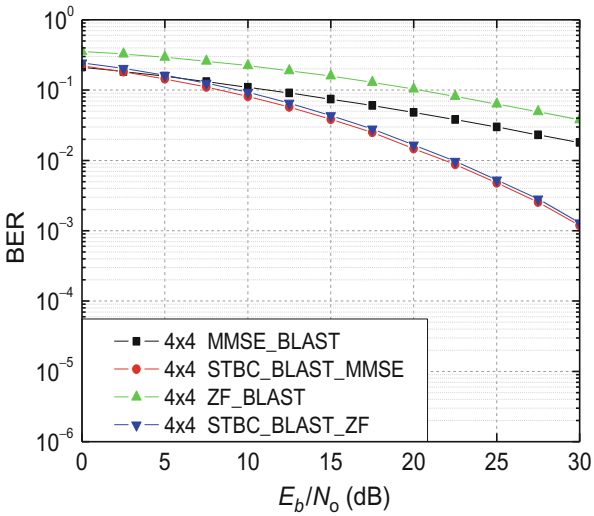

Fig. 20.61 BER performance of two systems using different decoding algorithms

1. When comparing a 2 × 2 STBC system and a 4 × 4 ZF_ BLAST system, it can be seen that there is a wide range between the error rates, and the error-rate curve of the STBC system is steeper than that of the BLAST system. This indicates that the STBC system can obtain a larger diversity gain without a partial multiplexing gain.
2. Comparing the bit-error performance of the hybrid space–time coding system between a 2 × 2 STBC system and a 4 × 4 ZF_ BLAST system, it can be seen that the performance of the hybrid space–time coding is significantly better than that of traditional BLAST codes. When the bit-error rate is 10^{-2}, relative to the 4 × 4 ZF_ BLAST system, the performance of the 4 × 4 hybrid space–time coding system is improved by approximately 14 dB. This shows that introducing the STBC code into layered space–time coding increases the diversity of the first translated layer, ensures the correctness of the first layer, and reduces error propagation.
3. The error performance of 4 × 4 hybrid space–time coding system is between that of a 4 × 5 ZF_ BLAST and that of a 4 × 6 ZF_ BLAST system. We note that the 4 × 4 hybrid space–time coding system obtains both reception-diversity gain and transmission-diversity gain.

The MMSE and ZF detection algorithms were used to analyze the traditional BLAST system and hybrid space–time coding system, and their bit-error performance is shown in Fig. 20.61. The following can be seen from the figure:

1. When the MMSE decoding algorithm is used in the hybrid space–time coding system, the bit-error performance of this scheme is obviously better than that of the traditional BLAST system.

2. In a traditional BLAST system, the performance of the MMSE algorithm is better than that of the ZF algorithm because it considers the influence of noise on the signal.

   However, in the hybrid space–time coding system, the performances of the two algorithms were very similar. When the bit-error rate was 2×10^{-3}, the bit-error performances of the two algorithms were the same.

Summary

In 2011, Qiu et al. [110] built a fiber-channel MIMO model using the modal dispersion of a multimode fiber. In 2011, Li et al. [111] performed a theoretical analysis of vertical layered space–time coding (V-BLAST) using the zero-forcing (ZF) detection, minimum mean-squared error (MMSE) detection algorithm, and maximum-likelihood (ML) detection algorithm for fiber-channel MIMO. The results showed that the ZF algorithm performed poorly in multimode fiber links and the MMSE algorithm performed better than the ZF algorithm; the ML algorithm obtained the minimum error probability of the original symbol, and its performance was the best. In 2011, Zhao et al. [112] analyzed the channel capacity of optical wireless space–time coding, and Xing [113] studied quasi-orthogonal space–time coding.

Space–time coding has gradually attracted attention in the field of optical wireless communication. Since 2007, the author has devoted himself to research on space–time coding in optical wireless communication [8–85]. Drawing on previous research results of space–time coding in the radio-frequency field, the author extended it to the field of optical wireless communication. Future directions include adaptive coding according to the channel changes to improve the channel capacity. Error-correction coding is added to adapt to the change in channel characteristics to improve the reliability of optical wireless communication.

Concatenated Code

Studies on space–time concatenated codes mainly investigate concatenation schemes and decoding methods between different codes to reduce the complexity of multistage iterative decoding algorithms [114–118]. Generally, error-correction code is used as the outer code, and space–time code is used as the inner code to construct a concatenated space–time code [119].

In 1966, Forney proposed a serial concatenated-coding technology [120] that used short component codes to construct long codes. It used non-binary and long codes as outer codes, and binary and short codes as inner codes. It achieved better error-code characteristics and decoding complexity within the allowable range.

Since the emergence of wireless laser communication technology, researchers have attempted to improve the performance of communication systems using concatenated-coding technology. In 2012, Xu et al. [121] studied a scheme for

concatenating turbo-product codes and space–time block codes, and the bit-error rate of the concatenated codes was clearly better than that of the space–time codes.

Cascaded Orthogonal Space–Time Coding

Cascaded Orthogonal Space–Time Block-Code Model

Concatenated coding technology uses two or more codes to concatenate and increase the total code length to improve the system performance without increasing the complexity of the system hardware. This method is particularly suitable for improving the performance of atmospheric laser communication systems. Because a non-binary RS code is a maximum-distance separable code that is easy to implement, it is the most natural choice as an external code. Our outer code uses the Reed–Solomon (RS) code, and the inner code uses orthogonal space–time coding. The principle model of cascaded space–time block coding is shown in Fig. 20.62.

After a serial-parallel transformation of the information sequence sent by the source, the sequence first enters the external-code encoder (RS code) for coding, and the external-code encoder outputs non-binary RS-code symbols. Because the PPM modulation symbols match the RS code, the RS code does not need to be converted into binary code, and the output of the external coder can be sent directly to the interleaver for interleaving. The interleaved information symbols are sent directly to the internal-code encoder (STBC encoder) for coding. For orthogonal space–time coding using PPM modulation, the orthogonality is reflected in the pulse position, so it can be directly transmitted by the laser.

The receiver sends the received PPM-modulated symbols to the internal-code decoder for decoding (STBC decoder) and then directly enters the external-code decoder (RS decoder) for decoding after deinterleaving. The original information can be recovered after a parallel-to-serial conversion. In this system, because of the interleaving technology, burst errors can be converted into random errors; thus, the number of scattered error codes falls within the range of error-correction decoding, which further improves the error-correction capability of the system.

Performance Analysis of Cascaded Orthogonal Space–Time Coding

The RS (n, k) code is a type of Bose–Chaudhuri–Hocquenghem (BCH) code with strong error-correction ability. For RS codes that can correct t sign errors, the minimum code distance is $d = 2\,t + 1$, and the number of supervision elements is

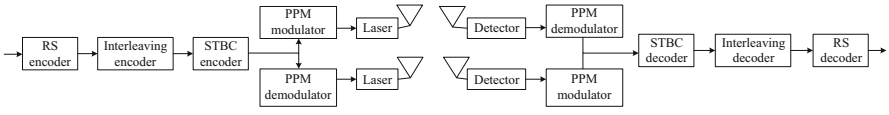

Fig. 20.62 Principle of cascaded space–time block coding

$r = 2\,t$. If the system takes the RS code as the outer code and adopts the errors-only decoding (EOD) algorithm for decoding, the internal-code decoder only needs to output the symbol decision. It does not need to provide symbol deletion or information about the symbol reliability [122].

Thus, if the bit-error rate output by the internal-code decoder is P_S, for an RS (n, k) code that can correct t symbol errors, the upper limit of the bit-error rate output after decoding is [123, 124]

$$P_b < \frac{2^{k-1}}{2^k - 1} \cdot \sum_{j=t+1}^{n} \frac{j+t}{n} \cdot C_n^j \cdot P_{\text{s_BCPSTBC}}^j \cdot \left(1 - P_{\text{s_BCOSTBC}}\right)^{n-j}. \tag{20.1}$$

In this manner, the upper limit of the output bit-error rate P_b of the concatenated code can be estimated from the output bit-error rate $P_{\text{S_BCOSTBC}}$ of the specific internal code. The upper bound of the decoding error rate of the concatenated code can also be estimated according to the relationship between the error rate and the word-error rate:

$$P_s = \frac{2(Q-1)}{Q} P_b. \tag{20.2}$$

With the total power E_s of the system unchanged and the channel parameters known, the Monte Carlo method was used to simulate the bit-error performance of the 1×1, 2×1, and 2×2 systems. Simulation parameter $\eta = 0.5$. The simulation results are shown in Figs. 20.63, 20.64, 20.65, and 20.66.

Figure 20.63 shows the word-error rate of the BCOSTBC and repeat codes [125, 126] after concatenating the RS (15, 7) code when SI = 0.4. To facilitate matching between symbols, 16-PPM modulation was adopted. The following can be observed from the figure:

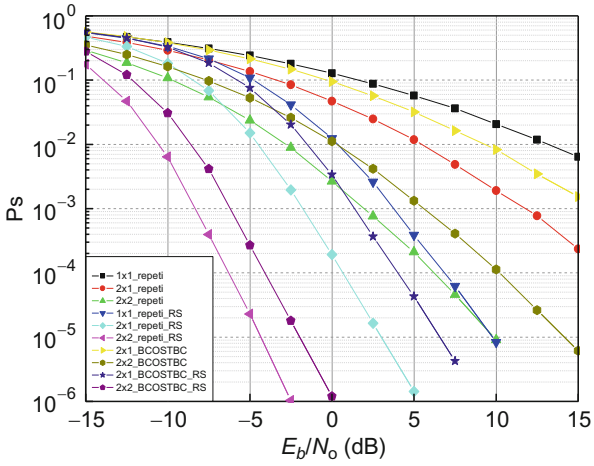

Fig. 20.63 Word-error rate of BCOSTBC code and repetitive code after concatenated RS (15, 7) when SI = 1

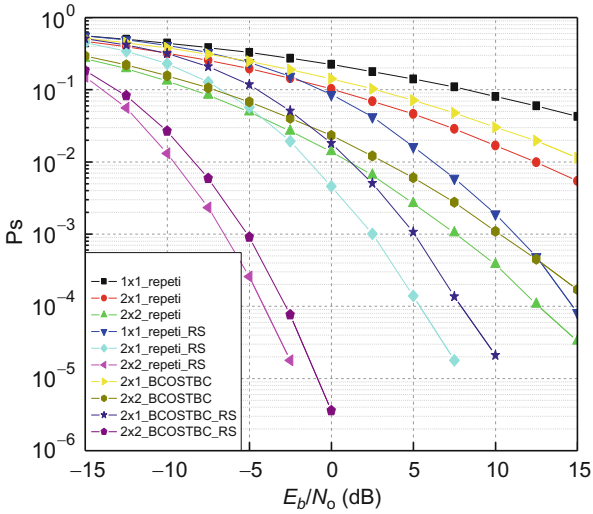

Fig. 20.64 Error rate of BCOSTBC code and repetitive code after concatenated RS (15, 7) when SI = 0.4

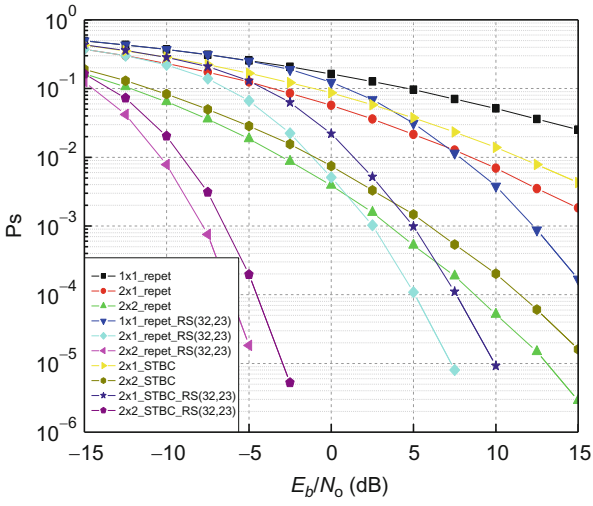

Fig. 20.65 When SI = 1, the error rate of BCOSTBC and repetitive codes after concatenated RS (32, 23) code

1. After concatenating the RS codes, the error rates of the BCOSTBC and repeat codes decrease significantly. When $P_s = 2 \times 10^{-3}$, in the 2×1 system, the BCOSTBC code after a concatenated RS (15, 7) achieves a 13.5-dB coding gain. After concatenating an RS (15, 7), a code gain of 12.5 dB is obtained. When $P_s = 2 \times 10^{-4}$, in the 2×2 system, the BCOSTBC code after a cascaded RS (15, 7) achieves a 13-dB coding gain. After concatenating RS (15, 7), a code gain of 12 dB is obtained. This shows that concatenated codes can significantly improve system performance.

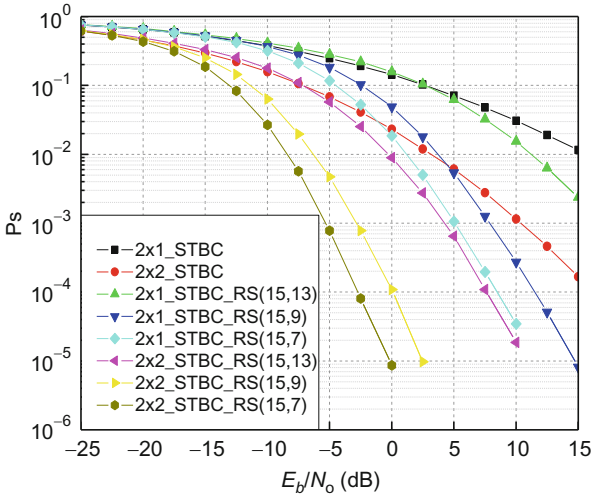

Fig. 20.66 Word-error rate of BCOSTBC code after concatenating different RS codes when SI = 1

2. In the same system, the performance gap between the two space–time codes before and after concatenation is significantly reduced. When $P_s = 2 \times 10^{-3}$, in the 2 × 1 system, the signal-to-noise ratio differences between the BCOSTBC code and the repeat code before and after concatenation are 4 dB and 3 dB, respectively. When $P_s = 2 \times 10^{-4}$, in the 2 × 2 system, the signal-to-noise ratio difference between the first two codes of the cascade is 4 dB, and that between the two cascade codes is 2 dB. This shows that in the BCOSTBC code, the error codes mainly originate from paired errors rather than random errors.
3. When the number of transmit apertures is the same, with an increase in the number of receive apertures, the bit-error performance gap between the two codes decreases significantly after concatenation. When $P_s = 2 \times 10^{-4}$, in the 2 × 1 and 2 × 2 systems, the signal-to-noise ratio differences between the two codes after concatenation are 3.3 dB and 2.2 dB, respectively. This indicates that the effect of the receiving diversity is better than that of the sending diversity.

Figure 20.64 shows the bit-error rate of the BCOSTBC and repeat codes after the concatenated RS (15, 7) code when SI = 1, also using 16-PPM modulation. It can be seen from the figure that the rule reflected in Fig. 20.64 is the same as that in Fig. 20.63, except that the improvement of the signal-to-noise ratio is greater at this time.

When $P_s = 2 \times 10^{-4}$, in the 2 × 1 and 2 × 2 systems, the signal-to-noise ratio differences between the two codes after concatenation are 2.5 dB and 1.2 dB, respectively. It can be seen that the performances of the two cascaded space–time codes are more similar, indicating that the cascaded space–time codes are more suitable for strong turbulence channels. In addition, the performance of the concatenated BCOSTBC code was slightly worse than that of the concatenated repetitive code, and the latter was more convenient for interleaving and concatenation.

Figure 20.65 shows the word-error rate of the BCOSTBC and repeat codes after concatenating the RS (32, 23) code when SI = 1. To facilitate the matching between symbols, 32-PPM modulation is adopted. Compared with Fig. 20.64, the coding gain of the last two space–time codes of the cascaded RS (15, 7) is greater than that of the last two space–time codes of the cascaded RS (32, 23) under a low SNR.

With the increase of SNR, the coding gain of the last two space–time codes of concatenated RS (32, 23) code increases dramatically. When the SNR is large, the coding gain of the last two space–time codes of the concatenated RS (15, 7) code is small. This shows that the error performance of the short code is better than that of the long code at a low SNR. However, with an increase in SNR, the high error-correction ability when using long codes can be brought into play.

Figure 20.66 shows the word-error rate of the BCOSTBC and repeat codes after concatenating the equal-length RS code when SI = 1. To facilitate matching between symbols, 16-PPM modulation was adopted. The following can be seen from the curve in the figure:

1. When the word-error rate $P_s \leq 10^{-3}$, the E_b/N_o requirements of various concatenated-code schemes are far less than those of non-concatenated ones. It can be seen that the concatenation of the RS code and space–time block code has obvious advantages.
2. The curves in the figure intersect. Before this intersection, the word-error rate decreases slowly with an increase in the SNR. Compared to concatenated codes with higher efficiency, concatenated space–time codes with lower efficiency exhibit poor bit-error performance. This is because the benefits of error correction cannot compensate for the impact of a higher bit-error rate caused by coding. After this intersection, the word-error rate curve rapidly becomes steeper. Compared to concatenated codes with higher efficiency, concatenated space–time codes with lower efficiency can obtain a higher coding gain. Therefore, an intersection is a turning point for codes with low efficiency.

Cascaded Layered Space–Time Codes

Cascaded Layered Space–Time Code Model

Figure 20.67 shows the basic structure of the LDPC-BLAST system. After information c is sent by the source, we encode it with LDPC to change it into a codeword x with a better code distance. After the serial-to-parallel conversion of the coded codeword x, layered space–time coding is performed, and the codeword is modulated using PPM modulation and then transmitted through an array of M lasers.

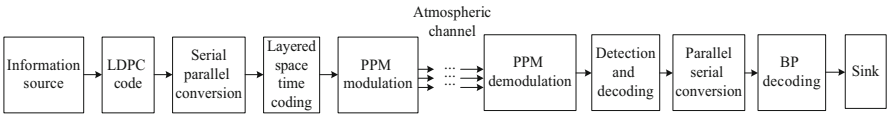

Fig. 20.67 LDPC-BLAST system model

At the receiving end, N detectors are used to receive signals, and PPM demodulation is performed on the received signals. The demodulated signals are detected and decoded to obtain the codeword. After a parallel-to-serial conversion, codeword y is obtained, and then the belief propagation (BP) decoding algorithm is applied to the codeword to obtain the final information c. Finally, we compare information c from the source with information c obtained at the receiver, calculate the corresponding bit-error rate, and judge the performance of the system according to the bit-error rate.

Analysis of Cascaded Layered Space–Time Codes

The maximum-likelihood, zero-forcing, and minimum mean-squared error detection algorithms were used to simulate the LDPC+BLAST cascade system with the D-BLAST and T-BLAST codes. The simulation conditions are as follows:

1. We assume the total power E_s is unchanged, and the value is 1 (normalized).
2. We assume that the channel characteristics and noise can be accurately estimated by the receiver.
3. The photoelectric-conversion efficiency is 0.6.
4. Under weak turbulence, the atmospheric channel follows a lognormal distribution, and the scintillation factor SI is 0.6. Under medium–strong and strong turbulence, the atmospheric channel follows a gamma–gamma distribution, and the scintillation factors SI are 1 and 3, respectively.
5. The system adopts pulse-position modulation, namely, 4-PPM.
6. LDPC code with binary domain rules is selected for coding, with a code rate of 0.5 and a code length of 2016 bits. A probabilistic BP decoding algorithm is adopted and the number of iterations is 100.
7. Antenna pairs 2×2, 2×4, 4×4, and 4×6 are used as examples.

Simulation of the LDPC+D-BLAST System

Figures 20.68 and 20.69 show the system simulation diagram when the scintillation SI $= 0.6$, that is, the curve of the bit-error rate and the signal-to-noise ratio of the

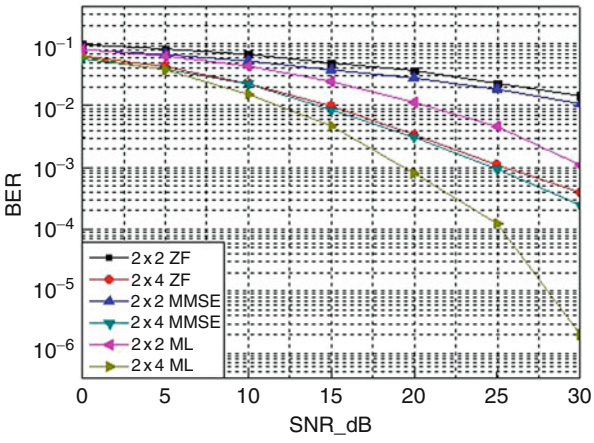

Fig. 20.68 Simulation diagram of 2×2 and 2×4 LDPC+D-BLAST systems (SI $= 0.6$)

LDPC+D-BLAST (LDPC code and D-BLAST cascade) system in weak turbulence. It can be seen that the bit-error rate of the system with four transmitters and multiple receivers is 10^{-6} when the SNR is 25 dB, while that of the system with two transmitters and multiple receivers can reach 10^{-6} only when the SNR is increased to 30 dB. Compared to the D-BLAST system without LDPC coding, the LDPC+D-BLAST system has better performance and lower signal-to-noise ratio requirements in the case of weak turbulence.

Figures 20.70 and 20.71 show the system simulation results when the scintillation index SI = 1, that is, the curve of the bit-error rate and the signal-to-noise ratio of the LDPC+D-BLAST system in the case of medium and strong turbulence. It can be observed that the enhanced SI has a greater impact on the bit-error rate. The LDPC+D-BLAST system needs to increase the system's signal-to-noise ratio

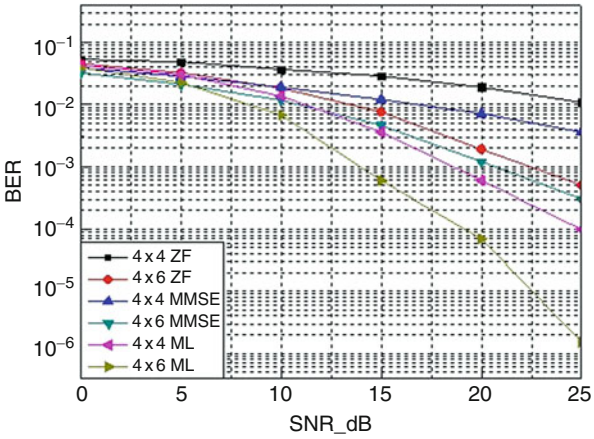

Fig. 20.69 Simulation diagram of 4 × 4 and 4 × 6 LDPC+D-BLAST systems (SI = 0.6)

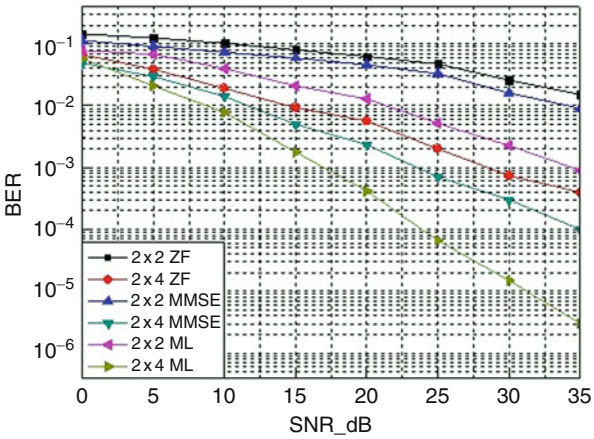

Fig. 20.70 Simulation diagram of 2 × 2 and 2 × 4 LDPC+D-BLAST systems (SI = 1)

to obtain the bit-error rate in a weak turbulence situation; that is, when the signal-to-noise ratio of the two-transmitter multi-receiver system is 35 dB, the bit-error rate can be close to 10^{-6}. This increases the system's transmitter-power requirements.

Figures 20.72 and 20.73 show the system simulation results when SI = 3, that is, the curve of the bit-error rate and signal-to-noise ratio of the LDPC+D-BLAST system in strong turbulence. It can be seen that when the signal-to-noise ratio is the same, the bit-error rate of the system in strong turbulence is much higher than that in weak turbulence (when the SNR is 25 dB, the bit-error rate in weak turbulence is 10^{-6}, and the bit-error rate in strong turbulence is 10^{-4}). In the case of strong turbulence, it is necessary to increase the transmission power at the transmitter and increase the signal-to-noise ratio to 40 dB to reduce the bit-error rate to nearly 10^{-6}.

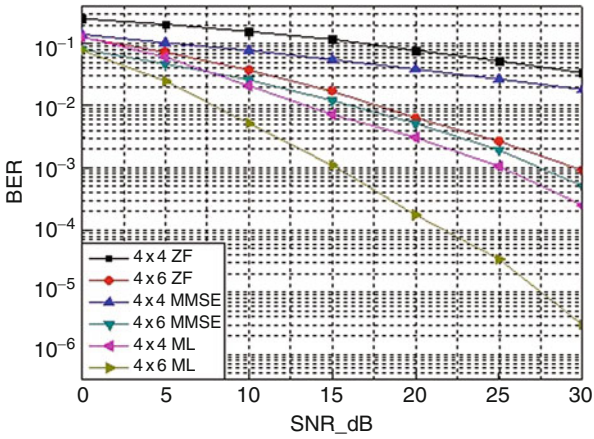

Fig. 20.71 Simulation diagram of 4 × 4 and 4 × 6 LDPC+D-BLAST systems (SI = 1)

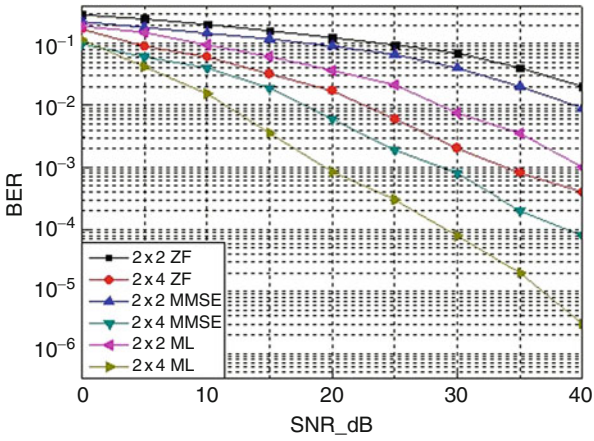

Fig. 20.72 Simulation diagram of 2 × 2 and 2 × 4 LDPC+D-BLAST systems (SI = 3)

LDPC+T-BLAST System

Figures 20.74 and 20.75 show the system simulation results when SI = 0.6, that is, the curve of the bit-error rate and signal-to-noise ratio of the LDPC+T-BLAST system in weak turbulence. Similar to the LDPC+D-BLAST system, under weak turbulence, the bit-error rate of the system with two transmitters and multiple receivers is close to 10^{-6} when the signal-to-noise ratio is 30 dB. This is slightly lower than that of the LDPC+D-BLAST system because the performance of diagonal layered space–time coding is better than that of spiral layered space–time coding. However, in a four-transmitter multi-receiver system, an SNR of only 25 dB can achieve a bit-error rate close to 10^{-6}. This indicates that the system performance can be significantly improved by increasing the number of transceiver antennas.

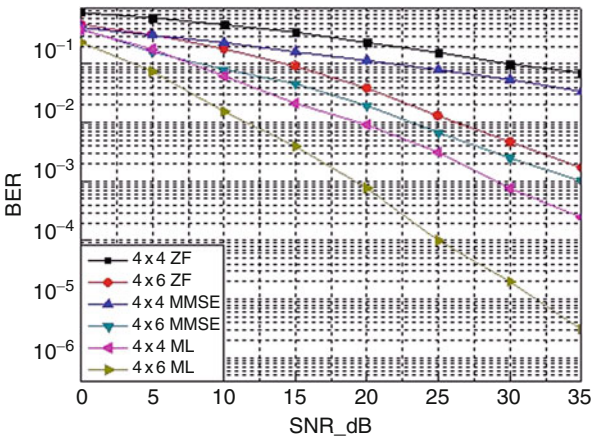

Fig. 20.73 Simulation diagram of 4 × 4 and 4 × 6 LDPC+D-BLAST systems (SI = 3)

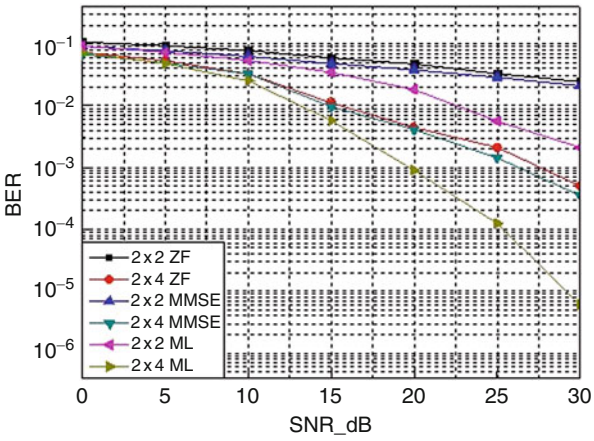

Fig. 20.74 Simulation diagram of 2 × 2 and 2 × 4 LDPC+T-BLAST systems (SI = 0.6)

Figures 20.76 and 20.77 show the system simulation results when SI = 1, that is, the curve of the bit-error rate and the signal-to-noise ratio of the LDPC+T-BLAST system in the case of medium and strong turbulence. It can be seen that the atmospheric-turbulence intensity affects the system performance to a certain extent. In a two-transmitter multi-receiver system, it is necessary to increase the signal-to-noise ratio to obtain the minimum bit-error rate under weak turbulence. The bit-error rate of the system is close to 10^{-6} when the SNR is 35 dB in moderate and strong turbulence. The bit-error rate also increases in the four-transmitter multi-receiver system. When the SNR increases to 30 dB, the bit-error rate decreases to approximately 10^{-6}.

Figures 20.78 and 20.79 show the system simulation results when SI = 3, that is, the curve of the bit-error rate and signal-to-noise ratio of the LDPC+T-BLAST system in strong turbulence. It can be observed that the performance of the system

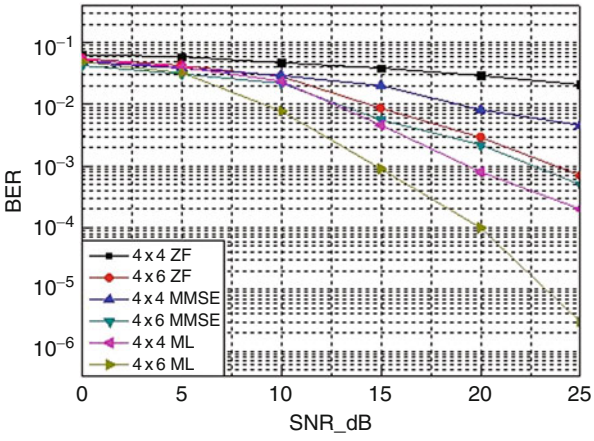

Fig. 20.75 Simulation diagram of 4 × 4 and 4 × 6 LDPC+T-BLAST systems (SI = 0.6)

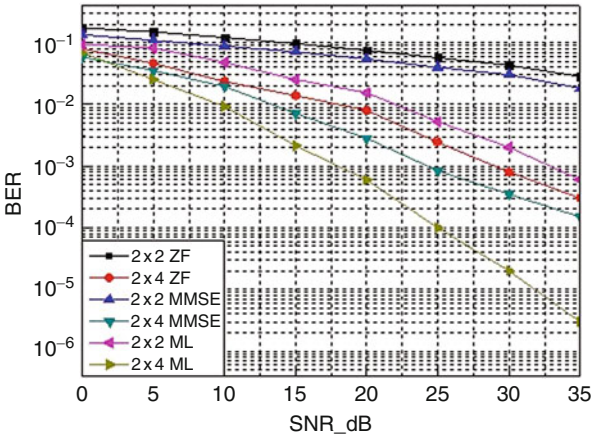

Fig. 20.76 Simulation diagram of 2 × 2 and 2 × 4 LDPC+T-BLAST systems (SI = 1)

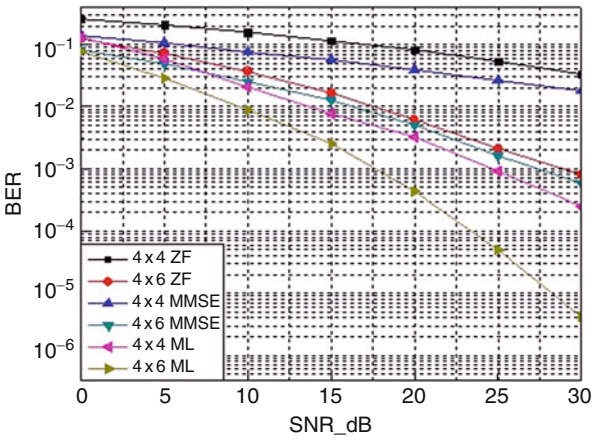

Fig. 20.77 Simulation diagram of 4×4 and 4×6 LDPC+T-BLAST systems (SI = 1)

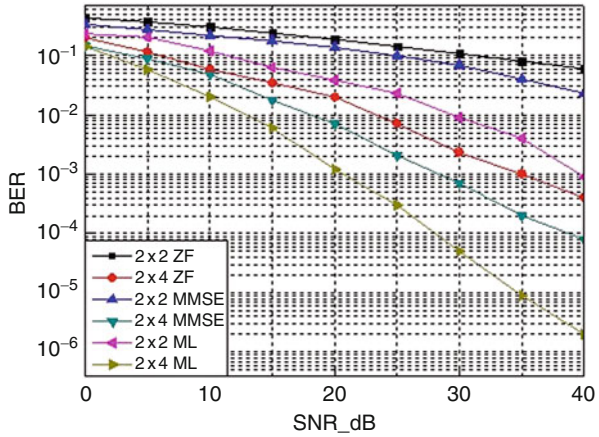

Fig. 20.78 Simulation diagram of 2×2 and 2×4 LDPC+T-BLAST systems (SI = 3)

worsens in the case of strong turbulence, and the bit-error rate value increases under the same SNR. When the signal-to-noise ratio is 25 dB, the bit-error rate of the two-transmitter multi-receiver system increases from 10^{-4} to 10^{-3}, while the bit-error rate of the 4×4 system increases from 10^{-5} to 10^{-4}.

To reduce the effect of strong turbulence on the system, it is necessary to increase the system transmission power, that is, to increase the signal-to-noise ratio. When the signal-to-noise ratio is increased to 40 dB in a two-transmitter multi-receiver system, the system's bit-error rate is close to 10^{-6}, while the signal-to-noise ratio of a four-transmitter multi-receiver system only needs to be increased to 35 dB.

Although the LDPC code increases the complexity of the system, the error rate of the LDPC+BLAST system decreases significantly. This shows that the LDPC code can improve the bit-error rate of the system, making it better than a single BLAST

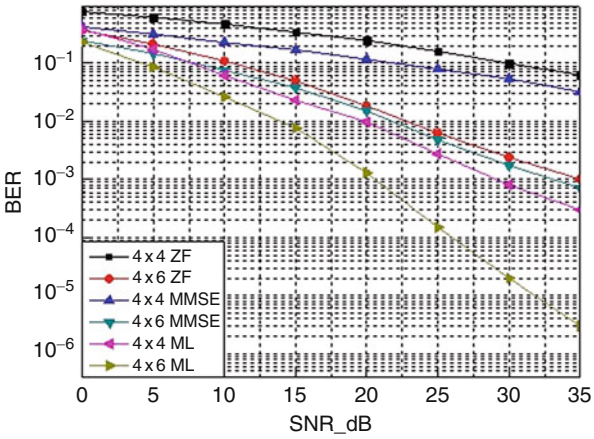

Fig. 20.79 Simulation diagram of 4×4 and 4×6 LDPC+T-BLAST systems (SI = 3)

system. When the signal-to-noise ratio is 30 dB in weak turbulence, the bit-error rate of the two-transmitter multi-receiver system decreases from 10^{-4} to 10^{-6}, indicating that the system with LDPC coding can better overcome the interference of noise in the system and improve the reliability of the system transmission information.

Cascade coding is an efficient coding method that has been widely used in recent years to enable the system error correction to approach the Shannon limit [127]. We constructed an RS-code concatenated space–time code and an LDPC-code concatenated space–time code. In contrast to [127, 128], we expanded the system to 4×4 and 4×6. Cascaded space–time codes can improve the bit-error rate of the system in different atmospheric-turbulence environments. Reducing the operational complexity of concatenated coding and improving operational efficiency are subjects for future study [129–132].

Abstract

Compared with direct detection, coherent detection has the advantages of a fast response speed, high detection sensitivity, and good filtering performance. It is the key technology for improving the receiving sensitivity of optical wireless communication systems (Xingzheng Ke, Ke Dong, Optical Wrieless Communication [M]. Springer Press, Beijing, 2022). This chapter summarizes the domestic and foreign research progress in the field of coherent detection in optical wireless communication systems, and introduces the research work of Xi'an University of Technology in coherent-detection technology. It mainly includes the effects of atmospheric-turbulence suppression, arrival-angle fluctuation, amplitude fluctuation, channel noise, optical-signal polarization, local vibration light power, and light-source linewidth on the performance of coherent-detection systems. It also describes the research progress on subcarrier-modulated nonoptical extraterritorial detection systems and a performance analysis of ideal and nonideal channels. Finally, the development directions of optical wireless coherent communication systems are prospected.

Keywords

Optical wireless communication · Coherent detection · Atmospheric turbulence · Wavefront aberration

Introduction

Compared to intensity modulation/direct-detection systems, coherent optical communication systems can have a gain in detection sensitivity of about 20 dB (up to 23 dB for zero-difference detection), which does not depend on the light used in the transmission, but rather on the coherent modulation used at the transmitter end and coherent techniques used for detection at the receiver end. It allows transmission over longer distances at the same transmit power and is more favorable to suppress atmospheric turbulence and channel fading [1]. This chapter describes coherent optical communication and its experiments.

Foreign Research Progress

Optical wireless coherence communication, as a supplement or extension of optical-fiber communication, breaks through the technical bottleneck of traditional communication. At present, the optical-fiber communication field is mature. To further promote the practical application of coherent communication and improve the sensitivity and transmission capacity of coherent detection, researchers have explored environmental factors, polarization technology, and other coherent-detection methods.

In the 1970s, Fink [3] gave a general equation for the signal-to-noise ratio (SNR) of a coherent receiver and showed that coherent detection was an effective method to obtain the quantum-detection limit in the spectral range.

In 1975, Cohen [4] analyzed the influence of wavefront deformability and optical-field distribution on heterodyne detection. He found that a heterodyne-detection system with a uniformly distributed signal-light amplitude was more likely to produce a serious wavefront mismatch than that with an Airy distributed signal light, and proposed a general equation for the signal-to-noise ratio of a coherent receiver.

In 1978, Takenaka et al. [5] studied the heterodyne efficiency of coherent detection. The communication quality could only be guaranteed when the value of the differential efficiency was greater than 0.8 in the system design. In addition, the signal-to-noise ratio of Gaussian-field optical heterodyne detection was studied.

In 1984, Tanaka et al. [6] studied the influence of background noise on the signal-to-noise ratio of a differential detection system with limited local light power. When the ratio of the signal power to local light power and the ratio of the background-noise power to local light power were both set to small values, the signal-to-noise ratio of the system was closer to the quantum noise limit.

In 1987, Tanaka and Ohta [7] analyzed the influence of the wavefront-inclination angle and the optical-axis offset on the differential efficiency when the signal light had a Gaussian distribution. When the signal light-front inclination angle was less than 10^{-4} and the optical-axis offset was less than one-fifth of the incident aperture, the heterodyne efficiency reached more than 60%.

In 1992, Iftekharuddin et al. [8] analyzed the advantages of using nondiffused beams in heterodyne detection. In this case, the maximum heterodyne efficiency was about 50% when the incident inclination angle of a Bezer beam was 1.4°.

In 1994, Kalman et al. [9] studied the performance of optical wireless coherent communication links using amplitude, phase, and frequency modulation. Compared with direct-detection links, optical wireless coherent communication links provided higher anti-interference ability.

In 1997, Chambers [10] analyzed the influence of the heterodyne efficiency on the wavefront aberration of a coherent communication system. When the wavefront-aberration root-mean-square (RMS) value was 0.1λ, the heterodyne efficiency decreased about 31%, when compared with an ideal beam with no wavefront aberration. In the same year, Das et al. [11] designed a hexagonal-array coherent detector to address the mismatch between the signal phase and local oscillator phase, which effectively improved the heterodyne efficiency and detection signal-to-noise ratio.

In 2000, Belmonte and Rye [12] analyzed the influence of atmospheric turbulence on the power performance of coherent heterodyne light by using numerical-simulation technology. When the transmission distance increased, the main influence brought by atmospheric turbulence was beam diffusion, which led to a serious decline in coherent received power.

In 2003, Belmonte [13] analyzed the signal degradation in a heterodyne-detection receiver caused by atmospheric turbulence. When a laser beam with a short

wavelength was transmitted through medium-strong turbulence, the smaller receiving aperture was basically the same as the larger receiving aperture, in terms of reducing the degree of coherent diffraction loss.

In 2004, Taylor [14] proposed a coherent-detection method using digital signal-processing technology, and experimentally demonstrated digital coherent-light detection using differential phase-shift keying (DPSK) modulation with a transmission rate of 10 Gbit/s. This method achieved the same high-sensitivity detection as zero-difference detection.

In 2006, Lange et al. [15] tested a binary phase-shift keying (BPSK) modulated communication link with 142-km zero-difference detection. The zero-difference detection link was free from background noise, and the transmission rate reached 5.625 Gbit/s.

In 2006, Toyoshima [16] studied the optimal relationship between a focused beam and the optical-fiber mode-field size in the presence of random angular jitter. When the ratio of the normalized random angular jitter to the mode-field radius was greater than 0.3, the average bit-error rate (BER) of the system was significantly reduced.

In 2008, Belmonte et al. [17] studied the influence of scintillation and phase distortion caused by atmospheric turbulence on the performance of optical wireless communication links. The study showed that high-order phase compensation could effectively improve the sensitivity of the receiving end. In the same year, Tsiftsis [18] derived the analytic expression of the interrupt probability and mean bit-error rate of a heterodyne-detection system under atmospheric turbulence. The results showed that the bit-error rate of the heterodyne-detection system could not reach 10^{-9} in practice.

In 2009, Sandalidis et al. [19] derived the bit-error rate expression under atmospheric-turbulence conditions, and further studied the bit-error performance of a optical wireless coherent communication system using differential phase-shift keying under different turbulence intensities. Numerical simulation proved that the bit-error rate of the system gradually increased with the increase of turbulence intensity.

In 2010, Djerroud et al. [20] conducted an experiment on a 5-km atmospheric-turbulence radio optical-coherent communication link and found that the phase noise of the communication link was mainly caused by atmospheric turbulence and mechanical jitter. In the same year, Salem et al. [21] derived an analytical expression for the heterodyne efficiency after frequency mixing using partially coherent Gauss–Schell model beams, and discussed the influence of wavefront deactivation and the detector radius on the heterodyne efficiency. They found that partially coherent beams were less affected by wavefront deactivation than coherent beams.

In 2011, Fice et al. [22] analyzed and evaluated in detail the Fice phase-locked synchronous homodyne coherent receiver. The evaluation results showed that a synchronous homodyne coherent receiver with a local vibro-optical phase lock could effectively recover the carrier of coherent optical detection.

In 2012, Bayaki et al. [23] established a optical wireless communication system model based on coherent and differential space-time coding, and compared it with an

intensity modulation/direct-detection (IM/DD) optical wireless communication system model. They found that the optical wireless communication system based on coherent and differential space-time coding obtained greater performance gains.

In 2016, Kikuchi [24] studied the application of digital signal-processing technology in a coherent receiver and analyzed the quantum-noise characteristics of its coherent detection. They found that the combination of coherent detection and digital signal processing provided effective compensation for the carrier recovery of a coherent receiver.

In 2022, Kakarla [25] studied receiver sensitivity using multipulse position modulation (M-PPM) and designed a communication link for a phase-sensitive optical-amplification receiver using M-PPM combined with quadrature phase-shift keying (QPSK) modulation. The results showed that when the BER $= 10^{-3}$, the optimal sensitivity of 2.1 dB could be provided by using the modulation mode combined with 64-PPM and QPSK.

In addition, the above literature shows that coherent detection [3] has very strict requirements on the detection mode [9, 14, 15, 23–25], laser light source [4, 8, 21], channel and other environmental factors [6, 12, 13, 18–20], and performance of the detector at the receiving end [11, 22]. In coherent detection, a suitable laser light source is the key to detection. Secondly, to ensure the optimal coherence detection sensitivity, polarization matching [11] and wavefront matching [10, 17] should be performed on the laser beam at the receiving end. The actual beam propagation and drift caused by atmospheric turbulence [16] also affects the efficiency of coherence detection, thus limiting the application of optical wireless coherence communication technology.

Domestic Research Progress

In the 1980s, with the rise of research in the field of optical wireless coherence communication, domestic scholars conducted in-depth research on coherence-detection technology. The optical-field distribution, atmospheric turbulence, polarization control, and phase matching all have significant effects on coherence detection, and scholars conducted in-depth theoretical research in this direction.

In 1985, Sun [26] proposed a 10.6-μm laser heterodyne receiver scheme, and experimentally tested the heterodyne-detection efficiency under different turbulence intensities. When the aperture of the receiving system D and atmospheric coherent length equaled r_0, the turbulence caused by the signal-power ups and downs was minimal and the heterodyne efficiency was the largest.

In 1988, Qian [27] analyzed the analytical relationship between the local oscillator gain, sensitivity, and power, and discussed several limiting factors of the local oscillator power. He found that the greater the local oscillator power, the greater the sensitivity improvement, and the closer the signal-to-noise ratio was to the quantum detection limit. The coherent optical heterodyne detection improved the receiving sensitivity by 10–30 dB, compared with the IM/DD mode.

In the same year, Zhang and Lin [28] conducted heterodyne-detection experiments and found that when a photodiode was used for heterodyne receiving, the optimal local-vibration power was related to the size of the applied bias. That is, using a higher bias in the operating-bias range could effectively improve the local-vibration power and avoid coherent-detection efficiency saturation.

In 1992, Zhang et al. [29] carried out a detailed analysis on the application of a limit-frequency discriminator (L-D) in a coherent receiver based on M-ary continuous-phase frequency-shift keying (CPFSK). The optimal modulation index was one when the beat linewidth of the normalized intermediate-frequency (IF) signal was no less than 2%.

In 1996, Min et al. [30] designed a polarization controller composed of four fiber-optic compounders to meet the polarization stability requirements in coherent communication. The fluctuation range of the output optical power was less than 1%, which met the requirements of practical communication.

In 1999, He [31] designed a coherent Lidar detection system based on the scattering-echo characteristics of targets and the phase-matching principle. The system successfully received the target echo signal 7.8 km away, after adding an adjustable beam expander in the local vibration path.

In 2003, Wang et al. [32] established a heterodyne-detection system for Gaussian and Airy speckle laser distribution, and analyzed the influence of wavefront loss on the differential efficiency. The simulation results showed that the maximum heterodyne efficiency between an Airy spot and a Gaussian beam was 0.82.

In the same year, Xiao et al. [33] analyzed the practical application of coherent-detection technology in an optical-fiber communication system. When a 1550-nm laser beam was used for transmission, the coherent-detection technology improved the sensitivity of the receiving end by 20–23 dB, and the transmission distance reached more than 100 km.

In 2005, Li et al. [34, 35] designed polarization controllers based on a simulated-annealing algorithm (SA) and a genetic algorithm (GA) to control the stability of the polarization state at the receiving end. For the polarization controller with the SA algorithm for feedback control, the output optical-power fluctuation range was less than 1%. After the GA feedback control, the output optical power fluctuation was less than 2%.

In 2007, Li et al. [36] studied the impact of arrival-angle fluctuation on the interference efficiency of the differential detection system, and experimentally tested the interference efficiency and signal-to-noise ratio of the system. Experiments showed that, under the influence of atmospheric turbulence, the beam arrival angle fluctuated obviously, and the signal-to-noise ratio decreased by 20 dB.

In the same year, Xu et al. [37] studied the spatial-coherence degradation caused by atmospheric turbulence and investigated the heterodyne-detection efficiency and signal-to-noise ratio under different turbulence intensities. They found that with the increase of atmospheric-turbulence intensity, the light spots shifted significantly and expanded to different degrees, and the heterodyne-detection efficiency and signal-to-noise ratio showed a decreasing trend.

In 2008, Zhang et al. [38] conducted a heterodyne-detection experiment and measured the echo signal of the target. When the local optical power remained unchanged and the signal optical power was reduced to a six orders of magnitude difference with the local optical power, the heterodyne signal could still be detected.

In 2010, Yazhou et al. [39] studied the influence of the dynamic tracking error on the mixing efficiency and conducted a numerical-simulation analysis. The simulation analysis showed that the receiver-aperture design of the optical wireless coherent communication system must match the alignment error to obtain the optimal bit-error performance of the link.

In the same year, Gao et al. [40] derived the mathematical model and SNR expression of a balanced detection process, and simulated the model. When the beam-splitting ratio range of the fiber beam splicer at the receiving end was [0.293, 0.707], the SNR of the balanced detection was higher than that of ordinary heterodyne detection.

In 2011, Liu et al. [41] deduced the analytical formula of heterodyne-detection efficiency under different distributions of signal light and local oscillator light for a coherent-communication receiving system. The results showed that the efficiency of heterodyne detection using two beams with a uniform amplitude distribution was about 72%, and the efficiency of heterodyne detection using two beams with Gaussian and uniform distributions was 82%. This further proved the rationality of replacing Gaussian beams with a uniform amplitude distribution. In the same year, Xiaoxi et al. [42] designed a heterodyne receiver using asynchronous demodulation, and experimentally compared it with a system using IM/DD to prove the feasibility of the design.

In 2013, Zhang [43] analyzed the influence of a collimation mismatch on the mixing efficiency of a optical wireless coherent communication system. The research results showed that a collimation mismatch could lead to a serious decline in mixing efficiency, and it was necessary to minimize the increase of the loss supporting role between the signal light and local light.

In the same year, Wu et al. [44] studied the influence of wavefront distortion on the signal-to-noise ratio of a BPSK modulated coherent-communication link in zero-difference detection under different atmospheric-turbulence conditions. The experimental results showed that the phase distortion caused by atmospheric turbulence destroyed the phase matching of the beam at the receiving end, resulting in a sharp decline in the mixing efficiency and a decrease in the signal-to-noise ratio of the system.

In 2014, Li et al. [45] studied the influence of light-source parameters on the beam-transmission polarization characteristics under atmospheric turbulence. When the transmission distance was short, the beam polarization was mainly affected by the light-source parameters. When the transmission distance was longer, the beam polarization was obviously affected by atmospheric turbulence.

In the same year, Liu et al. [46] designed and tested a balanced detector using a photodiode and transresistance amplifier. Experimental results showed that the balanced detector improved the signal-to-noise ratio of the system by about 10 dB in the coherent communication link.

In 2015, Li et al. [47] studied the heterodyne-detection efficiency of a Gaussian light distribution and conducted numerical simulations. They found that the heterodyne-detection efficiency was the best when the detector surface radius was greater than twice the waist radius of the local oscillator beam, and the waist radius of the signal beam was ensured to equal the local oscillator beam.

In the same year, Dai et al. [48] analyzed the formation mechanism of channel noise and designed 2.5-Gbit/s and 5-Gbit/s balanced-detection detectors that suppressed atmospheric channel noise. The sensitivity of the former coherent homodyne detection reached −41.2 dBm, and the sensitivity of the latter reached −34.3 dBm.

In 2016, Chang et al. [49] analyzed the working mechanism of a covariance coherent receiver using a Costas phase-locked loop and established a mathematical model for it. When the transmission rate was 5 Gbit/s, the receiving sensitivity reached −41.4 dBm.

In the same year, Wang et al. [50] studied the distance-measurement theory of the heterodyne principle of a double optical-frequency comb, and numerically simulated the relationship between the frequency-comb repetition-frequency difference and the ranging performance. When the signal jacks were sampled in time, the smaller the repetition-frequency difference was, the greater the cumulative noise was, and the worse the ranging accuracy was.

In 2017, Ma et al. [51] studied the relationship between the polarization state of the signal light and the mixing efficiency in coherent detection, and conducted numerical simulations. The maximum mixing efficiency could be obtained when the received signal light was in a circular polarization state.

In the same year, Nan et al. [52] studied the influence of spot-size deviation and optical-axis offset caused by optical elements on the mixing efficiency of the receiving end. It was found that when the spot-size deviation in the spatial optical mixer was less than 10 μm, it usually had little effect on the mixing efficiency. However, when the optical-axis offset range caused by the optical element in the spatial optical mixer was greater than 100 μrad, the effect on the mixing efficiency was usually greater than the spot-size deviation.

In 2018, Lei et al. [53] established an optical wireless communication system model based on the principle of coherent detection, and proved through numerical simulation that the receiver sensitivity of the optical wireless communication system could reach −49 dBm, which had high practical-application value.

In 2019, Feng et al. [54] studied the influence of light sources with different linewidths on the coherent-detection performance, and conducted field experiments on laser light sources with three linewidths. When conducting medium- and long-distance detection, the detection effect of light sources with linewidths of dozens of kilohertz was good.

In 2021, Sun et al. [55] established a random attenuation model of a satellite–ground laser-link channel and analyzed the bit-error rate performance of the model in heterodyne detection. The results showed that the link zenith angle should be less than 20° as far as possible to ensure good link communication.

Researchers in China have investigated coherence detection in terms of the optical-field distribution [32, 41, 47, 51], atmospheric turbulence [26, 36, 37, 44, 54, 55], polarization control [30, 34, 35, 45], phase matching [31, 43], and detector performance at the receiving end [27–29, 40, 42, 46, 48, 49, 53]. Compared with direct detection, the sensitivity and signal transmission capacity of coherent detection have significantly improved since the development of coherent-detection technology.

In domestic coherent-detection technology research, Xi'an University of Technology has also made good achievements. The polarization controller designed by Min [30], Li [34], and others stabilized the output optical power within 1%, effectively ensuring the polarization stability and improving the coherence-detection sensitivity.

Wang [32] and Liu [41] et al. summarized the different influences of the light-source distribution on the coherence detection efficiency. Li [47] and Feng [54] et al. conducted an in-depth study on how the linewidth of the light source affected the dry-detection performance of the receiving terminal. Xiao [33] demonstrated that the transmission distance of a coherent communication system using coherent detection could reach more than 100 km.

Experiment on Coherent Detection in Radio Optical Communication

Optical wireless coherent communication systems use a coherent-detection mode at the receiving end to obtain the best mixing efficiency and system signal-to-noise ratio. This helps to improve the detection sensitivity of coherent communication systems and detect weak signals.

In recent years, the research group of Professor Ke Xizheng from Xi'an University of Technology has extensively researched the influence of optical wireless coherent communication system performance on the optical-communication system design, signal transmission-code modulation, received-signal detection mode, and other aspects, and has made remarkable achievements. A space coherent optical communication system terminal was successfully developed, and an experiment on a optical wireless coherent communication system with a 1.3-km transmission distance was completed.

Coherent-Detection Techniques

Coherent-detection technology can improve the receiver sensitivity. Table 21.1 compares several coherent-detection technologies in terms of the difficulty of the engineering implementation and the heterodyne implementation method.

The principle of direct-detection technology is simple. The photodetector directly converts the optical signal detected by the receiving end into an electrical signal. It is suitable for communication systems with low equipment requirements and short

Table 21.1 Comparison of different probe modes [56]

Detection mode	Heterodyne gain	Applicable communication system	Laser wavelength tunability requirements	Polarization matching	Temperature control requirement	System equipment requirements
Nonoptical extraterri-toriality	Gain is generated by adding local light	Subcarrier modulation (SCM)	Does not require	Does not require	Relatively loose	Relatively loose
Coherent light detection	Gain is generated by adding local light	Amplitude-shift keying (ASK), phase-shift keying (PSK), frequency-shift keying (FSK), etc.	Requires a wide tuning range and a frequency discrimin-ator	Requires strict polarization matching	Very strict	Very strict
Self-zero detection	Gain is generated by adding a pre-fiber amplifier	DPSK	Does not require	Does not require	Relatively loose	Very strict
Direct detection	No gain	On-off keying (OOK), SCM	Does not require	Does not require	Relatively loose	Relatively loose

transmission distances, and the receiving sensitivity is low [57]. Coherent-detection technology requires high-precision optical devices and can meet the needs of communication systems with long transmission distances.

Autozero-detection technology has obvious advantages in receiving sensitivity and transmission distance; however, it requires the signal light to strictly match the local light, which is suitable for communication systems with strict limits on the laser linewidth. Nonoptical outfield detection technology overcomes the phase-matching problem, makes up for the shortcomings of direct-detection and coherent-detection technology, and has loose requirements for the communication system equipment.

Analysis of Coherent Detection Systems Under Atmospheric Turbulence

Beam drift, beam scintillation, and arrival-angle fluctuation caused by atmospheric turbulence affect the detection efficiency of coherent-detection systems [58]. Among them, the effect of atmospheric turbulence on light waves can be summarized as amplitude and phase disturbances.

Effect of Arrival-Angle Fluctuation on Coherent-Detection Systems

The arrival-angle fluctuation is the main factor that reduces the optical coherence of a signal. At the receiving end, the mixing efficiency of the signal light subjected to turbulence and the local oscillator light is reduced, and the heterodyne-detection efficiency is affected [59]. The parameters affecting the arrival-angle fluctuation include the zenith angle, turbulence intensity, internal and external atmospheric-turbulence scales, receiving aperture, and the ratio of the receiving-antenna aperture radius to the local beam-waist radius (Ω).

Figure 21.1 shows the effect of the zenith angle on the average mixing efficiency of a coherent-detection system. With the increase in zenith angle, the power of the optical signal received by the receiving end gradually decreases, and the heterodyne-detection efficiency obviously decreases. The larger the zenith angle is, the faster the average mixing efficiency decreases with the transmission distance. Therefore, the larger the zenith angle is, the greater the impact of turbulence will be, resulting in a more obvious decline in heterodyne-detection efficiency [60].

The results of this study are the same as those given in [55]. The researchers in [55] also carried out numerical simulations on the variation of the bit-error rate of a single-input single-output (SISO) system with the zenith angle. The results showed that the bit-error rate of the system increased with the increase of the zenith angle.

Figure 21.2 shows the influence of the turbulence intensity on the average mixing efficiency of a differential detection system. When the atmospheric refractive-index structure constant differs, the change of turbulence intensity significantly decreases the average mixing efficiency caused by the fluctuation of the arrival angle, and the heterodyne-detection efficiency also decreases [60].

Figure 21.3 shows the influence of the internal and external turbulence scales on the average mixing efficiency of an atmospheric-turbulence detection system. Under

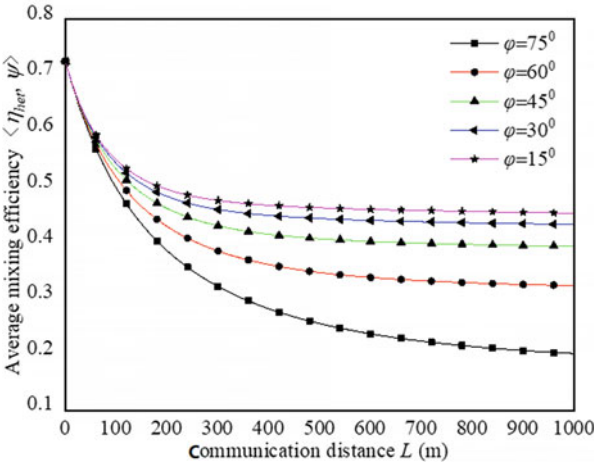

Fig. 21.1 Average mixing efficiency of different zenith angles varies with the transmission distance [60]

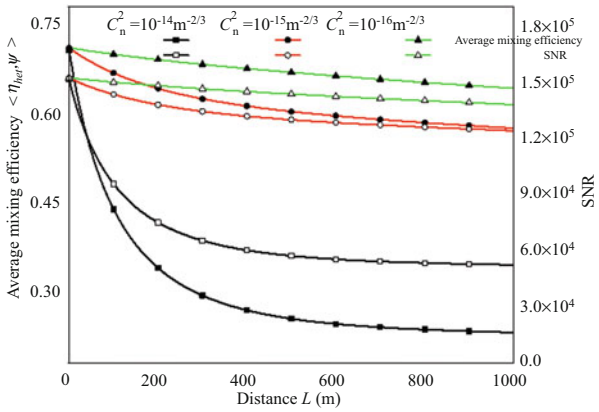

Fig. 21.2 Change of the average mixing efficiency with transmission distance L with different atmospheric refractive-index structure constants [60]

different atmospheric-turbulence intensity conditions, the average mixing efficiency increases with the increase of the internal turbulence scale. As the outer turbulence scale increases, it gradually decreases. This is because the variance of the arrival-angle fluctuation is directly proportional to the outer scale and inversely proportional to the inner scale [60].

Figure 21.4 shows the effect of the receiving aperture and Ω on the mixing efficiency of differential detection. Under medium-strong turbulence conditions, the average mixing efficiency decreases with the increase of the transmission distance, owing to the increase in the receiving aperture. Under weak-turbulence conditions, the gap between different Ω-value curves increases with the increase of receiving aperture.

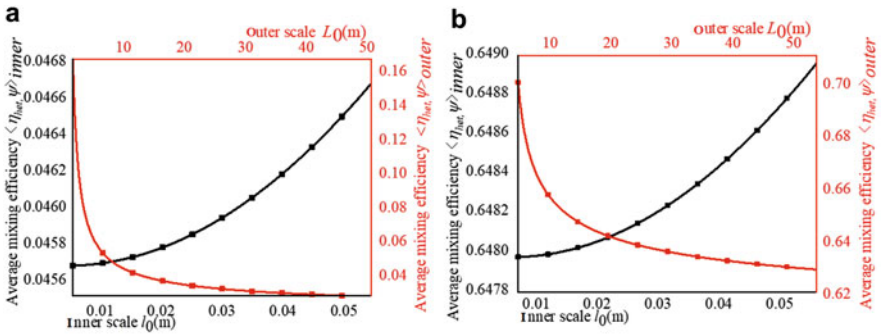

Fig. 21.3 Average mixing efficiency changes with internal/external turbulence scales under different atmospheric-turbulence intensities [60]. (**a**) $C_n^2 = 10^{-14}\ \mathrm{m}^{-2/3}$ (**b**) $C_n^2 = 10^{-16}\ \mathrm{m}^{-2/3}$

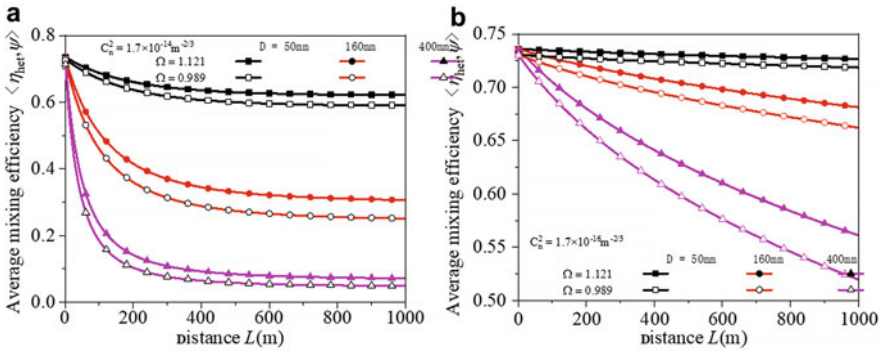

Fig. 21.4 Changes of the average mixing efficiency with transmission distance L under different turbulence conditions, when Ω and the receiving aperture have different values [60]. (**a**) $C_n^2 = 1.7 \times 10^{-14}\ \mathrm{m}^{-2/3}$ (**b**) $C_n^2 = 1.7 \times 10^{-16}\ \mathrm{m}^{-2/3}$

To suppress turbulence effects and improve the heterodyne efficiency of a coherent-detection system, an optical receiving system with an appropriately small diameter should be selected to meet the performance requirements of the communication system when realizing long-distance communication [60].

Effect of Amplitude Fluctuation on Coherent Detection Systems

The amplitude fluctuation affects the performance of an aberration detection system, and the influence is more complicated when phase and amplitude fluctuations coexist. Figure 21.5 shows the relationship diagram of the signal-to-noise ratio of heterodyne detection under the influence of amplitude fluctuation.

The variation of the SNR with the zenith angle is shown in Fig. 21.6, where Fig. 21.6a is the relation curve between the SNR and zenith angle under amplitude disturbance, and Fig. 21.6b is the relation curve between the SNR and zenith angle under amplitude and phase disturbances. The simulation results show that, with the

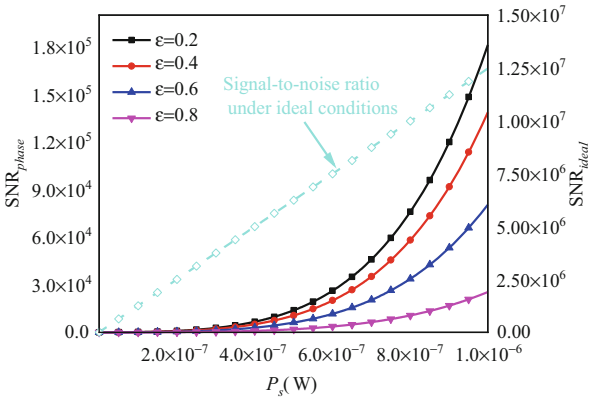

Fig. 21.5 Variation of the SNR with the signal optical power under ideal conditions and different occlusion ratios [61]

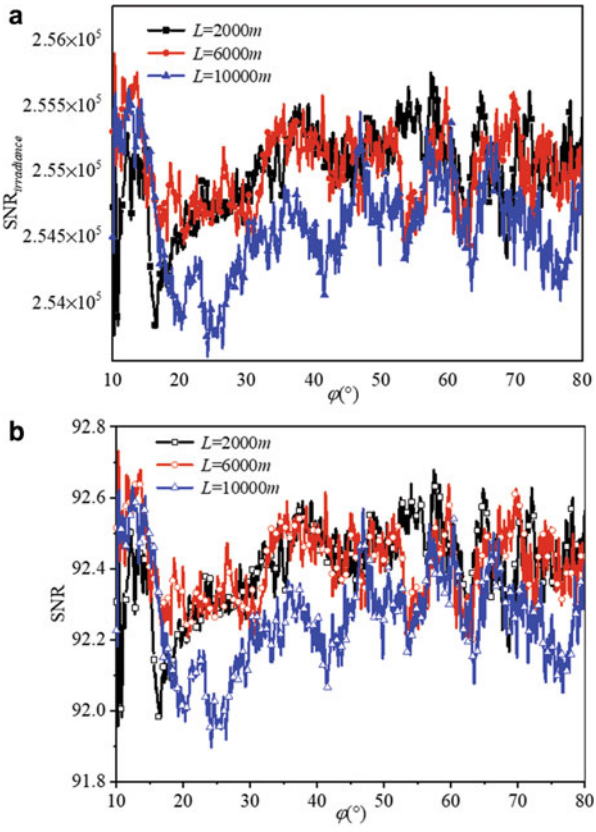

Fig. 21.6 Changes of SNR with the zenith angle under different disturbance conditions and transmission distances [61]. (**a**) Irradiance fluctuation (**b**) Irradiance and phase fluctuation

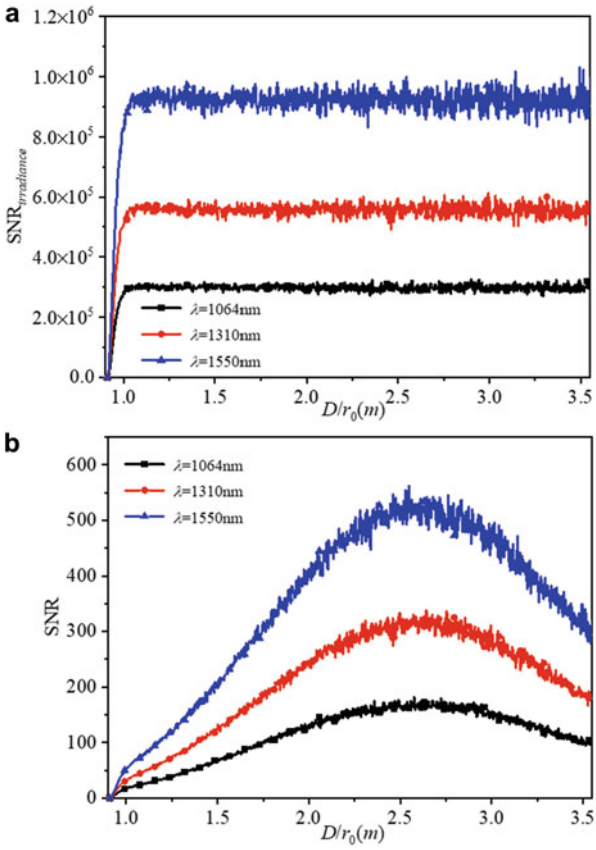

Fig. 21.7 Change of SNR with D/r_0. (**a**) Amplitude perturbation; (**b**) amplitude and phase perturbation [61]

increasing zenith angle, the signal-to-noise ratio of the heterodyne-detection system appears to fluctuate, but the overall trend is decreasing. This is because the distance the signal light travels in relatively strong turbulent regions increases as the zenith angle increases.

The variation of the SNR with atmospheric turbulence D/r_0 is shown in Fig. 21.7, where Figure 21.7a is the relation curve between the SNR and D/r_0 under an amplitude disturbance, and Figure 21.7b shows the relation curve between the SNR and D/r_0 under amplitude and phase disturbances. The simulation results show that the signal-to-noise ratio increases as the wavelength λ increases; therefore, the heterodyne-detection system should choose 1550 nm as the communication frequency band.

1.3-km Heterodyne-Detection System Experiment

The authors of Reference [61] established a 1.3-km heterodyne-detection communication link, and the system block diagram is shown in Fig. 21.8. At the transmitter end, a 1550-nm beam was used as the signal light. The source information was

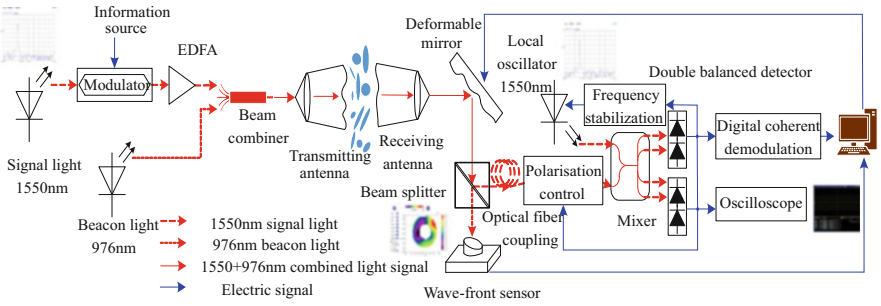

Fig. 21.8 Schematic diagram of the heterodyne-detection system

loaded onto the signal light through the phase modulator and fed into the transmitting optical system through an erbium-doped fiber amplifier (EDFA).

When transmitted in the atmospheric channel (1.3 km long), it was affected by turbulence, resulting in the dispersion of the received light spot and an increase in the system bit-error rate. In severe cases, the communication link might be interrupted [62]. Therefore, at the receiving end of the coherent-detection system, adaptive-optics (AO) technology was needed to correct the optical wavefront distortion of the signal [63].

After the correction, the signal light was mixed with the local oscillator light, and the baseband signal was recovered in real time using polarization control, laser-frequency stabilization, coherent detection, and digital coherent demodulation. The 1.3-km detection experiment was completed.

The experimental results showed that when the polarization control system closed the loop, the amplitude jitter caused by polarization obviously decreased, and the signal quality at the receiving end was effectively improved [61]. Under different weather conditions, the center frequency of the IF signal changed around 82 MHz, which was consistent with the control accuracy of the laser-frequency stabilization module [61]. After the AO system closed the loop, the quality of the IF signal was effectively improved, and the primary and secondary harmonics of the corrected IF signal power spectrum were “sharper” [64].

Figure 21.9 shows the variation of the IF signal amplitude measured by the 1.3-km detection experiment. As shown in Fig. 21.9a, the mixing efficiency under the influence of the polarization control increases by about 64%, and the coherence-detection efficiency is improved. The measured results in Fig. 21.9b are similar to those in Fig. 21.9a. The simulation results show that when the polarization control system closes the loop, the amplitude jitter caused by polarization obviously decreases, and the signal quality of the receiver is effectively improved.

Figure 21.10 shows the power-spectrum variation curve of the IF signal in open and closed loops of the AO system under different weather conditions. An analysis of the influence of heterodyne detection on the IF signals indicates that the AO system can effectively improve the IF signal quality after the closed loop, and the

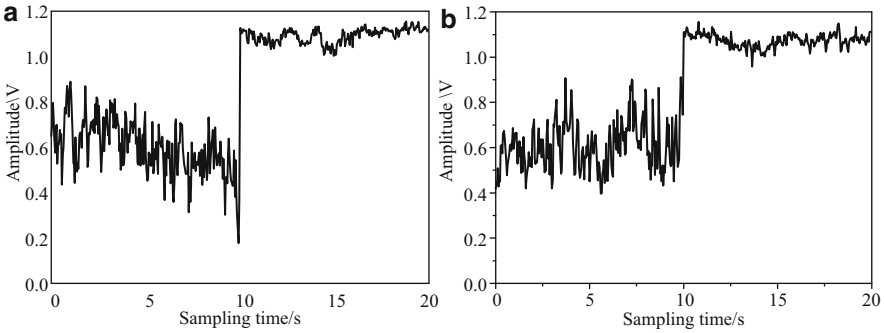

Fig. 21.9 Amplitude changes of the IF signal in open and closed loops of the polarization control system [61]. (**a**) 2018-04-23. (**b**) 2018-04-24

primary and secondary harmonics of the corrected IF signal power spectrum are "sharper" [64].

At the receiving end of the heterodyne-detection system, the IF signal light is mixed with the local oscillator light; the output is shown in Fig. 21.11. Figure 21.11a is the amplitude change curve of the IF signal, and Fig. 21.11b is the change curve of the power-spectrum analysis. The simulation results show that the center frequency of the IF signal changes around 82 MHz, which is consistent with the control precision of the laser-frequency stabilization module.

Analysis of a Coherent-Detection System Under the Influence of Channel Noise

Optical wireless coherent communication has a good effect on long-distance communication; however, it is generally affected by background optical noise, and affects the dry-detection efficiency of the receiving terminal. In addition, considering the influence of dark-current noise and electronic thermal noise [65], we focus on the noise statistical characteristics of the signal and various random circuit noises on the detection system, and estimate the performance.

Signal-to-Noise Ratio Analysis

Figure 21.12 shows the relationship curve between the signal-to-noise ratio and received optical power of the coherent-detection system. With the increase of the received optical power, the signal-to-noise ratios of coherent detection and direct detection under ideal conditions and direct detection affected by noise are compared and analyzed. The simulation results show that the signal-to-noise ratio of coherent detection is 4.1 dB higher than that of direct detection under ideal conditions, and the direct-detection signal-to-noise ratio exceeds nearly 23 dB under specific thermal noise and loose-particle noise.

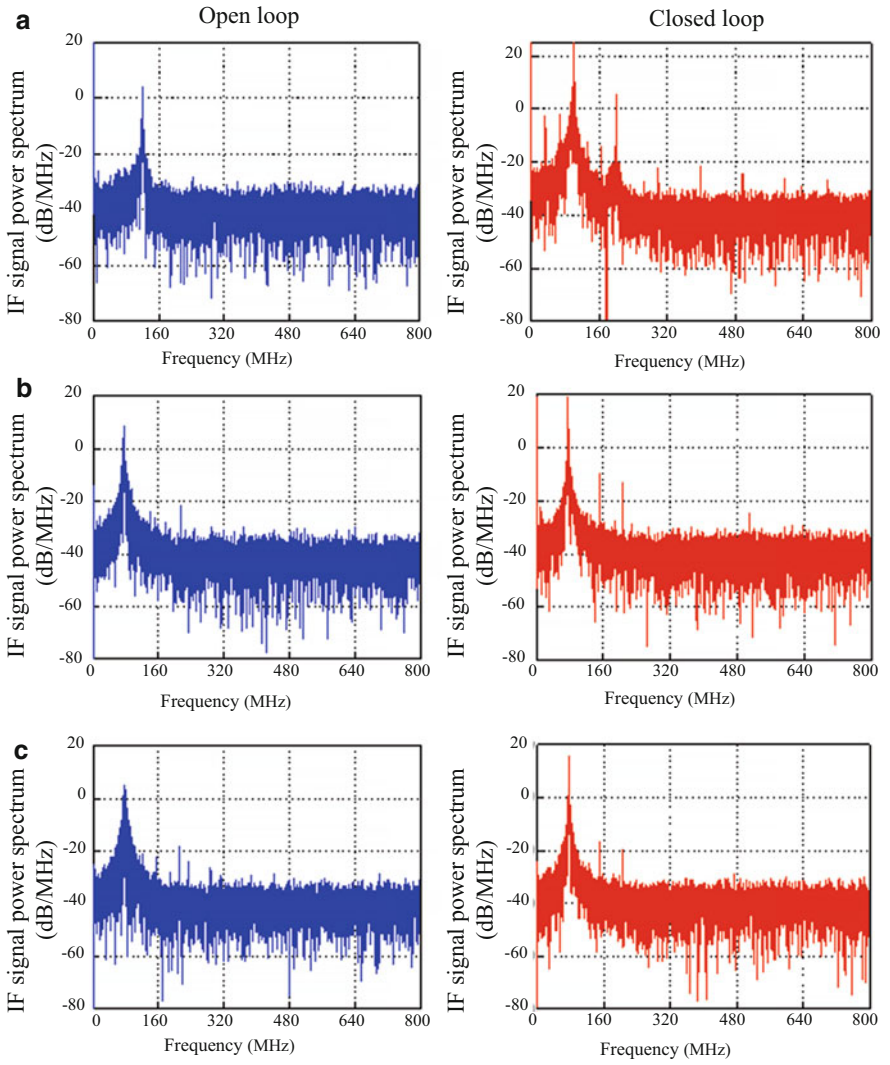

Fig. 21.10 Changes of the IF signal power spectrum in open and closed loops under different weather conditions [61]. (**a**) Cloudy, (**b**) sunny, (**c**) light rain

Analysis of the Influence of Relative-Intensity Noise

The constellation of different local lasers and relative-intensity noise (RIN) is shown in Fig. 21.13. Analysis results show that with the increase of RIN, the received signal-to-noise ratio decreases, the bit-error rate increases, and the coherence-detection efficiency is seriously affected. Under the same RIN influence, the coherence-detection efficiency decreases with the increase in local light power.

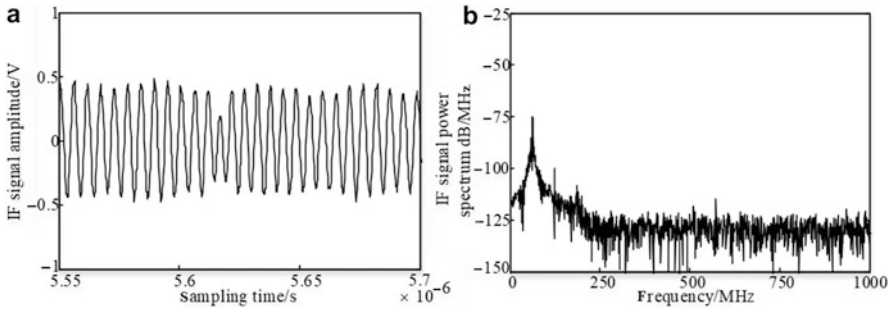

Fig. 21.11 IF signal output [61]. (**a**) The waveform of IF signal. (**b**) The power spectrum of IF signal

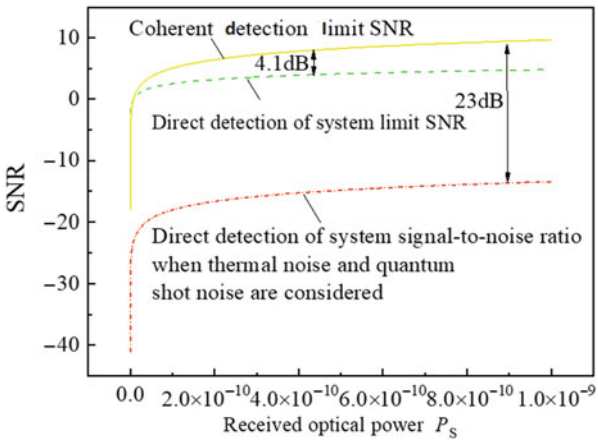

Fig. 21.12 Relationship between the received optical power and system SNR [66]

Thermal Noise–Effect Analysis

Figure 21.14 shows the QPSK demodulation signal constellation with different signal-to-noise ratios, when only thermal noise is considered. Figure 21.14a shows the constellation diagram of the QPSK demodulation signal when the signal-to-noise ratio is 30 dB. The constellation points at this time are easy to identify. Figure 21.14b corresponds to a signal-to-noise ratio of 10 dB.

When the signal-to-noise ratio in Fig. 21.14c is 1.5 dB, the constellation points are relatively dispersed, and the demodulation signal is seriously affected by noise. In Fig. 21.14d, in the case of the −1.5-dB signal-to-noise ratio, the distribution of the constellation points is very fuzzy, indicating that the dry-detection performance of the receiving terminal is seriously damaged. The analysis can be done when there is only thermal noise influence. When the signal-to-noise ratio decreases gradually, the degree of the constellation-map dispersion increases.

Analysis of the Influence of Optical-Signal Polarization on Coherent Detection Systems

The polarization of an optical signal has a direct influence on the coherent-detection system, and the polarization control algorithm also has a direct influence on the response time of the polarization control. This section introduces the advantages of the simulated annealing (SA), particle-swarm optimization (PSO), and single-particle optimization (SPO) algorithms, and compares them.

Advantages of the Three Algorithms

Figure 21.15 shows the optimization performance of the SA algorithm corresponding to V_{Pol} for different signal polarization-state change rates. As V_{Pol} decreases gradually, the IF-signal amplitude fluctuates less after convergence. When $V_{Pol} = 0$ rad/s, the amplitude fluctuation of the IF signal after convergence tends to stabilize with the increasing number of iterations, and the coherent-detection system shows good performance.

Figure 21.16 shows the optimization performance of the PSO algorithm corresponding to the polarization-state change rate of different signal lights V_{Pol}. With the increase in the number of iterations, the amplitude fluctuation of the IF signal stabilizes after convergence. Even if the polarization state of the signal light fluctuates, the PSO algorithm has better optimization performance.

The SPO algorithm was designed by combining the SA, PSO, and genetic algorithms. As shown in Fig. 21.17, in the face of rapid changes in the signal-light polarization state, the SPO algorithm shows a good control effect and can quickly stabilize the amplitude fluctuations of the intermediate-frequency signal [68].

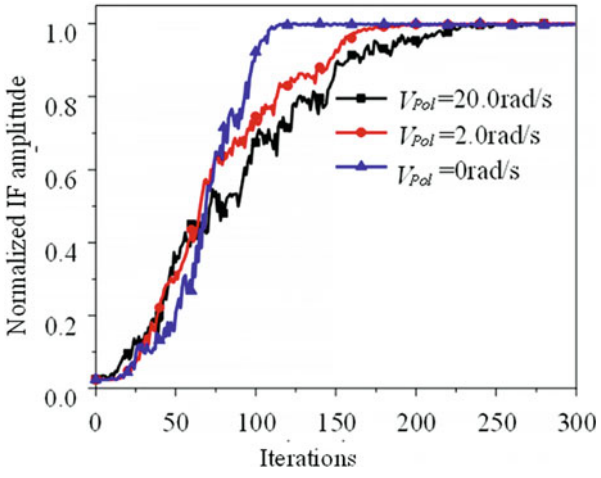

Fig. 21.15 Influence curve of the simulated annealing algorithm on the IF signal amplitude [67]

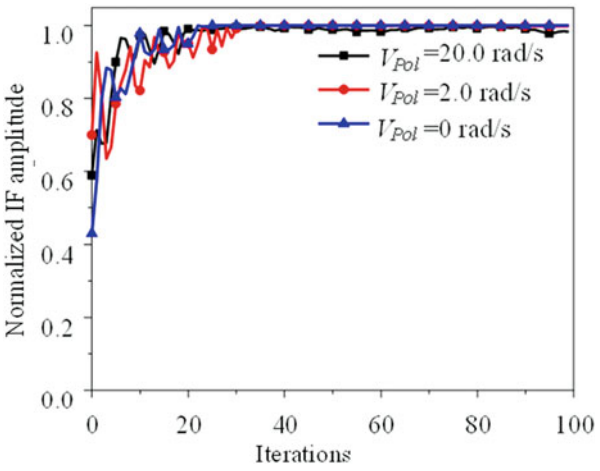

Fig. 21.16 Influence curve of the particle-swarm optimization algorithm on the IF signal amplitude [67]

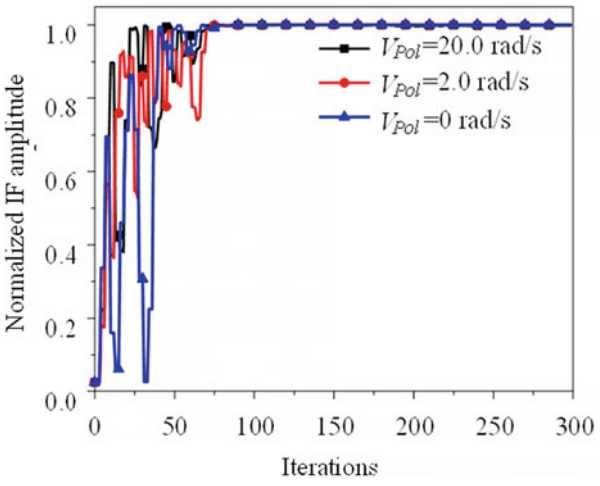

Fig. 21.17 Influence curve of the SPO algorithm on the amplitude of the IF signal [67]

Comparison of the Three Algorithms

From the perspective of the convergence time, the convergence speed of the SPO algorithm is much faster than that of the SA and PSO algorithms. This is mainly because the SA algorithm needs a large number of iterative operations to reach the optimum, and the existence of the second reset of the PSO algorithm makes it consume nearly twice the time in the control process [68].

In terms of the time required to reach the maximum IF signal amplitude, the SA algorithm requires the most convergence time, and the SPO algorithm has obvious advantages in convergence time compared with the others [67]. From the viewpoint

of parameter determination and algorithm complexity, the SPO algorithm is more complex than the SA and PSO algorithms.

Figure 21.18 compares and analyzes the IF-signal amplitude changes with the convergence time of the three algorithms. From the point of view of the time needed to reach the maximum amplitude of the IF signal, the SA algorithm needs the most convergence time. Compared with the SA and PSO algorithms, the SPO algorithm shows obvious advantages in convergence time.

To further verify the advantages of the SPO algorithm, we completed an experimental study of the SPO algorithm in a coherent-detection system. Figure 21.19 shows the experimental results. Figure 21.20a shows the amplitude change of the IF

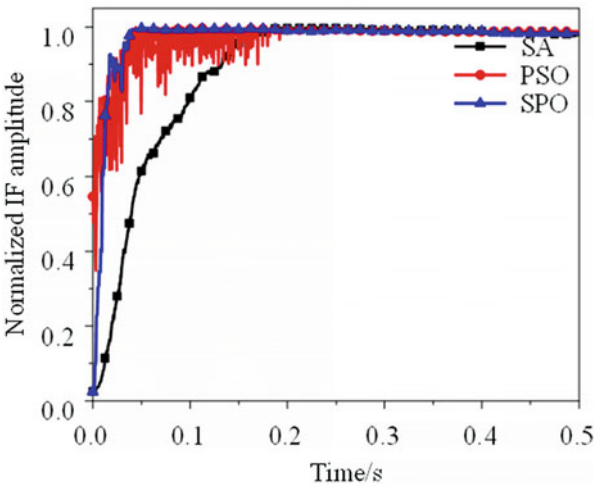

Fig. 21.18 Comparison of the convergence times of the three algorithms [67]

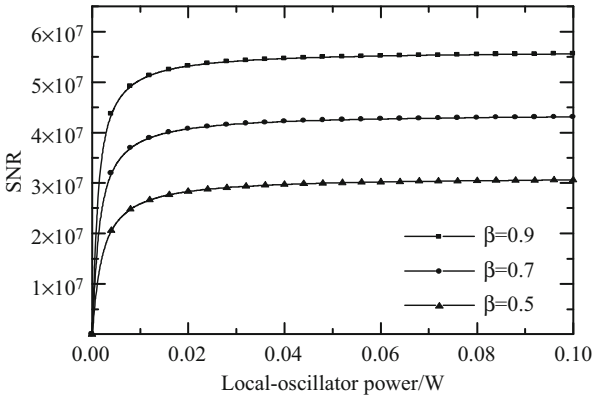

Fig. 21.20 Variation of the signal-to-noise ratio with local optical power [69]

signal output by oscilloscope when the polarization controller PLC-M02 is turned off. It can be seen that the IF signal amplitude changes to a cosine.

Figure 21.20b shows the amplitude change of the IF signal output by oscilloscope when the polarization controller PLC-M02 is turned on. The SPO algorithm is used. It can be seen that the amplitude of the IF signal is basically in a stable state, and the coherence gain at this time is the best.

Performance Analysis of the Light Source on a Coherent Detection System

Analysis of the Local-Vibration Optical Power on the Coherent-Detection System Performance

Figure 21.21 shows the influence curve of the local optical power on the signal-to-noise ratio of the coherent-detection system under ideal conditions. Along with the increase of the degree of response β, the coherent-detection system signal-to-noise ratio increases gradually. With a small change in the local light power, the signal-to-noise ratio of the coherent-detection system increases sharply to the maximum value and is no longer affected by the local light power. The analysis shows that the performance of the coherent-detection system will not change when the local power increases to a specific value.

Figure 21.21 shows the optical power of the coherent-detection system, considering the vibration output signal-to-noise ratio and the influence of the heterodyne current in a nonlinear state, when the parameters of α are not simultaneous [69]. As the α parameters increase gradually, the quantum-noise limited signal-to-noise ratio and heterodyne-detection efficiency decline. As the optical power of the vibration increases, the output current increases gradually, and with the increase of the α parameters, the output current decreases.

Figure 21.22 shows the optical power of the coherent-detection system of the vibration-output signal-to-noise ratio and the influence of the heterodyne current in a

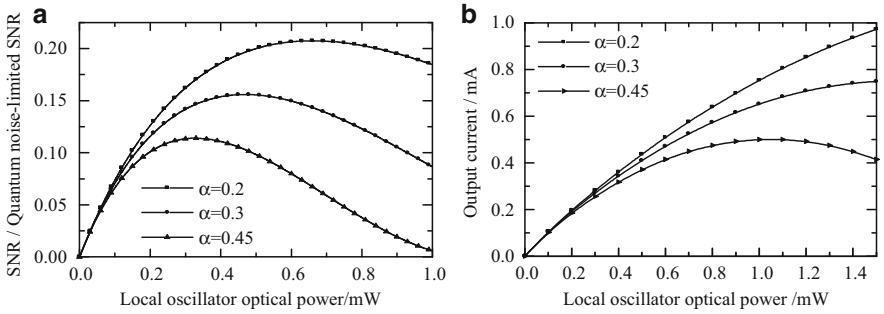

Fig. 21.21 α is not simultaneous when the receiver sensitivity varies with the vibration power relations [69]. (**a**) SNR versus the local oscillator power. (**b**) Output current versus the local oscillator power

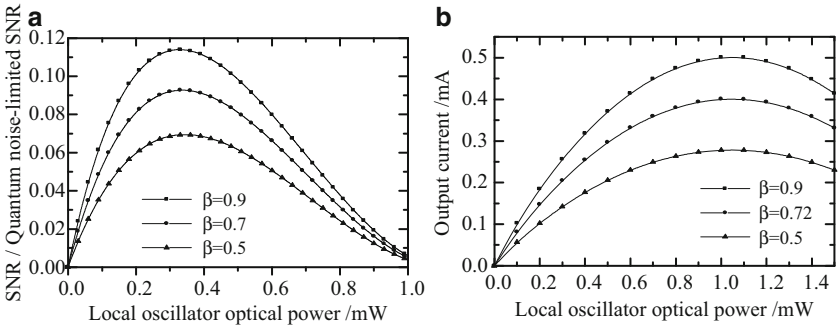

Fig. 21.22 Receiver sensitivity does not vary with the vibration power relations [69]. (**a**) SNR versus the local oscillator power. (**b**) Output current versus the local oscillator power

nonlinear state, when the responsivity β is not simultaneous [69]. With increase in the β response degree, the quantum-noise limit signal-to-noise ratio increases gradually. The output current increases gradually with the increase of the β response degree; in the light of the vibration power of 1 mW, it reached the maximum output current.

Analysis of the Light-Source Linewidth on the Performance of a Coherent Detection System

The small-linewidth drift of a laser will lead to a sharp increase in the transmission bit-error rate of a optical wireless coherent communication link, which has a great influence on the efficiency of coherent detection [70]. Figure 21.23 shows the influences of the light-source linewidth, atmospheric turbulence, transmission distance, and frequency-difference signal bandwidth on the transmission bit-error rate [71].

When the light-source linewidth, atmospheric-turbulence intensity, transmission distance, or bandwidth of the difference-frequency signal increase, the bit-error rate

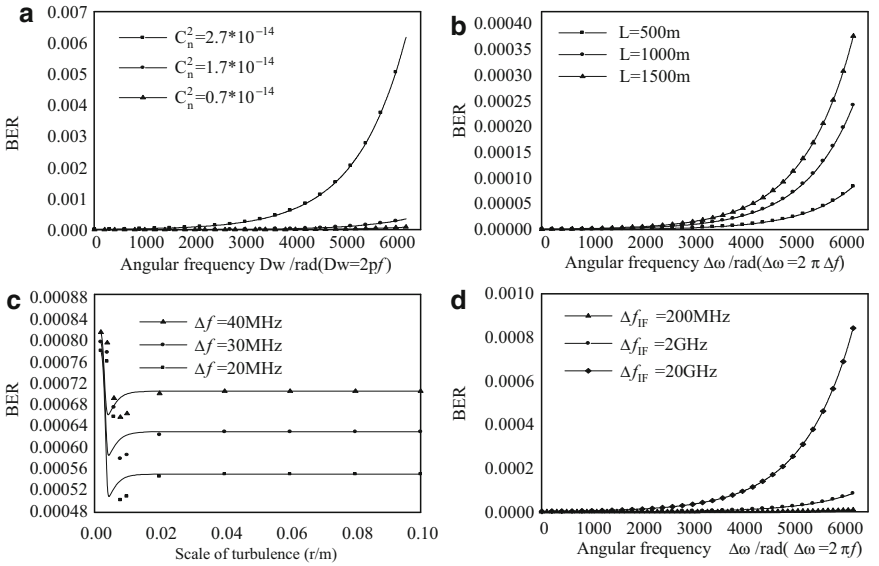

Fig. 21.23 Changing curve of the laser linewidth and BER [71]. (**a**) Laser linewidth effects on BER when turbulence intensity is not the same. (**b**) Laser linewidth effects on BER when transmission distance is not the same. (**c**) Turbulence scale effect on BER when line width is not the same. (**d**) Laser linewidth effects on BER when difference-frequency signal bandwidth is not the same

increases gradually. The simulation results show that the laser linewidth and turbulence intensity have different effects on the coherence-detection efficiency in optical wireless coherent communication systems.

Performance Analysis of a Subcarrier-Modulated (SCM) Nonoptical Outlier-Detection System

In this section, the effects of nonoptical outfield detection (NOD) on the sensitivity of the receiver in ideal and nonideal cases are analyzed.

Ideal-Channel NOHD

In an ideal channel, when an NOHD method using ASK, QPSK, hexadecimal phase-shift keying (16PSK), or other modulation modes is adopted for receiving, the power-change curve of the intermediate-frequency signal is obtained as shown in Fig. 21.24 [56]. These modulation modes all linearly amplify the sent signal, effectively improving the detection sensitivity. As shown in Fig. 21.25, from the signal eye plot after demodulation, when the ASK and QPSK modulation modes are adopted, the BER slope of the signal eye-plot contour is large and sensitive to timing errors. Using 16PSK modulation, the signal eye-map outline is clear. This indicates

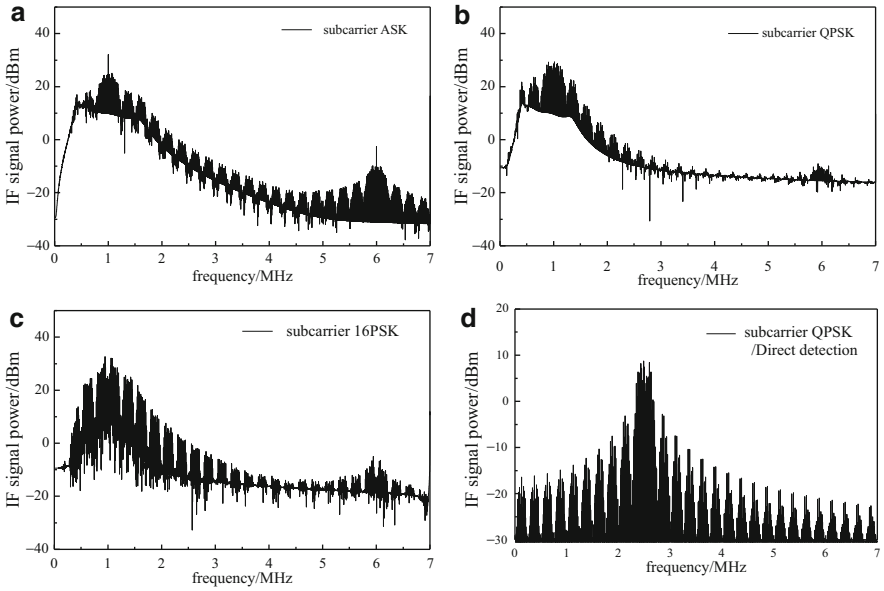

Fig. 21.24 Power spectrum of NOHD received and directly detected signals in an ideal channel with different subcarrier-modulation modes [56]. (**a**) SCM-ASK/NOHD. (**b**) SCM-ASK/NOHD. (**c**) SCM-ASK/NOHD. (**d**) SCM-ASK/NOHD

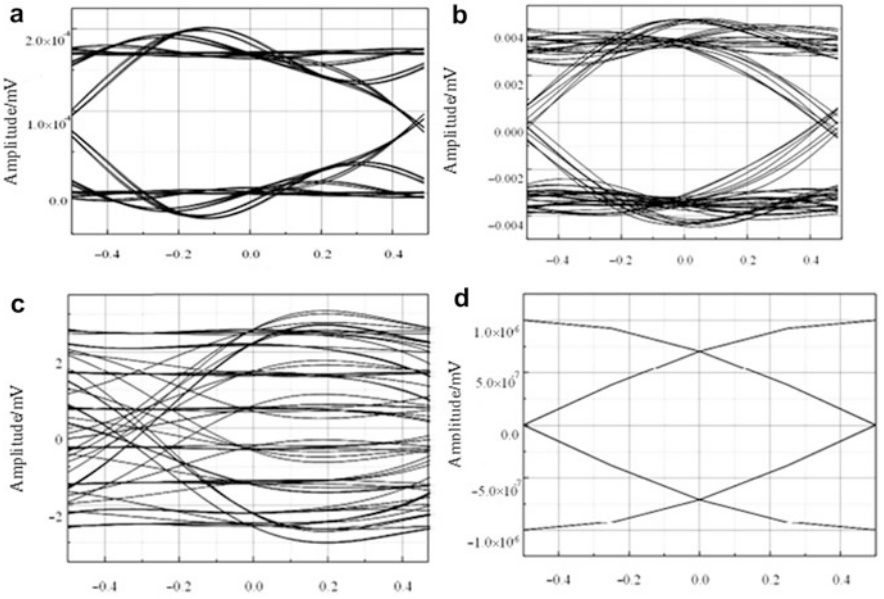

Fig. 21.25 Signal eyes for an ideal channel with different subcarrier-modulation modes under NOHD and direct detection [56]. (**a**) SCM-ASK/NOHD. (**b**) SCM-QPSK/NOHD. (**c**) SCM-16PSK/NOHD. (**d**) SCM-QPSK/DD

that the NOHD mode is suitable for optical-signal reception using various SCM modes.

Nonideal-Channel NOHD

The change curve of the signal-to-noise ratio of the receiver with relative-intensity noise is shown in Fig. 21.26 with Reference [56]. The analysis shows that when the relative-intensity noise is greater than −160 dB/Hz, the detection signal-to-noise ratio shows a decreasing trend, and the detection signal-to-noise ratio curve with a local power of 10 dBm is most seriously affected by the relative-intensity noise. In actual research and analysis, the detection signal-to-noise ratio of the system can be improved by reducing the relative-intensity noise.

Figure 21.27 shows that under the influence of different relative-intensity noise, when the local vibration-light power is greater than a specific value, the receiver's signal-to-noise ratio shows a downward trend, owing to the influence of the relative-intensity noise. The larger the relative-intensity noise, the smaller the signal-to-noise ratio of the receiver.

As shown in Fig. 21.28, when only the thermal noise of the receiver is considered, the signal-to-noise ratio of the receiver increases sharply with the increase in local optical power. When the local optical power is greater than 25 dBm, the signal-to-noise ratio of the receiver tends to stabilize. With the increase in signal optical power, the signal-to-noise ratio of the receiver shows an overall increasing trend, and with the increase of receiver bandwidth, the signal-to-noise ratio gradually decreases.

As shown in Fig. 21.29, when the lognormal distributed-channel model is adopted, in the case of weak turbulence, the received optical power is −30 dBm, the received signal-to-noise ratio is 9 dB, and the bit-error rate is 10^{-5}. This meets the requirements of optical wireless communication. With the increased variance of the light-intensity fluctuation, the average bit-error rate of the system increases gradually and tends to stabilize.

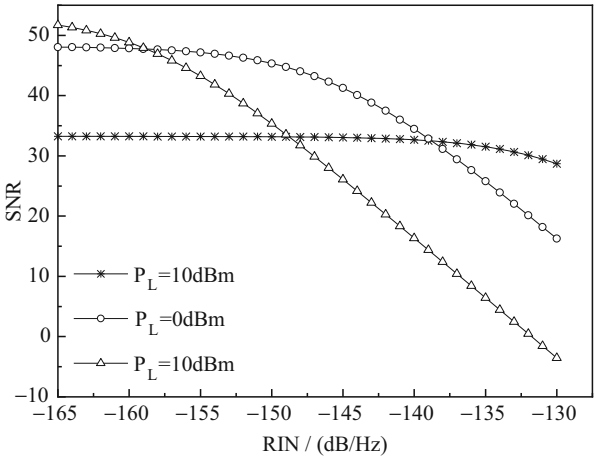

Fig. 21.26 Receiver SNR curve with relative-intensity noise (RIN) value [56]

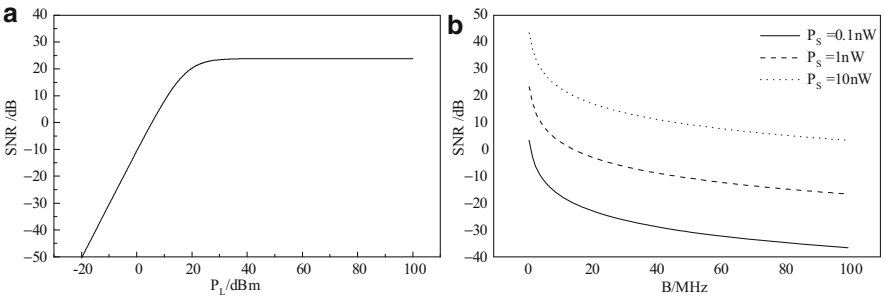

Fig. 21.28 SNR curve of the receiver under the influence of thermal noise [56]. (**a**) Variation of SNR with different values of local oscillator optical power. (**b**) Variation of SNR with different values of receiver bandwidth

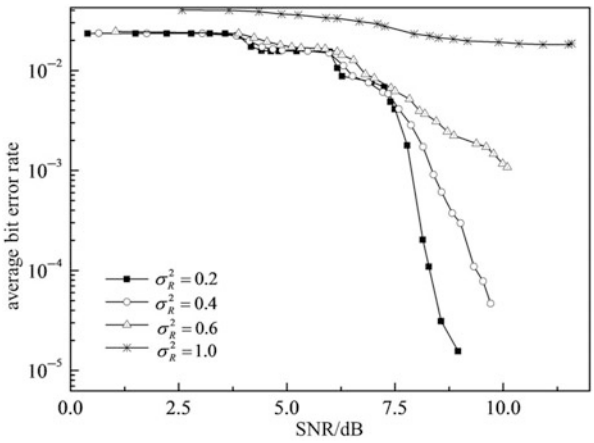

Fig. 21.29 Bit-error rate curve of a lognormal distributed channel under different intensity fluctuation variances [56]

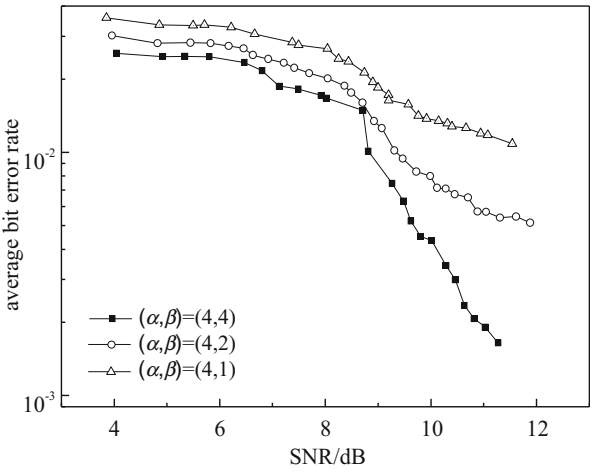

Fig. 21.30 Bit-error rate curves of a gamma–gamma channel with different turbulence intensities [56]

As shown in Fig. 21.30, for the SCM-QPSK/NOHD mode, the bit-error rate of the system increases with the increase of turbulence intensity in a gamma–gamma channel; that is, the phase noise introduced by the atmospheric channel will worsen the signal-to-noise ratio of the system.

NOHD System Experiment

The SCM/NOHD mode has a heterodyne gain approaching 20 dB [72]. As shown in Fig. 21.31, by comparing the NOHD received difference-frequency signal and the direct-detection signal of the SCM orthogonal frequency-division multiplexing (OFDM) signal and their power spectra, it can be seen that the time-domain waveform of the NOHD difference-frequency signal is less affected by noise, and the heterodyne gain of NOHD mode is about 19.2 dB higher than that of direct detection [56].

In the field of optical wireless coherence communication, to detect optical signals and improve the coherence gain, Professor Ke Xizheng's team at Xi'an University of Technology has conducted systematic analyses in the field of optical wireless coherence communication system detection.

1. Kong et al. [73] analyzed the effects of different optical-field distributions on the external difference efficiency under the influence of atmospheric turbulence. They proved that an Airy–Gauss distribution of a signal light and local-vibration light have the best turbulence-suppression effect.
2. Chen [56] proposed a new nonoptical outlier detection method, built an NOHD experimental system, and completed a 1-km communication experiment, proving that the system could obtain a heterodyne gain 20 dB higher than that of direct detection.

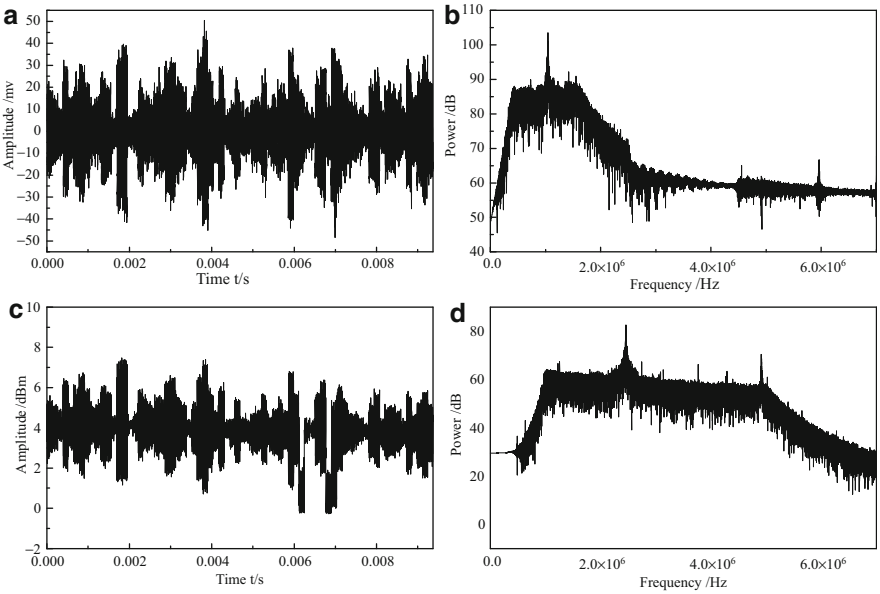

Fig. 21.31 Comparison of the subcarrier difference-frequency signal with the direct-detection signal and power spectrum [56]. (**a**) SCF-OFDM/NOHD, time domain waveform (**b**) SCF-OFDM/NOHD, power spectrum (**c**) SCF-OFDM/DD, time domain waveform. (**d**) SCF-OFDM/DD, power spectrum

3. Yang et al. [74] designed a system using a feedback control-loop circuit. The circuit made the carrier-frequency drift stability within ±2 MHz, and helped the receiver demodulation, which could tune the laser frequency to the laser-frequency tracking signal.
4. Chen [66] studied the change in receiving sensitivity of optical wireless coherent communication under the influence of turbulence, and built a new coherent-detection system. The system's gain was 20 dB higher than that of direct detection.
5. Wu [75] developed a wavefront sense-free heterodyne-detection communication system based on a stochastic parallel-gradient descent algorithm (SPGD). It improved the single-mode fiber coupling power of a optical wireless coherent communication link by about 25 dB.
6. Mao [76] studied the transmission characteristics of a beam in a optical wireless coherent communication system, and analyzed the polarization characteristics of the beam at the receiver, providing a theoretical basis for improving the gain at the receiver.
7. Tan [61] conducted a 1.3-km field experiment. When the IF signal voltage was greater than 260 mV, the bit-error rate was less than 10^{-6}, which effectively completed real-time communication.

8. Wang [77] designed a optical wireless coherence communication demodulation system based on heterodyne detection, and conducted video-transmission experiments with error rates less than 10^{-6} at 400 m and 1.3 km.
9. Ma [67] designed a polarization control scheme using intermediate-frequency signals as feedback signals, and proposed a polarization-control algorithm suitable for optical wireless coherent communication. Experimental results showed that the scheme improved the mixing efficiency by 64%.
10. Bai [78] set up an experimental platform for optical wireless coherence communication, and completed modulation and demodulation experiments of octal phase-shift keying (OPSK) signals at a bit-error rate of 10^{-3} by decoding QPSK intermediate-frequency signals. For details, see Table 21.2.

Color Difference of a Dual-Wavelength Free-Space Optical Communication System

In a free-space optical (FSO) communication system affected by a randomly fluctuating atmospheric refractive index, optical turbulence effects, such as phase distortion, light-intensity fluctuation, beam drift, and arrival-angle fluctuation will occur after a signal beam is transmitted through a free channel [79–81]. Based on real-time detection and correction, adaptive-optics technology can effectively suppress the influence of atmospheric turbulence on a signal light [82].

When the selected signal light has poor transmissibility or severe attenuation in an atmospheric channel, the system transmits a beacon light of other wavelengths through the common optical path with the signal light and detects the wavefront distortion of the beacon light to correct the wavefront distortion of the signal light [83]. However, when Gaussian beams of different wavelengths transmit through atmospheric channels, the angle of refraction and optical-path difference caused by turbulence are different, resulting in a wavefront-distortion difference between the signal light and beacon light, that is, a system color difference [84].

In recent years, extensive research has been conducted on the color difference in dual-wavelength free-space optical communication systems. From the beam-transmission point of view, when a Gaussian beam is transmitted in an atmospheric channel, it will be modulated by atmospheric turbulence and change the propagation direction of the wave vector, resulting in a random change in the beam-propagation direction. In the spatial-frequency domain, the randomly changed direction of the wave vector is constantly superimposed, causing the centroids of the beams in adjacent sampling periods to be in different positions, that is, arrival-angle fluctuation [85].

Italo established a scintillation model of an arrival angle under a non-Kolmogorov turbulence spectrum [86]. Voelz conducted a numerical analysis of the arrival angle of a light beam in strong and weak turbulence regions through ray tracing and wave optics [87]. Conan and Borgnino systematically analyzed the beam angle-of-arrival method on the receiving plane through a theoretical derivation and

Table 21.2 Research work in the field of coherent communication at Xi'an University of Technology

Researcher	Research contents	Research findings
Kong	The influence of atmospheric turbulence on heterodyne efficiency under different light-field distributions was studied	Proved that the Airy–Gauss distribution model had the best antiturbulence effect
Chen	A nonoptical heterodyne-detection method based on subcarrier modulation was proposed	The heterodyne gain of this detection method was about 20 dB higher than that of direct detection
Yang	To solve the problem of carrier-frequency drift, a feedback decision circuit was designed	This circuit stabilized the carrier-frequency drift within ± 2 MHz, which was helpful for demodulating at the receiver
Chen	A optical wireless coherent communication model was established and the influence of channel noise was analyzed	The simulation proved that the heterodyne-detection gain was 20 dB higher than the direct-detection gain
Wu	A wavefront sensorless heterodyne-detection system based on SPGD was designed	The system improved the coupling power of the single-mode optical fiber of a coherent communication link by about 25 dB
Mao	The beam-mode degeneration and polarization characteristics in coherent optical communication were studied	In an oblique-transmission downlink, the beam mode was least affected by turbulence
Tan	The influencing factors of heterodyne-detection performance in optical wireless coherent communication were studied	A 1.3-km video-transmission experiment was completed using the developed heterodyne-detection system
Wang	A demodulation system for radio-optical coherence communication based on heterodyne detection was designed	A video-transmission communication experiment was conducted with a bit-error rate of less than 10^{-6}
Ma	The polarization to frequency-mixing efficiency and a polarization-control algorithm were studied	A small step-backward reset algorithm was designed for polarization control in optical wireless coherent communication
Bai	The demodulation performance of an OPSK modulated optical wireless coherent communication system was verified	Modulation and demodulation experiments of an OPSK signal at a bit-error rate of 10^{-3} were completed

numerical calculation, and explained the spatiotemporal correlation and anisotropic variance of the angle-of-arrival fluctuation [88].

Akira described the correlation between dual-wavelength beams in a weak turbulent region through the cross-correlation power spectrum. Ben-Yosef experimentally measured the correlation coefficient of the light-intensity scintillation of

beams of different wavelengths [89]. Based on the above studies, to correct the color difference in dual-wavelength free-space optical communication systems, Shubenkova experimentally confirmed the correlation between the wavefront distortion of 530-nm and 1060-nm beams [90]. Fang proposed an adaptive-optics method to correct the arrival-angle fluctuation [91].

Kibblewhite designed a deforming mirror in an adaptive-optical system according to the fluctuating power spectrum of the beam arrival angle [92]. Lukin calculated the correction accuracy and efficiency of an adaptive-optical system when the wavelength of the beacon light was inconsistent with that of the signal light [93]. Jolissaint used a Shack–Hartmann wavefront sensor to measure the wavefront-distortion results after two-color laser transmissions in the atmospheric path, and revealed the correlation between different wavelength distortions [94]. Chen analyzed the correction residual of the wavefront fluctuation of different light waves in an adaptive-optical system, and gave the correction coefficient of the correction residual value between the wavefront fluctuations of the beacon and target [95].

The key to signal wavefront-distortion correction in dual-wavelength free-space optical communication is to determine the wavefront phase relationship between the signal light and beacon light. To correct the color difference in a dual-wavelength free-space optical communication system in a weak turbulence region, a certain phase relationship was obtained between the wavefront of a dual-wavelength beam through theoretical derivation. The expression of the relationship between the distortion phase of a Gaussian beam with different wavelengths was given. Finally, experiments were conducted to verify the conclusions of the study.

Correlation Function of Arrival-Angle Fluctuation at Different Wavelengths

After Gaussian beams with respective wavelengths of λ_1 and λ_2 are transmitted through the same atmospheric channel, the variances of the arrival angles between the beams at the receiving end are respectively α_{λ_1} and α_{λ_2}. The correlation between the two can be described by a cross-correlation function [96]:

$$\langle \alpha_{\lambda_1} \alpha_{\lambda_2} \rangle = \frac{F^2}{4k_1 k_2 w_0^2} \int d^4\rho \exp\left(-\frac{2\rho^2}{w_0^2}\right) \times \left\langle \frac{\partial s_1(F, \rho_1, \lambda_1)}{\partial \rho_1} \cdot \frac{\partial s_2(F, \rho_2, \lambda_2)}{\partial \rho_2} \right\rangle T\left(\vec{\rho}\right) \tag{21.1}$$

$$T\left(\vec{\rho}\right) = \begin{cases} 1 & \rho \le D \\ 0 & \rho > D \end{cases}, \tag{21.2}$$

where $F = \frac{z}{1+(z/f)^2}$ is the curvature radius of the beam wavefront, z is the transmission distance of the beam, f is the beam parameter, $k_1 = \frac{2\pi}{\lambda_1}$ and $k_2 = \frac{2\pi}{\lambda_2}$ are the wave vectors of the beam at different wavelengths, and ω_0 is the waist radius of the beam. D is the entrance-pupil diameter of the receiving optical system. $\rho = \rho_1 - \rho_2$

represents the distance between two points on the wavefront, ρ_1 and ρ_2; when $\rho = 0$, the two points coincide.

Equation (21.1) represents the ensemble average, and its specific expression is [97]

$$\left\langle \frac{\partial s_1(F,\rho_1,\lambda_1)}{\partial \rho_1} \cdot \frac{\partial s_2(F,\rho_2,\lambda_2)}{\partial \rho_2} \right\rangle = D_S''(\rho,\lambda_1,\lambda_2)\frac{\eta^2}{\rho^2} + D_S'(\rho,\lambda_1,\lambda_2)\left(1-\frac{\eta^2}{\rho^2}\right) \tag{21.3}$$

$$D_S = (L,\rho,\lambda_1,\lambda_2) = \frac{1}{1-h^2}\left[D_S(L,\rho,\lambda) - \frac{1}{h}D_x(Lh,\rho,\lambda)\right], \tag{21.4}$$

where $D_s(\rho,\ \lambda_1,\ \lambda_2)$ is a dual-frequency phase-structure function. $h = \frac{k_1-k_2}{k_1+k_2}$, $\lambda = \frac{2\pi}{k}$, $k = \frac{2k_1k_2}{k_1+k_2}$, D_x is the logarithmic-amplitude structure function, and $D_s(L,\ \rho,\ \lambda)$ is the phase-structure function.

Equations (21.2, 21.3, and 21.4) are substituted into Eq. (21.1), and the correlation function of the arrival-angle fluctuation of Gaussian beams with different wavelengths can be written as:

$$G_\alpha(Z,\lambda_1,\lambda_2) = \sigma_\alpha^2(\lambda_1,\lambda_2) = \frac{0.101\pi^2\Gamma(1/6)}{7.963\sqrt{2}}c_n^2F^3(zR)^{-1/3} \times \frac{16}{17} \times \mathrm{Re}\left[\frac{F\left(1,1/6,23/6,\frac{1}{1+ig_1}\right)}{(1+ig_1)^{1/6}} + \frac{F\left(1,1/6,23/6,\frac{1}{1+ig_2}\right)}{(1+ig_2)^{1/6}}\right], \tag{21.5}$$

where $g_1 = \frac{F(k_1+k_2)}{k_1k_2\alpha_0^2}$, $g_2 = \frac{F(k_1-k_2)}{k_1k_2\alpha_0^2}$, $F(a,\ b,\ c,\ z)$ is the Gaussian hypergeometric function, R is the equivalent curvature radius of the wavefront, and C_n^2 is the atmospheric refractive-index structure constant.

Different Wavelength Arrival-Angle Compensation Coefficients

In a dual-wavelength free-space optical communication system, the ratio function B of the variance of the arrival-angle fluctuation of different wavelengths is defined as the arrival-angle correction coefficient of the signal light to the beacon light. When a Gaussian beam is transmitted on a near-ground horizontal path with the Kolmogorov spectrum and internal turbulence scale satisfying $l_0 \le \sqrt{\lambda L}$ in a weak turbulent region, the variance of the arrival-angle fluctuation can be expressed as [98]

$$\sigma_\alpha^2 = \frac{0.101\pi^2\Gamma(1/6)}{8\sqrt{2}}C_n^2F^3(2\alpha_0)^{-1/3}\left\{1 + \frac{16}{17}\mathrm{Re}\left[\frac{F\left(1,1/6,\frac{23}{6},\frac{1}{1+ig}\right)}{(1+ig)^{1/6}}\right]\right\}, \tag{21.6}$$

where $g = \frac{2F}{k\alpha_0^2}$. The variance-compensation coefficient B of the arrival-angle fluctuation of different wavelengths is defined as

$$B = \frac{\sigma^2{}_{\lambda_1}}{\sigma^2{}_{\lambda_2}} = \frac{\frac{0.101\pi^2\Gamma(1/6)}{8\sqrt{2}} C_n^2 F_{\lambda_1}^3 \left(2\alpha_{0_{\lambda_1}}\right)^{-1/3} \left\{1 + \frac{16}{17}\,\mathrm{Re}\left[\frac{F\left(1, \frac{1}{6}, 23/6, \frac{1}{1+ig_1}\right)}{\left(1+\frac{1}{1+ig_{\lambda 1}}\right)^{1/6}}\right]\right\}}{\frac{0.101\pi^2\Gamma(1/6)}{8\sqrt{2}} C_n^2 F_{\lambda_2}^3 \left(2\alpha_{0_{\lambda_2}}\right)^{-1/3} \left\{1 + \frac{16}{17}\,\mathrm{Re}\left[\frac{F\left(1, \frac{1}{6}, 23/6, \frac{1}{1+ig_{\lambda 2}}\right)}{\left(1+\frac{1}{1+ig_{\lambda 2}}\right)^{1/6}}\right]\right\}}, \tag{21.7}$$

where

$$B_1 = \frac{C_n^2 F_{\lambda_1}^3 \left(2\alpha_{0_{\lambda_1}}\right)^{-1/3}}{C_n^2 F_{\lambda_2}^3 \left(2\alpha_{0_{\lambda_2}}\right)^{-1/3}} \tag{21.8}$$

$$B_2 = \frac{\left\{1 + \frac{16}{17}\,\mathrm{Re}\left[\frac{F\left(1, \frac{1}{6}, 23/6, \frac{1}{1+ig_1}\right)}{\left(1+\frac{1}{1+ig_1}\right)^{1/6}}\right]\right\}}{\left\{1 + \frac{16}{17}\,\mathrm{Re}\left[\frac{F\left(1, \frac{1}{6}, 23/6, \frac{1}{1+ig_{\lambda 2}}\right)}{\left(1+\frac{1}{1+ig_{\lambda 2}}\right)^{1/6}}\right]\right\}}. \tag{21.9}$$

Then, Eq. (21.7) can be simplified as

$$B = B_1 \cdot B_2. \tag{21.10}$$

Substituting the expression of F, α_0 into Eq. (21.8) yields

$$B_1 = \frac{F_{\lambda_1}^3}{F_{\lambda_2}^3} \cdot \frac{\left(2\alpha_{0_{\lambda_1}}\right)^{-1/3}}{\left(2\alpha_{0_{\lambda_2}}\right)^{-1/3}} = \frac{\left[1 + \frac{z^2\lambda_2^2}{\pi^2\omega_0^4}\right]^{7/6}}{\left[1 + \frac{z^2\lambda_1^2}{\pi^2\omega_0^4}\right]^{7/6}}. \tag{21.11}$$

After the reverse Maclaurin-series transformation of Eq. (21.11), we obtain

$$B_1 = \left\{\frac{[2(e^{qx_2} - qx_2) + 1]}{[2(e^{x_2} - x_2) + 1]}\right\}^{6/7}, \tag{21.12}$$

where $q = \frac{\lambda_1}{\lambda_2}$ and $x_2 = \frac{z\lambda_2}{\pi\omega_0^2}$. The Gauss hypergeometric function in Eq. (21.9) is expanded into a Mellin–Barnes integral expression, and the ratio M of the two Gaussian hypergeometric functions is calculated as:

$$M = \frac{\mathrm{Re}\left[F\left(1, \frac{1}{6}, 23/6, \frac{1}{1+ig_1}\right)\right]}{\mathrm{Re}\left[F\left(1, \frac{1}{6}, 23/6, \frac{1}{1+ig_2}\right)\right]} = \int \left(\frac{g_2}{g_1}\right)^s ds. \tag{21.13}$$

We set $y = \frac{g_2}{g_1}$, according to the effective condition of a Gauss hypergeometric function on the residue integral domain. Then, the calculation result of Eq. (21.13) is

$$M = \int (y)^s ds = \frac{y-1}{\log(y)}, \tag{21.14}$$

where $y = \frac{k_1 - k_2}{k_1 + k_2}$. According to Eqs. (21.9) and (21.14), the expression of B_2 can be written as:

$$B_2 = M + \frac{1-M}{1 + \frac{16}{17}\,\mathrm{Re}\left[F\left(1, \frac{1}{6}, 23/6, \frac{1}{1+ig_2}\right)\right]}. \tag{21.15}$$

In the absence of system delays and mechanical-vibration errors, Eq. (21.7) is the proportional relation between the variance of the arrival-angle fluctuation of the signal light with wavelength λ_1 and the beacon light with wavelength λ_2 in a dual-wavelength free-space optical communication system.

Phase Relationship Between Gaussian Beams of Different Wavelengths

As shown in Fig. 21.32, the incident light is incident forward along the z axis, and the entire wavefront is distributed within the XOY plane. The wavefront measuring

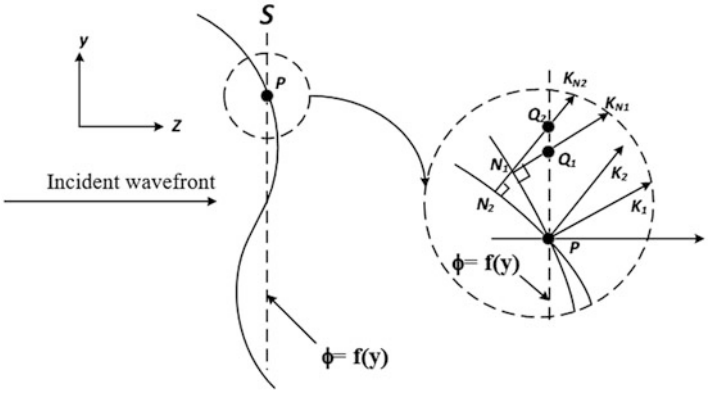

Fig. 21.32 Schematic diagram of the incident-wavefront section

surface S is perpendicular to the z axis, and the phase-distribution function of the incident light at the position of the measuring line is wave $\varphi = f(y)$.

Point P is a point on the measured wave surface. Owing to the phase distortion of the wavefront, there is a phase difference between point P on the wave surface and a nearby position. It is assumed that the wavelength of the signal light is λ_1 and the wavelength of the beacon light is λ_2. Points N_1 and N_2 are selected near point P along the equiphase plane of the two beam wavefronts, respectively. The distance between the two points PN_1 and PN_2 is ρ, and the transmission distance of the beam is L [99].

The vertical lines of the isophase plane of the beam of two wavelengths are made at points N_1 and N_2, respectively; that is, the propagation directions of the wave surface at points N_1 and N_2 are K_{λ_1} and K_{λ_2}, respectively. The two propagation vectors intersect the measuring plane S at points Q_1 and Q_2, respectively.

When ρ is small and approaches 0, triangles N_1Q_1P and N_2Q_2P can be considered as right triangles. Then, the phase difference between two points Q_1P and Q_2P is the wavefront phase difference corresponding to the beacon light and signal light, respectively. The wavefront phase difference of the corresponding signal is φ_{λ_1} and the wavefront phase difference of the beacon is φ_{λ_2}. Under the above conditions, the wavefront-distortion phases of the signal light and beacon light can be expressed as

$$\varphi_{\lambda_2} = \varphi_p - \varphi_Q = \frac{2\pi}{\lambda_2} N_2Q_2 = \frac{2\pi}{\lambda_2}\left(n_p - n_Q\right)L \tag{21.16}$$

$$\varphi_{\lambda_1} = \varphi_p - \varphi_{Q1} = \frac{2\pi}{\lambda_1} N_1Q_1 = \frac{2\pi}{\lambda_1}\left(n_p - n_{Q1}\right)L. \tag{21.17}$$

Because the signal light and beacon light are transmitted along the same path, the refractive index of air varies the same between corresponding points, so

$$n_p - n_{Q1} = n_p - n_{Q2}. \tag{21.18}$$

When the signal light and beacon light are transmitted in the same atmospheric channel, the random variation of the refractive index in atmospheric turbulence has different modulation effects on Gaussian beams of different wavelengths. There is also some difference between the wavefront fluctuation distortion; that is, the phase difference between PQ_2 and PQ_1 is different, and the corresponding wavefront-distortion phase difference is

$$\begin{aligned} \Delta &= \left|\varphi_{\lambda_1} - \varphi_{\lambda_2}\right| \\ &= \left|\left(\varphi_p - \varphi_Q\right) - \left(\varphi_p - \varphi_{Q1}\right)\right| \\ &= 2\pi\left(n_p - n_Q\right)L\left|\frac{\lambda_1 - \lambda_2}{\lambda_1\lambda_2}\right|. \end{aligned} \tag{21.19}$$

Then, the relationship between the phase of the signal-light front φ_{λ_1} and the phase of the beacon-light front φ_{λ_2} at point P is

$$\varphi_{\lambda_1} = \frac{\frac{2\pi}{\lambda_2}(n_p - n_Q)L \pm \Delta}{\frac{2\pi}{\lambda_2}(n_p - n_Q)L} \cdot \varphi_{\lambda_2}. \tag{21.20}$$

Equations (21.18) and (21.19) are substituted into Eq. (21.20), and the relationship between the phase distortion of Gaussian beams with different wavelengths is as follows:

$$\varphi_{\lambda_1} = \left(\frac{\lambda_2}{\lambda_1} \pm \left|\frac{\lambda_1 - \lambda_2}{\lambda_1 \lambda_2}\right|\right)\varphi_{\lambda_2}. \tag{21.21}$$

According to this relation, the wavefront-distortion phase difference of the beam with different wavelengths can be calculated, based on the known wavelength of the signal light and beacon light, the transmission distance L of the beam, and the change of refractive index. The wavefront-distortion measurement value of the signal light can also be calculated according to the wavefront-distortion measurement value of the beacon light.

Wavefront-Distortion Correction for Dual-Wavelength Free-Space Optical Communication Systems

The correction matrix is calculated according to the quantitative relationship between the wavefront-distortion phase of a Gaussian beam with a different wavelength, and the wavefront-reconstruction matrix of the beacon is corrected, so that the wavefront-reconstruction matrix of the signal light is obtained to correct the signal light. The distorted wavefront $W(x, y)$ can be expressed as follows:

$$W(x,y) = W^{'}(x,y) - W_0(x,y) = \sum_{j=0}^{j=\max} W_j Z_j(x,y), \tag{21.22}$$

where Z_j is a Zernike polynomial, W_j is the coefficient of the Zernike polynomial, and j is the order of the Zernike polynomial. $W(x, y)$ is used to measure the wavefront and $W_0(x, y)$ represents the reference-plane wavefront. The difference between the two produces the distorted wavefront. A Gaussian beam with wavelength λ_2 is emitted as a common optical path of the beacon light and the signal light with wavelength λ_1. A Shack–Hartmann wavefront sensor measures the beacon-light wavefront to obtain the beacon-light gradient matrix containing the distortion:

$$\begin{bmatrix} b_{\lambda_2}(x,y)|_1 \\ b_{\lambda_2}(x,y)|_2 \\ \vdots \\ b_{\lambda_2}(x,y)|_k \\ c_{\lambda_2}(x,y)|_1 \\ c_{\lambda_2}(x,y)|_2 \\ \vdots \\ c_{\lambda_2}(x,y)|_k \end{bmatrix} = \begin{bmatrix} g_1(x,y)|_1 & g_2(x,y)|_1 & \cdots & g_{j\max}(x,y)\Big|_1 \\ g_1(x,y)|_2 & g_2(x,y)|_2 & \cdots & g_{j\max}(x,y)\Big|_2 \\ & & \vdots & \\ g_1(x,y)|_k & g_2(x,y)|_k & \cdots & g_{j\max}(x,y)\Big|_k \\ h_1(x,y)|_1 & h_2(x,y)|_1 & \cdots & h_{j\max}(x,y)\Big|_1 \\ h_1(x,y)|_2 & h_2(x,y)|_2 & \cdots & h_{j\max}(x,y)\Big|_2 \\ & & \vdots & \\ h_1(x,y)|_k & h_2(x,y)|_k & \cdots & h_{j\max}(x,y)\Big|_k \end{bmatrix} \cdot \begin{bmatrix} W_1 \\ W_2 \\ \vdots \\ W_{j\max} \end{bmatrix}, \tag{21.23}$$

where $\frac{\Delta x(x,y)}{f}_{\lambda_2}\Big|_k = b_{\lambda_2}(x,y)|_k$ and $\frac{\Delta y(x,y)}{f}_{\lambda_2}\Big|_k = c_{\lambda_2}(x,y)|_k$. According to Eq. (21.21), we calculate the offset gradient of the Gaussian-beam distortion with two different wavelengths on the sensor measurement surface, and the following relation can be obtained:

$$\frac{\Delta x(x,y)}{f}_{\lambda_1}\Big|_k = \frac{1}{\gamma} \cdot \frac{\Delta x(x,y)}{f}_{\lambda_2}\Big|_k = b_{\lambda_1}(x,y)|_k \tag{21.24}$$

$$\frac{\Delta y(x,y)}{f}_{\lambda_1}\Big|_k = \frac{1}{\gamma} \cdot \frac{\Delta y(x,y)}{f}_{\lambda_2}\Big|_k = c_{\lambda_1}(x,y)|_k, \tag{21.25}$$

where $\frac{1}{\gamma} = \frac{\lambda_2}{\lambda_1} \cdot \left(\cos A\theta_2 + \frac{\sin A\theta_2}{\tan\theta_2}\right)$. According to this relation, a coefficient correction matrix can be obtained:

$$\gamma = \begin{bmatrix} \gamma_1 & 0 \cdots 0_k \\ 0 & \gamma_2 \cdots 0_k \\ & \ddots \\ 0\ 0 & \cdots \gamma_k \end{bmatrix}. \tag{21.26}$$

The wavefront-reconstruction matrix of the beacon light is obtained by multiplying it by the coefficient-correction matrix. In the AO control system, beacon-light wavefront-reconstruction matrix and beacon-light wavefront-reconstruction matrix obtained after correction are, respectively, used to correct the signal-light wavefront distortion. The signal-light Strehl ratio (SR) and three-dimensional light spot of the beam are obtained, as shown in Fig. 21.33.

Figure 21.33 shows the SR-value change curve of the system in the correction process. (a) is the SR curve when the distorted beacon-light wavefront is directly used to correct the signal-light wavefront distortion. (b) is the SR curve when the

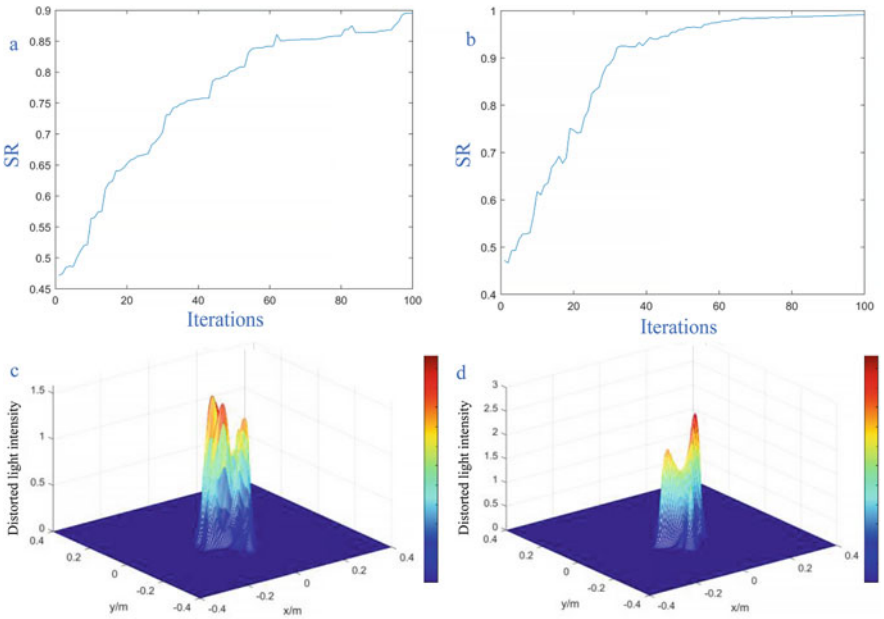

Fig. 21.33 Distorted beacon-light front. Corrected distorted signal-light front. (**a**, **c**) Without the correction coefficient; (**b**, **d**) with the wavefront-correction coefficient

wavefront distortion of the beacon is corrected by the wavefront phase matrix modified by Eq. (21.21) to correct the wavefront distortion of the signal.

As can be seen from the figure, the corrected SR ratio of the wavefront reconstructed matrix after correction converges to 1, and the overall SR ratio increases by 10%; the wavefront reconstructed matrix converges to 0.9 before correction. When correcting the signal light after correcting the beacon-light wavefront-distortion matrix, the SR of the system converges quickly, and tends to stabilize when the number of iterations is 80. The jitter of the SR is obviously reduced, which verifies the correctness of the phase relationship between the signal light and the beacon-light wavefront derived from Eq. (21.21).

Experimental Results and Analysis

The experimental schematic diagram is shown in Fig. 21.34. The signal light and beacon light are transmitted through the common optical path of the beam synthesizer, then through the same atmospheric channel, reflected by the plane mirror, and transmitted to the receiving antenna on the fifth and seventh floors.

After the beam combination, the beam is reflected by the deformable mirror and the reflector and then incident on the beam-splitter mirror. The beam-splitter mirror separates the signal light and beacon light, and the wavefront sensor, respectively, detects the wavefront distortion of the beacon light and signal light. After adaptive-

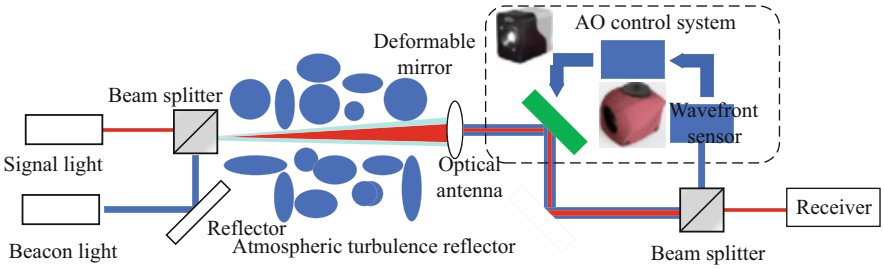

Fig. 21.34 Schematic diagram of experimental structure

Table 21.3 Parameters of the experimental equipment

Equipment	Model number	Parameter
Wavefront sensor	THORLABS-HASO4-NIR	Wavelength range: 1500–1600 nm Subaperture parameter: 32 × 40
Wavefront sensor	THORLABS-HASO4-FIRST	Wavelength range: 400–1100 nm Subaperture number: 32 × 40
Beacon laser light source	MW-GX-650	Wavelength: 650 nm, linewidth: 0–3 nm, output power: 35 mW
Signal laser source	KOHERA-BASIK Module	Wavelength: 1550 nm, linewidth: 0.1 kHz, output power: 0–200 mW
Deformable mirror	ALPAO-DM	Number of deformed mirrors: 69, effective aperture: 10.5 mm Frequency: 800 Hz
Optical antenna	Maksutov–Cassegrain	Diameter: 25 mm, focal length: 300 mm
Laser collimator	F810APC	Wavelength: 1550 nm/650 nm, focal length: 37.13 mm

PID algorithm control, the optical wavefront-distortion of the signal is corrected [19]. Table 21.3 shows the corresponding experimental instrument parameters.

After the AO system captures the beacon light, the wavefront detector measures its gradient matrix, generates the wavefront-reconstruction matrix, and uses it to correct the signal optical-wavefront distortion. The wavefront peak–valley (PV) value and the wavefront phase-fluctuation RMS value of the signal light before and after correction are shown in Figs. 21.35 and 21.36, respectively.

The mean value of the wavefront PV value of the signal light is 2.08 μm and the variance of the PV value is 0.90 μm^2 after directly correcting the signal-light distortion data. The mean RMS of the wavefront fluctuation is 0.40 μm^2, and the variance of the wavefront fluctuation is 0.04 μm^2. Then, the wavefront-reconstruction matrix of the beacon light is multiplied by the coefficient-correction matrix to obtain the wavefront-reconstruction matrix of the signal light. The AO system corrects the wavefront of the signal light according to its wavefront-reconstruction matrix, and obtains the wavefront PV value and wavefront phase-fluctuation RMS value of the signal light, as shown in Fig. 21.36.

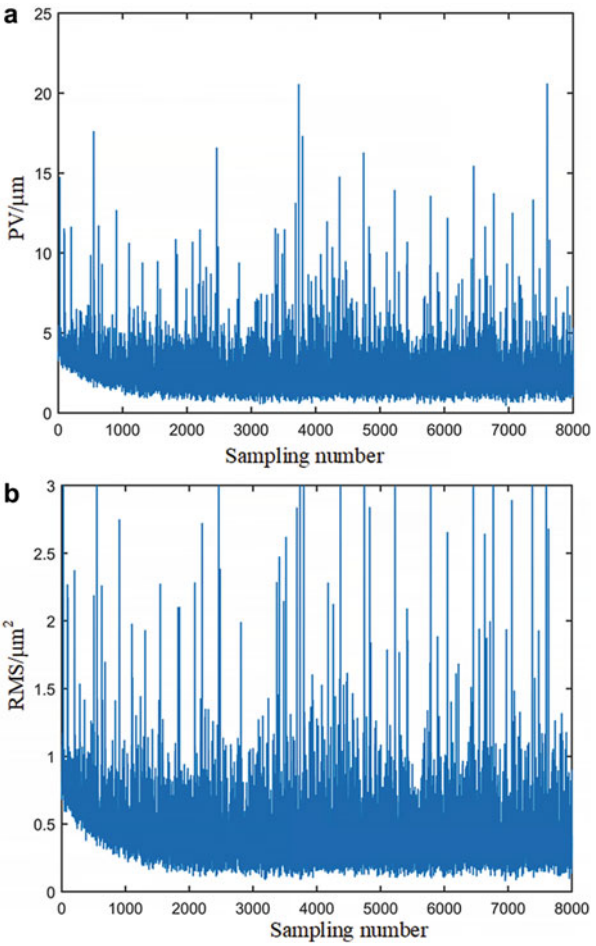

Fig. 21.35 Beacon-light correction signal. (**a**) Wavefront PV-value change curve; (**b**) change curve of wavefront RMS value

The mean PV value and variance of the signal wavefront are 2.05 μm and 0.46 μm^2, respectively, after correcting the signal wavefront using the beacon light–corrected wavefront-reconstruction matrix. The mean RMS of the wavefront phase fluctuation is 0.35 μm^2, and the variance of the RMS of the wavefront phase fluctuation is 0.01 μm^2. Compared with the wavefront-reconstruction matrix, the variance of the wavefront PV value decreased by 49.05% and the variance of the wavefront phase-fluctuation RMS decreased by 35.58% in the signal optical-reconstruction matrix correction mode.

The color difference of an adaptive optical system is a systematic error caused by the inconsistency between the wavelength of the system signal light and that of the beacon light. In this chapter, the correlation between the arrival-angle fluctuations of different wavelengths is analyzed. Moreover, the correlation between the number function of the correlation between the arrival-angle fluctuations of Gaussian beams

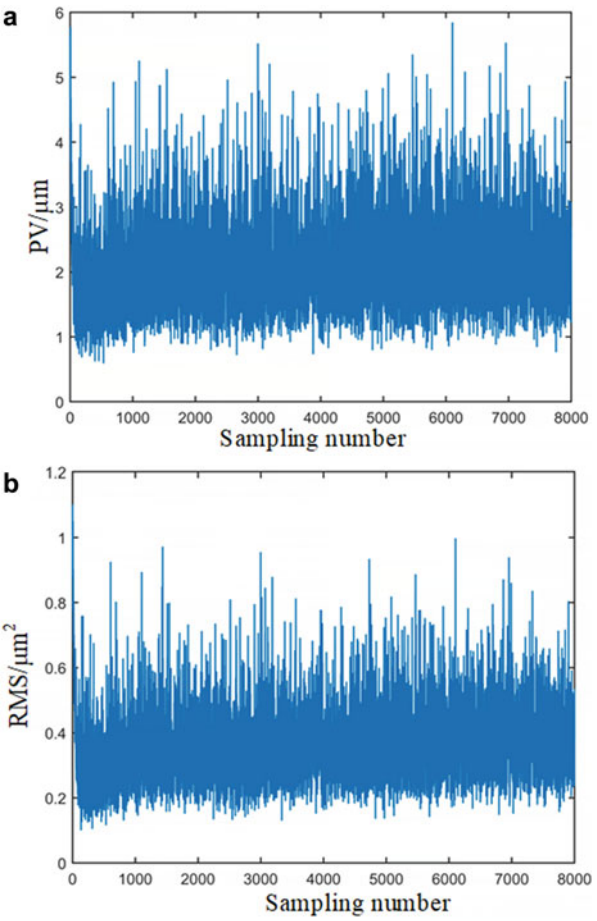

Fig. 21.36 Beacon light–corrected wavefront-reconstruction matrix correcting the signal light. (**a**) Change curve of the wavefront PV value; (**b**) change curve of the wavefront RMS value

of different wavelengths and the wavefront phase of distorted Gaussian beams of different wavelengths is deduced. The effects of the transmission distance, atmospheric refraction-index structure constant, Gaussian beam-waist radius, and wavelength difference on the correlation number of the arrival-angle fluctuation are analyzed by simulation.

The results show that the mutual correlation between the arrival-angle fluctuations of different wavelengths increases with the increase of the transmission distance. With the increase of the refraction-index structure constant, the correlation gradually decreases. The correlation is mainly affected by the wavelength and is negatively correlated with the wavelength difference between the signal light and beacon light. The smaller the beam waist radius is, the more the correlation between the arrival-angle fluctuation of different wavelengths decreases, the smaller the

wavelength difference is, and the smaller the difference between the distortion phase of the Gaussian beam of a different wavelength is.

The correction-coefficient matrix of the wavefront-reconstruction matrix is obtained according to the relationship between the phases of different-wavelength beams, and it is applied to the simulation correction experiment. The simulation experiment results show that the SR value of the signal light is improved by 10% by using the modified wavefront-reconstruction matrix for signal-light correction.

In the field experiment, the PV variance and RMS variance of the signal light were 0.9 μm^2 and 0.046 μm^2, respectively, without using the wavefront-reconstruction matrix correction coefficient. The wavefront PV variance and RMS variance of the signal light were 0.46 μm^2 and 0.012 μm^2, respectively, when correcting using the modified wavefront-reconstruction matrix. The PV variance and RMS variance of the signal light were reduced by 49.05% and 35.58%, respectively.

Coherent-Detection Performance Optimization

Influence of the Polarization State of Partially Coherent Light on the Sensitivity of Coherent Detection in Non-Kolmogorov Atmospheric Turbulence

Theoretical Analysis

Compared with traditional incoherent optical communication, spatial coherent optical communication can increase its receiving sensitivity by 20–23 dB and allow longer transmission distances under the same transmission power, which is more conducive to the suppression of atmospheric turbulence and channel fading [1]. When a beam is transmitted in an atmospheric channel, the atmospheric flicker, arrival-angle fluctuation, and beam drift will occur, owing to the influence of the random fluctuation of the atmospheric refractive index, which significantly reduces the performance of the optical wireless communication link. It was found that, compared with fully coherent light, partially coherent light was less affected by turbulence and had stronger stability [100].

The sensitivity of a coherent optical communication system is often described using the performance parameters of the detector; however, the performance of the detector is not the only determining factor, it is also affected by other parts of the system, such as granular noise, phase noise, local light power, mixing efficiency, etc. The influence of the former is main and direct; the influence of the latter is secondary and indirect. These factors have been the subjects of intense research.

For a sensitivity analysis of a heterodyne-detection system of space completely coherent light, Abbas and Slusher et al. [101, 102] studied the influence of scattered particle noise caused by local vibration light on the sensitivity of the coherent-detection system. He et al. [103] studied the noise-suppression mechanism of coherent optical balance detection, which effectively suppressed the influence of the noise fluctuation on the system output and improved the sensitivity.

Nan hang et al. [104] studied the influence of the loss of support between the local light and signal light on the detection sensitivity of spatially coherent optical communication under atmospheric turbulence. Liang et al. [105] studied the influence of local vibration power on the coherent-detection sensitivity of a space balanced detector.

Most physically realizable light sources radiate randomly, owing to inhomogeneity in the laser resonator and the spontaneous emission of atoms. In other words, the actual radiation is a partially coherent light beam; hence, it is of great significance to study the sensitivity of a heterodyne system of partially coherent light beams.

In recent years, the performance of partially coherent light for heterodyne detection has been extensively studied. Tanaka et al. [106] calculated the heterodyne efficiency for heterodyne detection when both the signal light and local oscillator light were partially coherent beams. Pu et al. [107] studied the system performance of partially coherent laser beams used in the heterodyne detection of lidar. Salem and Rolland et al. [108] studied the effect of the angular error between the signal light and local oscillator light of a partially coherent beam on the performance of a coherent-detection system. Li et al. [11] discussed the influence of turbulence on a heterodyne-detection system, based on the theory of partially coherent beams.

The above work is based on the scalar theory of partially coherent light fields. In addition, the polarization phenomenon of the electromagnetic field cannot be ignored, and the polarization of the beam usually changes with the propagation of the beam. Salem et al. [109] studied the influence of coherence and polarization changes on the heterodyne detection of random electromagnetic beams propagating in free space. Wang et al. [110] studied the coherent polarization matrix of a Gaussian–Schell electromagnetic beam under a horizontal link and deduced the analytical expression of the heterodyne-detection system.

In the above research work, the influence of atmospheric turbulence on the heterodyne efficiency of a coherent optical communication system is based on Kolmogorov turbulence. In fact, atmospheric turbulence greatly deviates from the turbulence described by the Kolmogorov power spectrum, while non-Kolmogorov turbulence is closer to the actual situation of atmospheric turbulence.

At present, little research has been conducted on the influence of the beam-polarization state on the sensitivity of coherent detection when a partially coherent beam is transmitted up and down in non-Kolmogorov atmospheric turbulence. Based on the above research, we derived the expression of the sensitivity of a heterodyne-detection system when partially correlated light was transmitted in an oblique path under the non-Kolmogorov turbulence spectrum. The effects of the power-spectrum power law, turbulence scale, transmission distance, receiving height, and detector diameter on the sensitivity of an electromagnetic Gaussian–Schell model (EGSM) beam transmitted through uplinks and downlinks under non-Kolmogorov atmospheric turbulence were analyzed, and meaningful results were obtained.

A partially coherent Gauss–Schell model (GSM) is a scalar light field that can be considered to be completely polarized, regardless of its vector properties [111]. However, the light field is usually not absolutely polarized, but partial polarization

of the electromagnetic field occurs, in the form of partially polarized light. A partially coherent EGSM beam is a vector GSM beam, and its polarization is considered.

In this study, an EGSM beam is taken as the research object, and the system performance of an EGSM beam for heterodyne detection under non-Kolmogorov turbulence is discussed. As shown in Fig. 21.37, it is considered that both the signal light and local oscillator light are partially coherent EGSM beams, and frequency mixing occurs on the detector photosensitive surface at $z = 0$. k_o and k_s are wave vectors of the local and signal light, respectively. Assuming that both the signal light and local oscillator light are parallel to the optical axis and perpendicular to the detector surface, the two light fields on the detector surface can be expressed as [112]

$$U_o(\boldsymbol{\rho}, t) = \left[U_{ox}(\boldsymbol{\rho})\boldsymbol{e}_x + U_{oy}(\boldsymbol{\rho})\boldsymbol{e}_y\right] \exp(j\omega_o t) \tag{21.27}$$

$$U_s(\boldsymbol{\rho}, t) = \left[U_{sx}(\boldsymbol{\rho})\boldsymbol{e}_x + U_{sy}(\boldsymbol{\rho})\boldsymbol{e}_y\right] \exp(j\omega_s t), \tag{21.28}$$

where $\boldsymbol{e}_x$ and $\boldsymbol{e}_y$ are unit vectors, and ω_o and ω_s are the angular frequencies of the local light and signal light, respectively.

The polarization properties and spatial-coherence properties of partially coherent beams can be represented by beam-coherence polarization (BCP) matrix J_s. The two types of signal transmission in the z direction of the vibration signal light and the light beam of BCP matrix $J_s(\rho_1, \rho_2)$ and $J_o(\rho_1, \rho_2)$ can be, respectively, represented as [112]

$$J_s(\boldsymbol{\rho}_1, \boldsymbol{\rho}_2) = \begin{bmatrix} \left\langle U_{sx}^*(\boldsymbol{\rho}_1) U_{sx}(\boldsymbol{\rho}_2) \right\rangle & \left\langle U_{sx}^*(\boldsymbol{\rho}_1) U_{sy}(\boldsymbol{\rho}_2) \right\rangle \\ \left\langle U_{sy}^*(\boldsymbol{\rho}_1) U_{sx}(\boldsymbol{\rho}_2) \right\rangle & \left\langle U_{sy}^*(\boldsymbol{\rho}_1) U_{sy}(\boldsymbol{\rho}_2) \right\rangle \end{bmatrix} \tag{21.29}$$

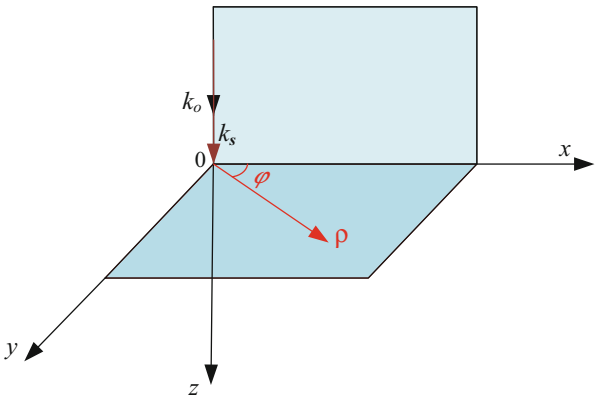

Fig. 21.37 Mixing model of a beam on the detector in the $z = 0$ plane

$$J_o(\boldsymbol{\rho}_1,\boldsymbol{\rho}_2) = \begin{bmatrix} \left\langle U_{ox}^*(\boldsymbol{\rho}_1)U_{ox}(\boldsymbol{\rho}_2)\right\rangle & \left\langle U_{ox}^*(\boldsymbol{\rho}_1)U_{oy}(\boldsymbol{\rho}_2)\right\rangle \\ \left\langle U_{oy}^*(\boldsymbol{\rho}_1)U_{ox}(\boldsymbol{\rho}_2)\right\rangle & \left\langle U_{oy}^*(\boldsymbol{\rho}_1)U_{oy}(\boldsymbol{\rho}_2)\right\rangle \end{bmatrix}, \tag{21.30}$$

where ρ_1 and ρ_2 represent the position vector of any two points on the receiving end face. According to the heterodyne-detection principle and the double-balance detection principle, the power of the IF signal is obtained as [112]

$$P_{IF} = 2\Re^2 \iint\iint \mathrm{Re}\{\mathrm{Tr}[J_o(\boldsymbol{\rho}_1,\boldsymbol{\rho}_2)J_s(\boldsymbol{\rho}_1,\boldsymbol{\rho}_2)]\}d^2\boldsymbol{\rho}_1 d^2\boldsymbol{\rho}_2, \tag{21.31}$$

where Tr is the type of matrix trace, $\Re = e\eta/h\nu$ is the response of the detector, e is the electron charge, η is the quantum efficiency, and $h\nu$ is the photon energy. Here, it is convenient for analysis that the response of the detector $\Re$ is evenly distributed on the surface of the photosensitive detector. The main noise source in the coherent-detection system is the loose particle noise generated by the local vibration light, which can be expressed as [112]

$$P_n = eB\Re \iint \mathrm{Tr}[J_o(\boldsymbol{\rho},\boldsymbol{\rho})]d^2\boldsymbol{\rho}, \tag{21.32}$$

where B is the bandwidth of the detector. By definition, the signal-to-noise ratio of the coherent-detection system for partially coherent EGSM beams is [112]

$$SNR_{EGSM} = \frac{2\Re \iint\iint \mathrm{Re}\{\mathrm{Tr}[J_o(\boldsymbol{\rho}_1,\boldsymbol{\rho}_2)J_s(\boldsymbol{\rho}_1,\boldsymbol{\rho}_2)]\}d^2\boldsymbol{\rho}_1 d^2\boldsymbol{\rho}_2}{eB\iint \mathrm{Tr}[J_o(\boldsymbol{\rho},\boldsymbol{\rho})]d^2\boldsymbol{\rho}}. \tag{21.33}$$

According to the definition of heterodyne efficiency [112], the expression of the heterodyne efficiency of a partially coherent EGSM beam for heterodyne detection can be given as:

$$\eta_{EGSM} = \frac{\iint\iint \mathrm{Re}\{\mathrm{Tr}[J_o(\boldsymbol{\rho}_1,\boldsymbol{\rho}_2)J_s(\boldsymbol{\rho}_1,\boldsymbol{\rho}_2)]\}d^2\boldsymbol{\rho}_1 d^2\boldsymbol{\rho}_2}{\iint \mathrm{Tr}\left[J_o(\boldsymbol{\rho},\boldsymbol{\rho})d^2\boldsymbol{\rho}\right]\iint \mathrm{Tr}\left[J_s(\boldsymbol{\rho},\boldsymbol{\rho})d^2\boldsymbol{\rho}\right]}. \tag{21.34}$$

The performance of the system when an EGSM beam is used for heterodyne detection under turbulent conditions will now be analyzed based on the EGSM beam. Considering an electromagnetic Gaussian–Schell model beam radiated by a Gaussian–Schell source, its BCP matrix is [113]

$$J_{\alpha ij}^{(0)}(\boldsymbol{r}_1,\boldsymbol{r}_2) = I_{\alpha ij}\exp\left[-\frac{{\boldsymbol{r}_1}^2+{\boldsymbol{r}_2}^2}{4w_\alpha^2} - \frac{(\boldsymbol{r}_1-\boldsymbol{r}_2)^2}{2\delta_{\alpha ij}^2}\right], \tag{21.35}$$

where r_1 and r_2 represent the position vectors of any two points at the source field $z = 0$; $I_{\alpha ij}$ as the light intensity, w_α is the radius of the beam, $\delta_{\alpha ij}$ is the coherence

length of the space, and the subscript α for s or o, respectively, corresponds to the vibration signal light and the light, $i, j = x, y$.

In atmospheric turbulence, the EGSM beam is transmitted from the source plane $z = 0$ to $z > 0$. According to the generalized Huygens–Fresnel principle, the expression of each element of the BCP matrix of the beam at the receiving end is [114]

$$\begin{aligned} J_{\alpha ij}(\boldsymbol{\rho}_1, \boldsymbol{\rho}_2, z_\alpha) = I_{\alpha ij}\left(\frac{k}{2\pi z_\alpha}\right)^2 \iint d^2\boldsymbol{r}_1 \iint d^2\boldsymbol{r}_2 \times \exp\left[-ik\frac{(\boldsymbol{\rho}_1 - \boldsymbol{r}_1)^2 - (\boldsymbol{\rho}_2 - \boldsymbol{r}_2)^2}{2z_\alpha}\right] \\ \times \exp\left[-\frac{\boldsymbol{r}_1{}^2 + \boldsymbol{r}_2{}^2}{4w_\alpha^2} - \frac{(\boldsymbol{r}_1 - \boldsymbol{r}_2)^2}{2\delta_{\alpha ij}^2}\right] \\ \times < \exp[\psi^*(\boldsymbol{\rho}_1, \boldsymbol{r}_1, z_\alpha) + \psi(\boldsymbol{\rho}_2, \boldsymbol{r}_2, z_\alpha)] >_m, \end{aligned} \tag{21.36}$$

where z_α is the beam-propagation distance; k = 2π/λ, the spatial wave number for freedom for wavelength λ; * is the complex conjugate;$< >_m$ is the ensemble average of the turbulent medium, and $\psi(\boldsymbol{\rho}, \boldsymbol{r}, z_\alpha)$ is a complex turbulent-medium random disturbance.

$< \exp [\psi^*(\boldsymbol{\rho}_1, \boldsymbol{r}_1, z_\alpha) + \psi(\boldsymbol{\rho}_2, \boldsymbol{r}_2, z_\alpha)]>_m$, which describes the effect of turbulence, can be expressed as [115]

$$\begin{aligned} &< \exp[\psi^*(\boldsymbol{\rho}_1, \boldsymbol{r}_1, z_\alpha) + \psi(\boldsymbol{\rho}_2, \boldsymbol{r}_2, z_\alpha)] >_m \\ &= \exp\left[-\frac{1}{2}D_\phi(\boldsymbol{\rho}_1 - \boldsymbol{\rho}_2, \boldsymbol{r}_1 - \boldsymbol{r}_2)\right]. \end{aligned} \tag{21.37}$$

In this formula, $D_\phi(\boldsymbol{\rho}_1 - \boldsymbol{\rho}_2, \boldsymbol{r}_1 - \boldsymbol{r}_2)$ is the wave-structure function that transmits the signal instantaneously to the receiving end [116]:

$$\begin{aligned} &< \exp[\psi^*(\boldsymbol{\rho}_1, \boldsymbol{r}_1, z_\alpha) + \psi(\boldsymbol{\rho}_2, \boldsymbol{r}_2, z_\alpha)] >_m \\ &\cong \exp\left[-\frac{1}{2}\left(M_1\boldsymbol{r}_d^2 + M_2\boldsymbol{r}_d\boldsymbol{\rho}_d + M_3\boldsymbol{\rho}_d^2\right)\right], \end{aligned} \tag{21.38}$$

where $\boldsymbol{\rho}_d = \boldsymbol{\rho}_1 - \boldsymbol{\rho}_2$; $\boldsymbol{r}_d = \boldsymbol{r}_1 - \boldsymbol{r}_2$; M_1, M_2, and M_3 are

$$\begin{cases} M_1 = 2\pi^2 k^2 \sec\varphi \int_{h_0}^{H}\int_0^\infty \Phi_n(\kappa, h)(1-\xi)^2\kappa^3 d\kappa dh \\ M_2 = 4\pi^2 k^2 \sec\varphi \int_{h_0}^{H}\int_0^\infty \Phi_n(\kappa, h)(1-\xi)\xi\kappa^3 d\kappa dh \\ M_3 = 2\pi^2 k^2 \sec\varphi \int_{h_0}^{H}\int_0^\infty \Phi_n(\kappa, h)\xi^2\kappa^3 d\kappa dh \end{cases}, \tag{21.39}$$

where, in the uplink, $\xi = 1 - (h - h_0) / (H - h_0)$, H is the height of the receiving end, and h_0 is the height of the light source. In the downlink, $\xi = (h - h_0) / (H - h_0)$, H is the height of the light source, and h_0 is the height of the receiving end. φ is the zenith angle. For $\Phi_n(\kappa, h)$, a non-Kolmogorov turbulence spectrum is adopted, and its expression is [117]

$$\Phi_n(\kappa, h, \alpha) = A(\alpha)\widetilde{C}_n^2 \frac{\exp\left[-\kappa^2/\kappa_m^2\right]}{\left(\kappa^2 + \kappa_0^2\right)^{\alpha/2}}, 0 \le \kappa < \infty, 3 < \alpha < 4. \tag{21.40}$$

For non-Kolmogorov turbulence, $\int_0^\infty \Phi_n(\kappa, h, \alpha)\kappa^3 d\kappa$; after integration, we can obtain

$$\int_0^\infty \Phi_n(\kappa, h, \alpha)\kappa^3 d\kappa = \frac{A(\alpha)}{2(\alpha - 2)}\widetilde{C}_n^2 \left[\kappa_m^{2-\alpha}\beta \exp\left(\frac{\kappa_0^2}{\kappa_m^2}\right)\Gamma\left(2 - \frac{\alpha}{2}, \frac{\kappa_0^2}{\kappa_m^2}\right) - 2\kappa_0^{4-\alpha}\right], \tag{21.41}$$

where $\beta = 2\kappa_o^2 - 2\kappa_m^2 + \alpha\kappa_m^2$, α is the power-spectrum power law; $\kappa_0 = 2\pi/L_0$, L_0 is the outer turbulence scale; $A(\alpha) = \Gamma(\alpha - 1)\cos(\alpha\pi/2)/(4\pi^2)$, $\Gamma(x)$ indicates the gamma function; and $\kappa_m = c(\alpha)/l_0$, l_0 is a turbulent scale in which $c(\alpha)$ is a function of the power-spectrum power law α, with the following type [119]:

$$c(\alpha) = \left[\Gamma\left(5 - \frac{\alpha}{2}\right)A(\alpha)\frac{2}{3}\pi\right]^{1/(\alpha-5)}, \tag{21.42}$$

where $\widetilde{C}_n^2$ is the Kolmogorov-turbulence atmospheric refractive-index structure constant, with unit $m^{3-\alpha}$, proposed by the International Telecommunication Union—Radiocommunication Sector (ITU-R), and changes with the height of the atmospheric refractive-index structure constant model; its expression is as follows [118]:

$$\begin{aligned} C_n^2(h) = {} & 8.148 \times 10^{-56} v_{RMS}^2 h^{10} e^{-h/1000} + 2.7 \times 10^{-16} e^{-h/1500} \\ & + C_0 e^{-h/100}, \end{aligned} \tag{21.43}$$

where

$$v_{RMS} = \sqrt{v_g^2 + 30.69 v_g + 348.91}, \quad \widetilde{C}_n^2 = \gamma C_n^2,$$

where γ is a constant 1, v_{RMS} is the vertical-path wind speed, v_g is the near-surface wind speed, and v_g is approximately 2.8 m/s when the surface wind speed is unknown. C_0 represents the atmospheric structure constant near the surface.

By substituting Eq. (21.37) into Eq. (21.36) and integrating, we can obtain

$$J_{\alpha ij}(\boldsymbol{\rho}_1,\boldsymbol{\rho}_2,z_\alpha)=\frac{I_{\alpha ij}}{Q_{\alpha ij}}\exp\left[-H_{\alpha ij}(\boldsymbol{\rho}_1-\boldsymbol{\rho}_2)^2\right]$$
$$\times\ \exp\left[-\frac{1}{8w_\alpha^2 Q_{\alpha ij}}(\boldsymbol{\rho}_1+\boldsymbol{\rho}_2)^2+ikT_{\alpha ij}\left({\boldsymbol{\rho}_2}^2-{\boldsymbol{\rho}_1}^2\right)\right],\qquad(21.44)$$

where

$$Q_{\alpha ij}=1+\left(\frac{z_\alpha}{kw_\alpha\theta_{\alpha ij}}\right)^2+\frac{{z_\alpha}^2M_3}{k^2w_\alpha^2}$$

$$H_{\alpha ij}=\frac{1}{2\theta_{\alpha ij}^2Q_{\alpha ij}}+\frac{1}{Q_{\alpha ij}}\left(\frac{M_3}{2}+\frac{M_2}{2}\right)+\frac{M_1}{2}-\frac{\left(\frac{M_2}{2}\right)^2{z_\alpha}^2}{2w_\alpha^2k^2Q_{\alpha ij}}\qquad(21.45)$$

$$\frac{1}{\theta_{\alpha ij}^2}=\frac{1}{4w_\alpha^2}+\frac{1}{\delta_{\alpha ij}^2}$$

$$T_{\alpha ij}=\frac{k^2w_\alpha^2Q_{\alpha ij}+\left(\frac{M_2}{2}\right){z_\alpha}^2-k^2w_\alpha^2}{2k^2z_\alpha w_\alpha^2Q_{\alpha ij}}.$$

For a random electromagnetic beam, the polarization degree is defined as [115]

$$P(\boldsymbol{\rho},\boldsymbol{\rho},\mathrm{z})=\sqrt{1-\frac{4\mathrm{Det}J(\boldsymbol{\rho},\boldsymbol{\rho},\mathrm{z})}{[TrJ(\boldsymbol{\rho},\boldsymbol{\rho},\mathrm{z})]^2}},\qquad(21.46)$$

where *Det* and *Tr*, respectively, represent the determinant and trace of matrix *J*.

By substituting Eq. (21.44) into Eq. (21.46), the polarization degree of the point on the beam axis in the receiving plane at $z>0$ is obtained as:

$$P(\boldsymbol{\rho}=0,\mathrm{z})=\sqrt{1-\frac{4\left(\frac{I_{\alpha xx}I_{\alpha yy}}{Q_{\alpha xx}Q_{\alpha yy}}-\frac{I_{\alpha xy}I_{\alpha yx}}{Q_{\alpha xy}Q_{\alpha yx}}\right)}{\left(\frac{I_{\alpha xx}}{Q_{\alpha xx}}+\frac{I_{\alpha yy}}{Q_{\alpha yy}}\right)^2}}.\qquad(21.47)$$

The degree of polarization is $0\le P\le 1$. When $P=1$, the beam is fully polarized. When $0<P<1$, the beam is partially polarized. When $P=0$, the beam is unpolarized.

We substitute Eq. (21.44) into Eq. (21.31), and convert the operation into a polar coordinate system. The *IF* signal output by the detector can be expressed as

$$P_{IFij}=2\Re^2\int_0^{2\pi}\int_0^{2\pi}\int_0^{D/2}\int_0^{D/2}\mathrm{Re}\left[J_{oij}(\boldsymbol{\rho}_1,\boldsymbol{\rho}_2,z_\alpha)\times {J_{sij}}^*(\boldsymbol{\rho}_1,\boldsymbol{\rho}_2,z_\alpha)\right]\rho_1\rho_2d\rho_1d\rho_2d\varphi_1d\varphi_2,\qquad(21.48)$$

where D is the diameter of the effective detector area, the Cartesian coordinate system is established with the center of the detector as the origin, and φ is the included angle of the position vector $\boldsymbol{\rho}$ and the x-axis.

To facilitate an integral calculation, a Gaussian-type aperture or soft aperture is considered to replace a hard aperture here. The relation between the soft aperture W and hard aperture D is [115] $D^2 = 8\ W^2$. Based on the relation between the soft aperture and hard aperture, Eq. (21.48) can be arranged as follows:

$$\begin{aligned} P_{IFij} = 2\Re^2 \frac{I_{oij} I_{sij}}{Q_{oij} Q_{sij}} \int_0^{2\pi} \int_0^{2\pi} \int_0^{\infty} \int_0^{\infty} \mathrm{Re}\left\{ \frac{I_{oij}}{Q_{oij}} \exp\left[-H_{oij}(\boldsymbol{\rho}_1 - \boldsymbol{\rho}_2)^2\right] \exp\left[-\frac{1}{8w_o^2 Q_{oij}}(\boldsymbol{\rho}_1 + \boldsymbol{\rho}_2)^2\right] \right. \\ \times \exp\left[-ikT_{oij}\left(\boldsymbol{\rho}_1^2 - \boldsymbol{\rho}_2^2\right)\right] \times \frac{I_{sij}}{Q_{sij}} \exp\left[-H_{sij}(\boldsymbol{\rho}_1 - \boldsymbol{\rho}_2)^2\right] \exp\left[-\frac{1}{8w_s^2 Q_{sij}}(\boldsymbol{\rho}_1 + \boldsymbol{\rho}_2)^2\right] \\ \left. \times \exp\left[ikT_{sij}\left(\boldsymbol{\rho}_1^2 - \boldsymbol{\rho}_2^2\right)\right] \exp\left[-\frac{\boldsymbol{\rho}_1^2 + \boldsymbol{\rho}_2^2}{W^2}\right] \right\} \rho_1 \rho_2 d\rho_1 d\rho_2 d\varphi_1 d\varphi_2. \end{aligned} \tag{21.49}$$

Substituting the following relationship, $\boldsymbol{\rho}_1 \boldsymbol{\rho}_2 = \rho_1 \rho_2 \cos(\varphi_1 - \varphi_2)$, Eq. (21.49) can be arranged as

$$\begin{aligned} P_{IFij} = 2\Re^2 \frac{I_{oij} I_{sij}}{Q_{oij} Q_{sij}} \int_0^{2\pi} \int_0^{2\pi} \int_0^{\infty} \int_0^{\infty} \mathrm{Re}\left\{ \exp\left[-g_{ij}\left(\rho_1^2 + \rho_2^2\right)\right] \times \exp\left[ik\left(T_{sij} - T_{oij}\right)\left(\rho_1^2 - \rho_2^2\right)\right], \right. \\ \left. \times \exp\left[2q_{ij}\rho_1\rho_2\cos(\varphi_1 - \varphi_2)\right] \right\} \rho_1 \rho_2 d\rho_1 d\rho_2 d\varphi_1 d\varphi_2 \end{aligned} \tag{21.50}$$

where

$$\begin{aligned} g_{ij} &= H_{oij} + \frac{1}{8w_o^2 Q_{oij}} + H_{sij} + \frac{1}{8w_s^2 Q_{sij}} + \frac{1}{W^2} \\ q_{ij} &= H_{oij} - \frac{1}{8w_o^2 Q_{oij}} + H_{sij} - \frac{1}{8w_s^2 Q_{sij}}. \end{aligned} \tag{21.51}$$

Through a simplifying calculation, we can obtain

$$P_{IFij} = \frac{2\pi^2 \Re^2 I_{oij} I_{sij}}{Q_{oij} Q_{sij}\left(g_{ij}{}^2 + s_{ij}{}^2 - q_{ij}{}^2\right)}, (i, j = x, y). \tag{21.52}$$

The local optical power is

$$P_{oii} = \Re \iint J_{oii}(\boldsymbol{\rho}, \boldsymbol{\rho}) d^2\boldsymbol{\rho} = \frac{2\Re\pi I_{oii} W^2 w_o^2}{W^2 + 2w_o^2 Q_{oii}}, (i = x, y). \tag{21.53}$$

According to the above results,

$$SNR_{EGSM} = \frac{\sum_{i,j=x,y} P_{IFij}}{eB\sum_{i=x,y} P_{oii}}. \tag{21.54}$$

Similarly, the signal-light power is

$$P_{sii} = \Re \iint J_{sii}(\boldsymbol{\rho},\boldsymbol{\rho}) d^2\boldsymbol{\rho} = \frac{2\Re\pi I_{sii} W^2 w_s^2}{W^2 + 2w_s^2 Q_{sii}}, (i = x, y). \tag{21.55}$$

The heterodyne efficiency of the heterodyne detection can be expressed as

$$\eta_{EGSM} = \frac{\sum_{i,j=x,y} P_{IFij}}{2\sum_{i=x,y} P_{oii} \sum_{i=x,y} P_{sii}}. \tag{21.56}$$

According to Eqs. (21.54) and (21.56), $\mathrm{SNR_{EGSM}}$ can be written as

$$\begin{aligned} SNR_{EGSM} &= \frac{\sum_{i=x,y} P_{sii} \sum_{i,j=x,y} P_{IFij}}{eB\sum_{i=x,y} P_{oii} \sum_{i=x,y} P_{sii}} \\ &= \frac{2\sum_{i=x,y} P_{sii}}{eB} \eta_{EGSM}. \end{aligned} \tag{21.57}$$

The bit-error rate of the receiver is also an important parameter to measure the performance of a coherent optical communication system. The expression for the bit-error rate of a binary phase-shift keying (BPSK) receiver is [119]

$$BER = \frac{1}{2} erfc\left(\frac{SNR_{EGSM}}{2}\right)^{1/2}. \tag{21.58}$$

The detection system sensitivity refers to the minimum input signal power that can be detected under a certain bit-error rate. It can be obtained from Eq. (21.59):

$$\sum_{i=x,y} P_{sii} = \frac{eB}{2\eta_{EGSM}} SNR_{EGSM}, \tag{21.59}$$

where B is the bandwidth of the detector.

Experimental Study

The influence of an oblique transmission of an EGSM beam under non-Kolmogorov atmospheric turbulence on the sensitivity of differential detection under different polarization states was studied by numerical analysis.

As can be seen from Eq. (21.59), the sensitivity of the EGSM beam for heterodyne detection is determined by the turbulence size, turbulence scale, detector size, transmission distance, height of receiving end, height of light source H, etc. This study mainly analyzes how each factor affects the sensitivity of the heterodyne-detection system when the given bit-error rate $\mathrm{BER} = 10^{-9}$.

Firstly, the values of several global parameters are given. In the subsequent analysis, the values of these parameters are all given here, unless otherwise specified. The wavelength value for $\lambda = 650$ nm, internal and external turbulence scale values are $l_0 = 5 \times 10^{-3}$ m and $L_0 = 1$ m, power-spectrum power law of $\alpha = 3.7$, atmospheric structure constant $C_0 = 1.7 \times 10^{-14}$ m$^{-2/3}$, radius of the vibration signal light and sending light $w_o = w_s = 3$ mm, detector diameter $D = 3$ mm, quantum efficiency $\eta = 0.8$, Planck's constant $h = 6.623 \times 10^{-34}$ J·s, carrier frequency $v = 1.9 \times 10^{14}$ m/s, and detector bandwidth $B = 200$ MHz.

To ensure that the polarization characteristics of the laser remain unchanged in the atmospheric channel, the beam space lengths of the signal light and local light are taken as $\delta_{oxy} = \delta_{oyx} = 0.2$ mm, $\delta_{oxx} = \delta_{oyy} = 0.2$ mm, $\delta_{sxx} = \delta_{syy} = 0.4$ mm, and $\delta_{sxy} = \delta_{syx} = 0.4$ mm, respectively.

To analyze the influences of various factors on the sensitivity of heterodyne detection under different polarization states during the oblique transmission of an EGSM beam in a more detailed and visual manner, the sensitivity of the EGSM beam under the three states of complete polarization, unpolarization, and partial polarization for heterodyne detection was analyzed in detail in this study, as shown in Figs. 21.38, 21.39, and 21.40.

According to Eq. (21.48), when $I_{oxy} = I_{sxy} = 1$, $I_{oyx} = I_{syx} = 1$, $I_{oxx} = I_{oyy} = 1$, and $I_{sxx} = I_{syy} = 1$, the degree of polarization $P = 1$; then the signal light and the local

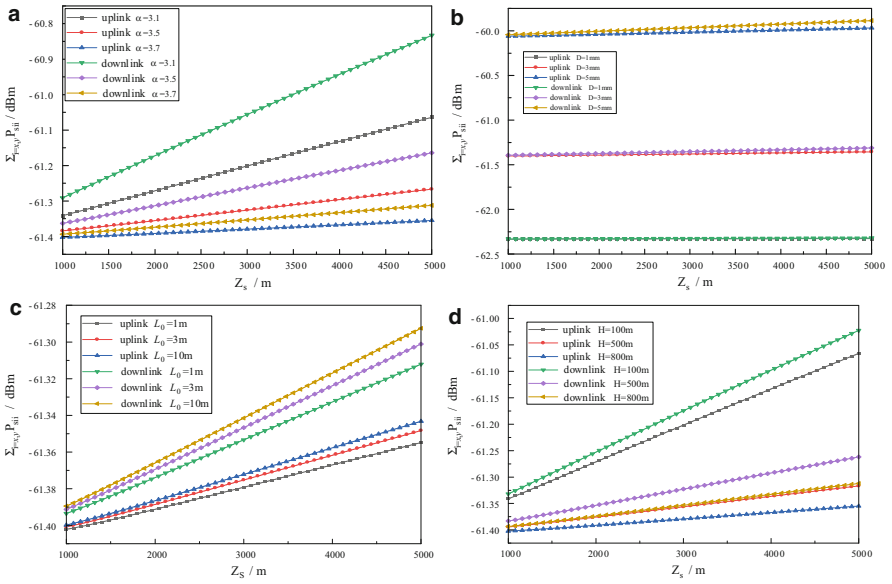

Fig. 21.38 System sensitivity of a fully polarized EGSM beam for heterodyne detection varying with the transmission distance, both up and down. (**a**) Different power-spectrum power laws α. (**b**) Different detector diameters D. (**c**) Different outer turbulence scales L_0. (**d**) Different heights of receiving end or light source H

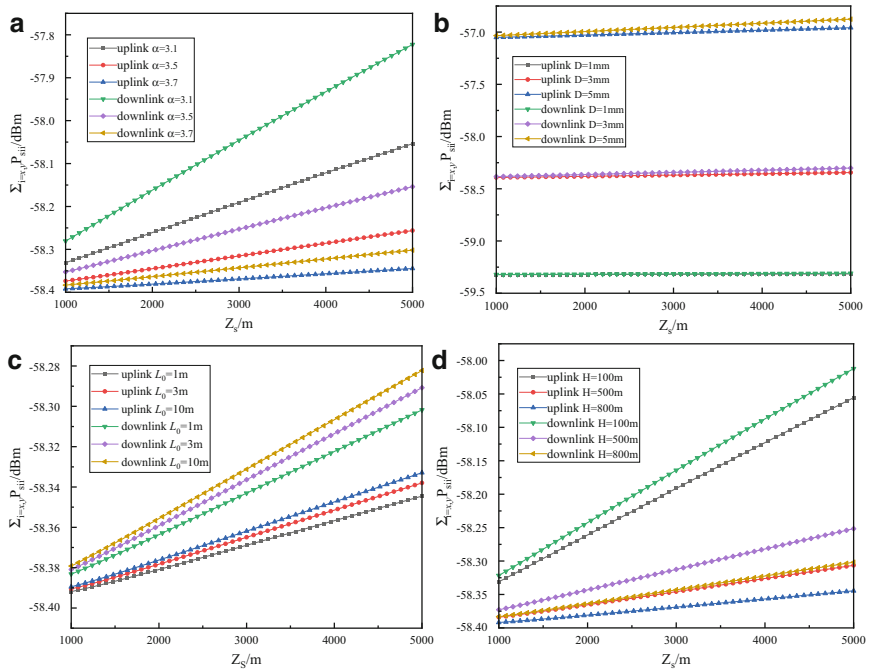

Fig. 21.39 System sensitivity of an unpolarized EGSM beam for heterodyne detection varying with the transmission distance, both up and down. (**a**) Different power-spectrum power laws α. (**b**) Different detector diameters D. (**c**) Different outer turbulence scales L_0. (**d**) Different heights of receiving end or light source H

oscillator light are fully polarized beams. Figure 21.38a–d respectively show the variation curves of the system sensitivity with the transmission distance when fully polarized EGSM beams are used for heterodyne detection under different power-spectrum power laws, detector diameters, outer turbulent scales, height of receiving end, or height H of light source, when the beam is transmitted up and down through atmospheric turbulence.

As can be seen from Fig. 21.38, the detection sensitivity of the system decreases with the increase in transmission distance. Because the beam is affected by the refractive index of the random fluctuation of the atmosphere when it is transmitted in atmospheric turbulence, the wavefront phase distortion will be more serious when the transmission distance is longer; hence, the turbulence will have a greater impact on the beam, resulting in a decrease in sensitivity.

Figure 21.38a shows that under a certain transmission distance, the detection sensitivity of the system increases with the increase of the power-spectrum power law. When the power-spectrum power law α is 3.1, the turbulence has a greater influence on the beam and the sensitivity is minimal. The sensitivity change of a turbulent downlink is greater than that of a turbulent uplink.

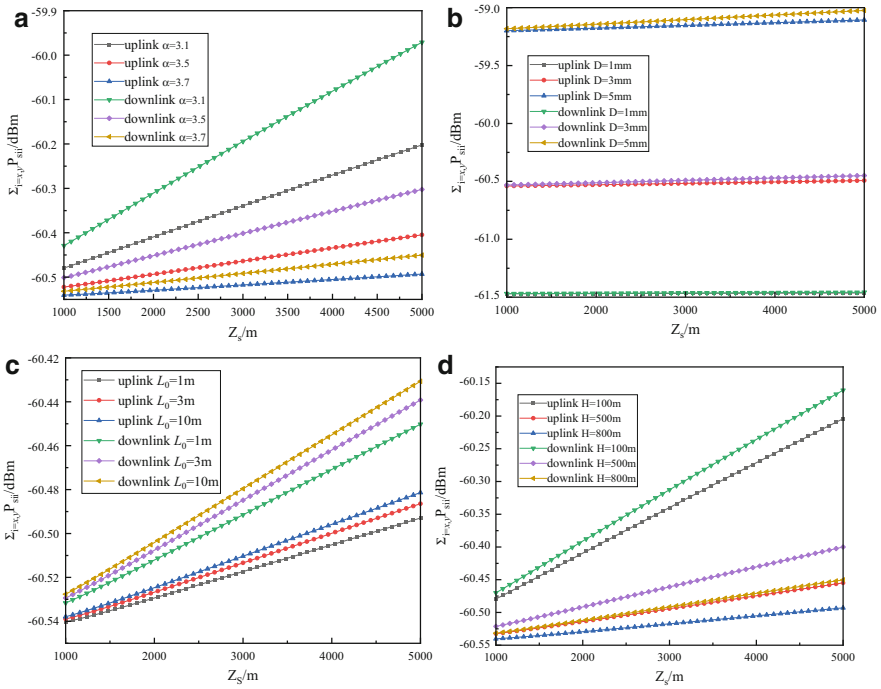

Fig. 21.40 System sensitivity of a partially polarized EGSM beam for heterodyne detection varying with the transmission distance, both up and down. (**a**) Different power-spectrum power laws α. (**b**) Different detector diameters D. (**c**) Different outer turbulence scales L_0. (**d**) Different heights of the receiving end or light source H

As can be seen from Fig. 21.38b, under a certain transmission distance, the detection sensitivity of the system decreases with the increase of the diameter of the detector. Considering the limitation of the spatial coherence of the signal light, the two beams with a smaller detector size have a better match, so the detection sensitivity of the system with a smaller detector size is larger. When the transmission distance increases gradually, the system sensitivity changes slowly with the transmission distance.

Figure 21.38c shows that, under a certain transmission distance, the detection sensitivity of the system decreases with the increase of the outer turbulence scale, because as the outer turbulence scale increases, the corresponding intensity of the atmospheric turbulence gradually increases, and the more serious the diffraction during beam transmission. This results in a decrease in the spatial coherence of the signal light and a decrease in sensitivity.

Figure 21.38d shows that under a certain transmission distance, the detection sensitivity of the system decreases with the decrease of the height of different receiving ends or the height H of the light source. In the transmission process, when the transmission height is less than 10 km, the refractive-index structure constant of atmospheric turbulence increases with the decrease of the height.

When the transmission distance remains unchanged, the smaller H is, the closer it is to a horizontal transmission, and the transmission path of the signal light in the strong turbulent region increases, resulting in a decrease of system sensitivity.

In addition, as can be seen from Fig. 21.38 as a whole, the sensitivity of the uplink is greater than that of the downlink, which is caused by the difference in the turbulence terms M_1, M_2, and M_3 in Eq. (21.39). In Eq. (21.39), the value of the turbulence term of the uplink is smaller than that of the turbulence term of the downlink. Therefore, the sensitivity is larger.

According to Eq. (21.48), when $I_{oxy} = I_{sxy} = 0$, $I_{oyx} = I_{syx} = 0$, $I_{oxx} = I_{oyy} = 1$, and $I_{sxx} = I_{syy} = 1$, the degree of polarization $P = 0$, then the signal light and local light are unpolarized beams. In Figs. 21.39a–d, when unpolarized EGSM beams are used for heterodyne detection, the sensitivity of the system varies with the transmission distance, when the beams are transmitted up and down through atmospheric turbulence under different power-spectrum power laws, detector diameters, outer turbulence scales, heights of the receiving end, or heights H of the light source.

As can be seen from the figure, with the increase in transmission distance, the smaller the power-spectrum power law, the larger the detector diameter, the larger the turbulence intensity, the lower the height of the receiving end or the height H of the light source, and the smaller the detection sensitivity of the system. By comparing Figs. 21.38 and 21.39, it can be seen that under the same link conditions, the sensitivity of an unpolarized EGSM beam for heterodyne detection is lower than that of a fully polarized beam, on the whole.

According to Eq. (21.48), when $I_{oxy} = I_{sxy} = 0.8$, $I_{oyx} = I_{syx} = 0.8$, $I_{oxx} = I_{oyy} = 1$, and $I_{sxx} = I_{syy} = 1$, the degree of polarization $P = 0.8$; then, the signal light and local light are partially polarized beams. In Fig. 21.40a–d, partially polarized EGSM beams are used for heterodyne detection. With different power-spectrum power laws, detector diameters, outer turbulence scales, receiving end heights or light-source heights H, the system sensitivity varies with the transmission distance when the beam is transmitted up and down through atmospheric turbulence.

By comparing Figs. 21.38, 21.39, and 21.40, it can be seen that under the same link conditions, the variation trend of the different polarization states is basically similar. The difference is that the detection sensitivity of a partially polarized EGSM beam for heterodyne detection is between that of an unpolarized beam and that of a fully polarized beam.

Because partially polarized light can be regarded as a combination of fully polarized light and unpolarized light, the performance of the system should be between unpolarized light and fully polarized light, when a partially polarized EGSM beam is used for heterodyne detection. It was obtained by numerical analysis that the optimal state sensitivity of a partially polarized EGSM beam for heterodyne detection was −61.5 dBm, which is between the optimal state of a fully polarized beam, −62.3 dBm, and the optimal state of unpolarized light, −59.3 dBm.

Based on the non-Kolmogorov turbulence spectrum, a theoretical model of the sensitivity of an EGSM beam for the heterodyne detection of an oblique transmission was established. Based on the numerical results, the system performance of EGSM beams with different polarization states, when transmitting up and down in

atmospheric turbulence, was studied in detail. The results showed that the sensitivity of the system was restricted by the power-spectrum power law α, and the detection sensitivity of fully polarized, partially polarized, and unpolarized EGSM beams for heterodyne detection increased with the increase of power-spectrum power law α.

Under the same conditions, the sensitivity of the EGSM beam was greater when it was transmitted upward in atmospheric turbulence than when it was transmitted downward. The detection sensitivity of an EGSM beam in the partially polarized state was between the fully polarized state and unpolarized state, and the sensitivity in the fully polarized state was the highest.

The sensitivity of a heterodyne-detection system can be adjusted by controlling the detector parameters, local-vibration parameters, transmission distance, turbulence scale, receiving height, etc. For a certain detector, a higher detection sensitivity can be obtained by adjusting the optimal value of the parameters of indirect factors, in addition to detector parameters.

Effect of the Optical Spatial Distribution on the Mixing Efficiency

Coherent optical communication systems are widely used in inter-satellite communication because of their high communication rate, good confidentiality, long-distance information transmission, and the small impact of background light [1]. Compared with intensity modulation/direct detection (IM/DD), coherent detection has high sensitivity and approaches the quantum detection limit [2]; however, the requirements of the receiving optical system are stricter, which not only requires a higher local power, but also ensures the efficient mixing of signal light and local light.

The mixing efficiency can be improved by ensuring as much as possible coherence matching between the signal light and local light. Coherence matching includes spatial-distribution (including amplitude and phase) and polarization-state matching. Polarization-state matching between the signal light and local vibration light can enable the beam to be realized through specific optical components, etc.

Scholars have more intently observed the influence of the spatial distribution of light on the mixing efficiency [120]. David et al. [121] pointed out that the optimal local light distribution should be the same as the signal-field distribution on the detector surface. On a circular detector, the signal light was the optimal detector radius when the local light was uniformly distributed. Cohen et al. studied the influence of lost supporting characters and the spot radius on mixing efficiency. It was found that the mixing efficiency was insensitive to the spatial-angle mismatch when the signal light had an Airy distribution.

Tanaka et al. [122] studied the changes in mixing efficiency of the system when the incident direction of the signal light was tilted and offset, under the premise that both the signal light and local light had a Gaussian distribution. Xiang et al. [123] studied the optical heterodyne efficiency of the combination of an Airy signal light

and Gaussian local oscillator light, and analyzed the optical mixing-efficiency loss caused by different aberrations, such as tilt, defocus, spherical aberration, coma, and astigmatism.

Liu et al. [124] studied the efficiency of mixing a signal light with a Gaussian and uniform distribution and different local modes in an interplanetary coherent optical communication system. Li et al. [125] studied the influence of collimation loss on the mixing efficiency of external error detection in a heterodyne-detection system, where the signal light had an Airy distribution and the local oscillator light had a Gaussian distribution.

Coherent Detection System

The schematic diagram of a coherent-detection system is shown in Fig. 21.41. After the signal light is transmitted through the atmospheric channel and reaches the receiving end, it synthesizes a beam with the local oscillator light emitted by the local oscillator laser, and then converges to the surface of the photodetector through the focusing lens for frequency mixing [126, 127].

The essence of frequency mixing is the interference between the signal light and local light on the surface of the photodetector. When two light beams are superimposed, the phase difference is fixed and the polarization direction is the same, which are the necessary conditions for the interference of two beams [128, 129]. The output IF signal of the photodetector contains multiple types of noise, so the mixing-efficiency evaluation index is introduced to evaluate the mixing performance of the system [130].

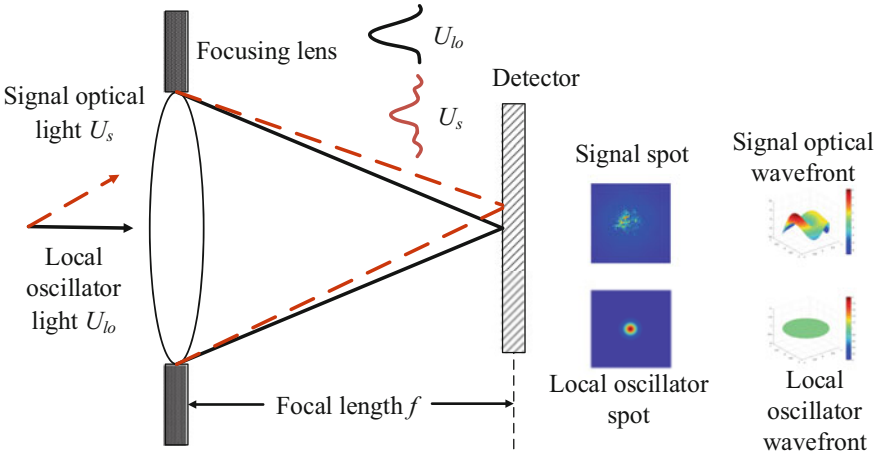

Fig. 21.41 Schematic diagram of a coherent-detection system

Mixing Efficiency of Coherent Detection Under Ideal Conditions

The mixing efficiency of optical heterodyne detection is the ratio of the IF signal power obtained from actually mixing two optical fields to the IF signal power obtained from the ideal mixing of two optical waves [131]. The ideal case here means that the spatial distribution of the two beams is the same, including amplitude and phase.

Assuming that the geometric centers of the two light fields coincide and the detector is distributed in circular symmetry, the mixing efficiency can be expressed as

$$\eta = \frac{\left|\int_0^{2\pi}\int_0^{r_0} U_s(r,\varphi)U_{lo}(r,\varphi)\exp[i\Delta\varphi(r,\varphi)]rdrd\varphi\right|^2}{\int_0^{2\pi}\int_0^{r_0}[U_{lo}(r,\varphi)]^2 rdrd\varphi\int_0^{2\pi}\int_0^{\infty}[U_s(r,\varphi)]^2 rdrd\varphi}, \tag{21.60}$$

where r_0 is the probe radius, $U_s(r, \varphi)$ is the detector signal-light amplitude distribution, $U_{lo}(r, \varphi)$ is the probe on the surface of the vibration amplitude of the light distribution, and $\Delta\varphi(r, \varphi)$ is the phase difference of the local vibration light and the signal light.

When the phase effect is not considered and the geometric centers of the signal light and local vibration light are assumed to coincide without an alignment error, the mixing efficiency Eq. (21.60) can be simplified as [132]

$$\eta = \frac{\left|\int_0^{r_0} U_s(r)U_{lo}(r)rdr\right|^2}{\int_0^{r_0}[U_{lo}(r)]^2 rdr\int_0^{\infty}[U_{lo}(r)]^2 rdr}. \tag{21.61}$$

Mixing Efficiency of Coherent Detection in a Turbulent Flow

The above discussion is based on the fact that the phase difference between the signal light and the local oscillator light is constant. However, in practice, when the signal light passes through the atmosphere, the uneven refractive index of the atmosphere will distort the phase of the signal light wavefront [133]. The additional phase difference brought by atmospheric turbulence will decrease the mixing efficiency and affect the performance of the coherent optical communication system.

The expression of a signal light transmitted through atmospheric turbulence is

$$E_{S1}(r,\varphi,t) = U_{S1}(r,\varphi)\exp[i(\omega_{s1}t+\varphi_{s1})] = U_S(r,\varphi,t)\exp(\Phi), \tag{21.62}$$

where U_{s1}, ω_{s1}, and φ_{s1}, respectively, refer to the amplitude, angular frequency, and initial phase of the signal light after atmospheric turbulence; Φ is the expression for atmospheric turbulence caused by amplitude and phase fluctuations. $U_s(r, \varphi, t)$ is the

probe at any point on the complex amplitude of the signal light field. The relation of $U_s(r, \varphi, t) = U_s(r, \varphi)\exp[i(\omega_0 t + \varphi_s)]$ changes over time, where U_s, ω_s, and φ_s are, respectively, the amplitude, angular frequency, and initial phase of the signal light. The $U_s(r, \varphi, t)$ expression in Eq. (21.62) is [18]

$$\Phi = \ln \frac{U_{S1}(r, \varphi)}{U_S(r, \varphi)} + i[\Phi_{S1} - \Phi_S] = \chi + iS, \tag{21.63}$$

where χ is the light-intensity change, S is the wavefront phase distortion, ln is the natural logarithm function of e, and Φ_S and Φ_{S1} are, respectively, the signal light affected by atmospheric turbulence before and after the joint expression of amplitude and phase fluctuations. We substitute Eq. (21.63) into Eq. (21.62) to obtain

$$U_{S1} = U_S(r, \varphi) \exp[i(\omega_S t + \varphi_S)] \exp(\chi + iS). \tag{21.64}$$

Equation (21.64) is substituted into Eq. (21.63) as the signal light:

$$\eta = \frac{\left| \int_0^{r_0} U_s(r) U_{lo}(r) \exp(-iS) r dr \right|^2}{\int_0^{r_0} [U_{lo}(r)]^2 r dr \int_0^{\infty} [U_{lo}(r)]^2 r dr}, \tag{21.65}$$

where S is the wavefront phase distortion, and $U_s(r)$ and $U_{lo}(r)$ are the amplitude distributions of the signal light and local light on the detector surface, respectively.

From Eq. (21.65), it can be seen that the mixing efficiency of coherent detection is affected by atmospheric turbulence. Because a Gaussian signal light is transmitted over a long distance, the optical-field distribution when it reaches the detector surface at the receiving end is a plane wave [134]. Phase fluctuations under the influence of atmospheric turbulence can be described by Kolmogorov statistical theory, and phase fluctuations of plane waves can be expressed as [135]

$$S = 2.914 C_n^2 L k^2 \rho^{5/3}. \tag{21.66}$$

In Eq. (21.66), C_n^2 is the atmospheric refractive-index structure constant, L is the signal optical-transmission distance, k is the wavenumber, and r is the length of the two-dimensional space vector between the inner and outer turbulence scales. By substituting Eq. (21.66) into Eq. (21.65), the mixing efficiency of a coherent optical communication system affected by atmospheric turbulence can be written as

$$\eta = \frac{\left| \int_0^{r_0} U_s(r) U_{lo}(r) \exp\left(-i\left(2.914 C_n^2 L k^2 \rho^{5/3}\right)\right) r dr \right|^2}{\int_0^{r_0} [U_{lo}(r)]^2 r dr \int_0^{\infty} [U_{lo}(r)]^2 r dr}. \tag{21.67}$$

A Gaussian beam is typically used as a signal light in coherent optical communication systems. The light spot of a Gaussian beam becomes larger after a long-distance transmission, and the signal light received by the detector takes up a small proportion, which can be approximately considered to be evenly distributed [136]. Selecting the local oscillator light that best matches the signal light is helpful to improve the mixing efficiency of the system.

The following will be divided into two categories, according to whether the signal light is Gaussian, uniform, or a vortex beam, and the mixing efficiency when the local light is a different spatial distribution will be discussed. In the subsequent analysis process, the wavelength λ and radius of the Gaussian beam ω_0 are unified as $\lambda = 1550$ nm and $\omega_0 = 1.6\,\lambda$.

Mixing Efficiency of a Gaussian-Distributed Signal Light and Various Local Vibration Lights

After a lens-focused Gaussian beam reaches the surface of the detector, it still has a Gaussian distribution; however, the coefficient of the Gaussian distribution function changes, because in the process of computing the mixing efficiency, the molecular denominator will appear at the same time. The constant coefficient of the vibration light and signal light expressions can be reduced by a fraction.

We set the expression of a Gaussian signal light as $U_s(r) = \exp(-r^2/{\omega_0}^2)$. The local vibration light can be Gaussian or Airy: $U_s(r) = 2\,J_1(\pi r/F\lambda)\,/\,(\pi r/F\lambda)$. In the uniform distribution, $U_s(r) = 1$, J_1 is the first type of first-order Bessel function, and F is the F number of the receiving optical system. In the below analysis, we set $X = \pi r/F\lambda$, $X_0 = \pi r_0/F\lambda$, $Q = r/\omega$ and $Q_0 = r/\omega_0$.

Local Vibration Light Is Uniformly Distributed

When the local vibration light has a uniform distribution, it can be concluded that under the influence of atmospheric turbulence, the mixing efficiency η_{G-U} is as follows:

$$\eta_{G-U} = \frac{\left|\int_0^{r_0} \exp\left(-Q^2\right)\exp\left(-i\left(2.914C_n^2Lk^2\rho^{5/3}\right)\right)rdr\right|^2}{\int_0^{r_0} rdr\int_0^{\infty}\left[\exp\left(-Q^2\right)\right]^2 rdr}. \tag{21.68}$$

Figure 21.42 shows the mixing-efficiency curves when the transmission distance $L = 500$ m and two-dimensional space radius-vector length is $\rho = 0.1$ m, for different values of turbulence (C_n^2). The mixing efficiency has a maximum value of 81.45%, with the increase of the parameters of the receiving optical system. It decreases rapidly with the increase of the parameters of the receiving optical system, indicating that the mixing efficiency of this model is more sensitive to these

parameters; therefore, it is necessary to adjust these parameters to obtain a higher mixing efficiency. The mixing efficiency decreases with the increase of C_n^2, and the mixing efficiency is less than 40% when $C_n^2 = 10^{-14}\ \mathrm{m}^{-2/3}$.

Local Vibration Light Has a Gaussian Distribution

When the local vibration light has a Gaussian distribution, it can be concluded that the mixing efficiency η_{G-G} under the influence of atmospheric turbulence is

$$\eta_{G-G} = \frac{\left|\int_0^{r_0} \exp\left(-Q^2\right) \exp\left(-i\left(2.914 C_n^2 L k^2 \rho^{5/3}\right)\right) rdr\right|^2}{\int_0^{r_0} \left[\exp\left(-Q^2\right)\right]^2 rdr \int_0^{\infty} \left[\exp\left(-Q^2\right)\right]^2 rdr}. \tag{21.69}$$

In combination with Eq. (21.69), the variation curves of the mixing efficiency with different values of C_n^2 under turbulent conditions are obtained, as shown in Fig. 21.43. Without turbulence, the mixing efficiency rapidly increases to the maximum value of 100% with the increase of the parameters of the receiving optical system. The mixing efficiency gradually decreases under the influence of atmospheric turbulence. When $C_n^2 = 10^{-16}\ \mathrm{m}^{-2/3}$, the mixing efficiency is greater than 80%, indicating that the mixing performance of this model is less affected by atmospheric turbulence.

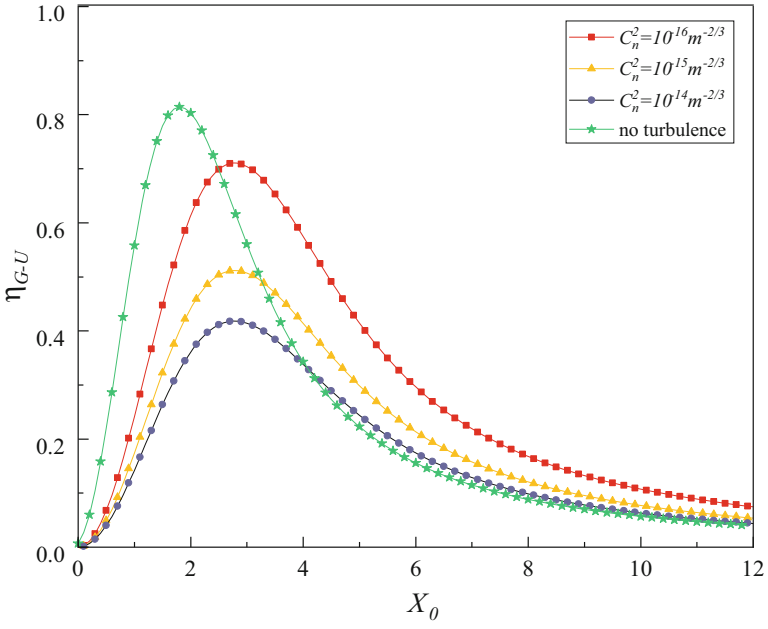

Fig. 21.42 Mixing efficiency of a Gauss–uniform distribution model

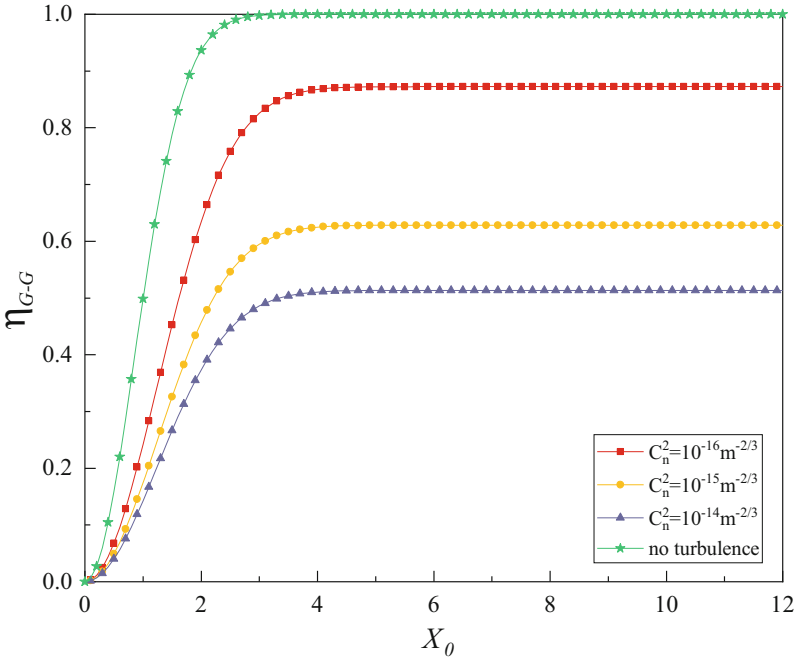

Fig. 21.43 Mixing efficiency of a Gauss–Gaussian distribution model

Local Oscillator Light Has an Airy Distribution

When the local oscillator light has an Airy distribution, it can be concluded that the mixing efficiency η_{G-A} under the influence of atmospheric turbulence is as follows:

$$\eta_{G-A} = \frac{\left|\int_0^{r_0} [J_1(X)/(X)] \exp\left(-Q^2\right) \exp\left(-i\left(2.914 C_n^2 L k^2 \rho^{5/3}\right)\right) rdr\right|^2}{\int_0^{r_0} [J_1(X)/(X)]^2 rdr \int_0^{\infty} \left[\exp\left(-Q^2\right)\right]^2 rdr}. \tag{21.70}$$

Figure 21.44 shows the variation curve of the mixing efficiency when C_n^2 takes different values, under ideal conditions and turbulent conditions. In the case with no turbulence, the mixing efficiency can be close to 100% when appropriate parameters are selected for the receiving optical system. However, when the parameters of the receiving optical system continue to increase, the mixing efficiency decreases instead of increasing, but still remains at about 80%. With the increase of the turbulence intensity, the mixing efficiency gradually decreases. When C_n^2 is 10^{-14} $m^{-2/3}$, the mixing efficiency is less than 50%, which is 50% lower than that without turbulence.

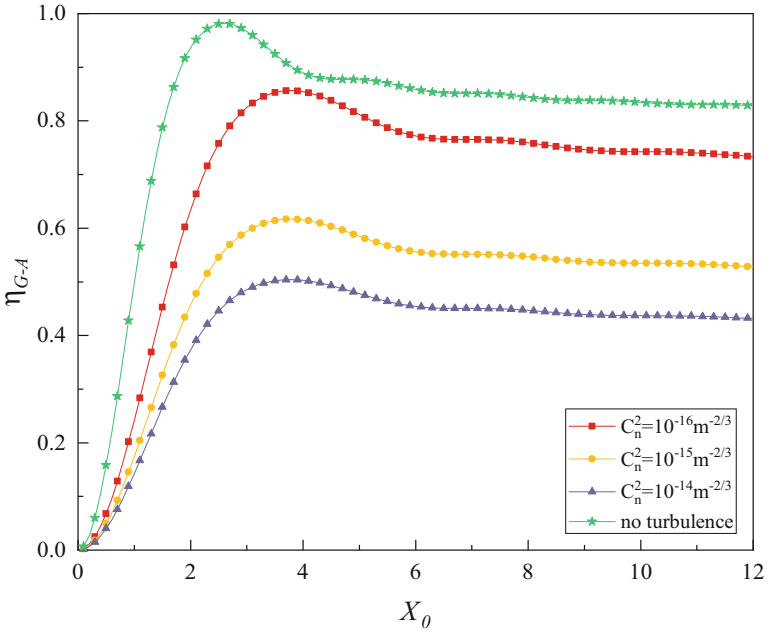

Fig. 21.44 Mixing efficiency of a Gauss–Airy distribution model

Mixing Efficiency When the Signal Light Has an Airy Distribution with Varying Local Vibration Lights

When a uniform signal light passes through the diffraction of the lens in Fig. 21.41, the spatial distribution becomes an Airy distribution when it focuses on the detector surface. The signal light is considered to have an Airy distribution below [19]. The local oscillator light can be a Gaussian, Airy, or uniformly distributed beam, and the mixing efficiency can be calculated by various equations.

Local Vibration Light Is Uniformly Distributed

When the local vibration light has a uniform distribution, it can be concluded that, under the influence of atmospheric turbulence, the mixing efficiency η_{A-U} is as follows:

$$\eta_{A-U} = \frac{\left|\int_0^{r_0} [J_1(X)/(X)] \exp\left(-i\left(2.914 C_n^2 L k^2 \rho^{5/3}\right)\right) rdr\right|^2}{\int_0^{r_0} rdr \int_0^{\infty} [J_1(X)/(X)]^2 rdr}. \tag{21.71}$$

According to Eq. (21.71), the variation curve of the mixing efficiency when C_n^2 takes different values is shown in Fig. 21.45. When the signal light has an Airy

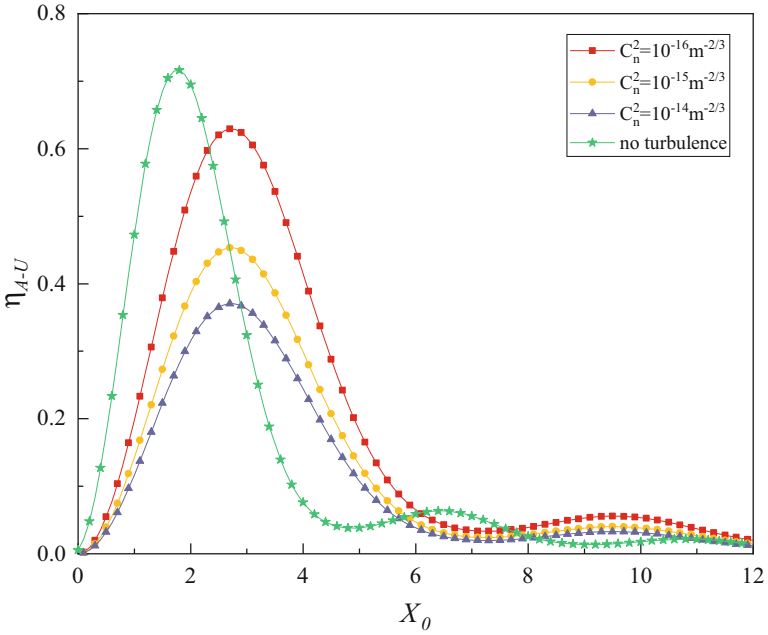

Fig. 21.45 Mixing efficiency of an Airy–uniform distribution model

distribution and the local oscillator light is uniformly distributed, the mixing efficiency quickly reaches the maximum value of 72.1% and then decreases. This indicates that this model is greatly affected by the parameters of the receiving optical system, and the conditions for reaching the maximum value are strict. Moreover, when atmospheric turbulence exists, the parameters of the receiving optical system required to reach the maximum mixing efficiency increase. When $C_n^2 = 10^{-14}\ \mathrm{m}^{-2/3}$, the mixing efficiency is less than 40%.

Local Oscillator Light Has an Airy Distribution

When the local oscillator light has an Airy distribution, it can be concluded that the mixing efficiency $\eta_{A\text{-}A}$ under the influence of atmospheric turbulence is as follows:

$$\eta_{A-A} = \frac{\left|\int_0^{r_0} [J_1(X)/(X)]^2 \exp\left(-i\left(2.914 C_n^2 L k^2 \rho^{5/3}\right)\right) rdr\right|^2}{\int_0^{r_0} [J_1(X)/(X)]^2 rdr \int_0^{\infty} [J_1(X)/(X)]^2 rdr}. \tag{21.72}$$

Combined with Eq. (21.72), the variation curve of the mixing efficiency when C_n^2 takes different values is shown in Fig. 21.46. When both the signal light and local light are Airy distributed, the mixing efficiency increases rapidly to about 80%

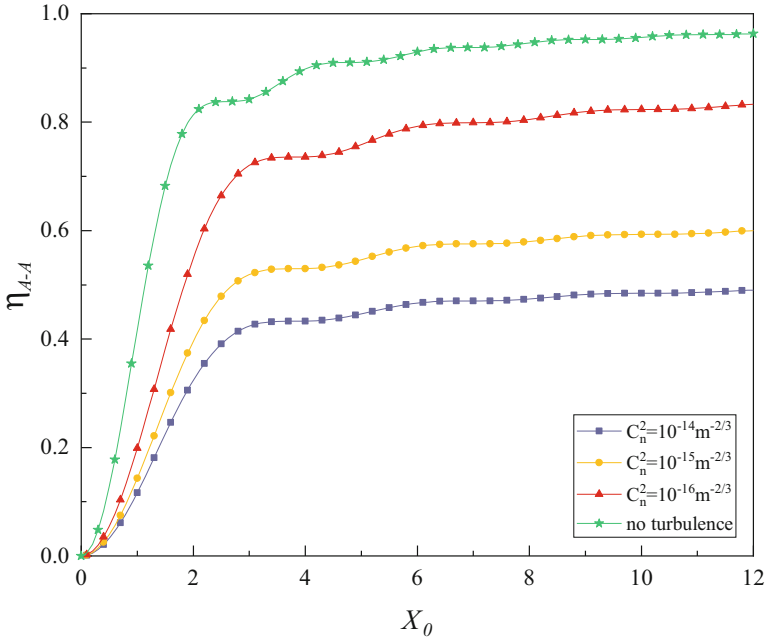

Fig. 21.46 Mixing efficiency of an Airy–Airy distribution model

with the increase of the parameters of the receiving optical system, then increases slowly, and gradually tends to 100%. The mixing efficiency decreases with the increase of C_n^2.

Local Light Has a Gaussian Distribution

When the local vibration light has a Gaussian distribution, it can be concluded that the mixing efficiency η_{A-G} under the influence of atmospheric turbulence is as follows:

$$\eta_{A-G} = \frac{\left|\int_0^{r_0} [J_1(X)/(X)] \exp\left(-Q^2\right) \exp\left(-i\left(2.914 C_n^2 L k^2 \rho^{5/3}\right)\right) rdr\right|^2}{\int_0^{\infty} [J_1(X)/(X)]^2 rdr \int_0^{r_0} \left[\exp\left(-Q^2\right)\right]^2 rdr}. \tag{21.73}$$

According to Eq. (21.73), the variation curve of the mixing efficiency when C_n^2 takes different values is shown in Fig. 21.47. When the signal light has an Airy distribution and the local vibration light has a Gaussian distribution, the mixing efficiency can reach 83.42% under the most suitable parameters of the receiving optical system. As can be seen from the figure, with the increase of the detection radius, the mixing efficiency linearly increases and reaches the maximum value of 83.42%. It then remains stable, indicating that the model has a strong adaptability to

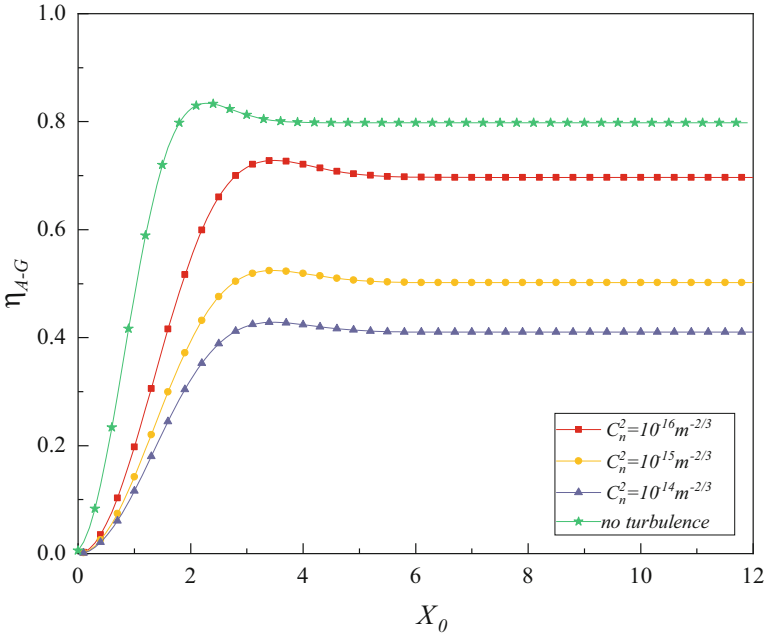

Fig. 21.47 Mixing efficiency of an Airy–Gauss distribution model

the receiving optical system. Under the influence of atmospheric turbulence, the mixing efficiency decreases with the increase of C_n^2.

The signal light has an Airy distribution and the local light has a Gaussian distribution, which is the most commonly used model in practical systems. The factors affecting the mixing efficiency of this model are analyzed in detail below. It can be seen from Eq. (21.73) that in the case of no turbulence, the mixing efficiency is related to the F number of the receiving optical system and the waist radius of the Gaussian beam. The two influencing factors are studied below. Figure 21.48 shows the corresponding mixing efficiencies for different X_0 and ω_0.

It can be seen from Fig. 21.48 that the mixing efficiency in the initial stage increases linearly with the increase of the parameters of the receiving optical system. This is because, with the increase of these parameters, the energy of the received signal light increases, so the mixing efficiency also increases. However, when the detection radius continues to increase, the mixing efficiency remains unchanged or even decreases. When the parameters of the receiving optical system increase to a certain extent, the background noise entering the detector also increases [128], which reduces the mixing efficiency. The mixing efficiency cannot continue to increase with the increase of the parameters of the receiving optical system.

Figure 21.49 shows the relation curve between the mixing efficiency and the waist radius of the Gaussian beam when the detector radius r_0 is 40 μm and the F number of the receiving optical system varies. It can be seen from Fig. 21.49 that the mixing efficiency of the system can be improved by selecting an appropriate

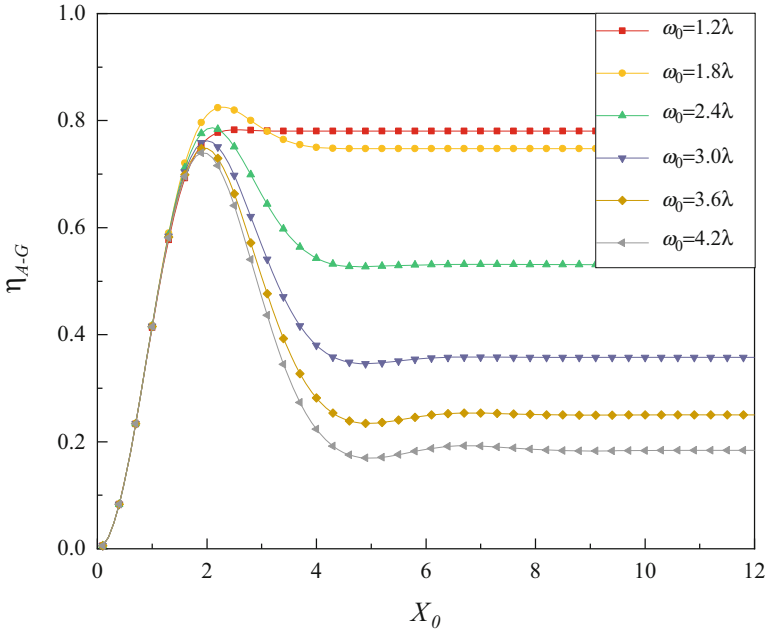

Fig. 21.48 Mixing efficiency of an Airy–Gaussian model with different ω_0

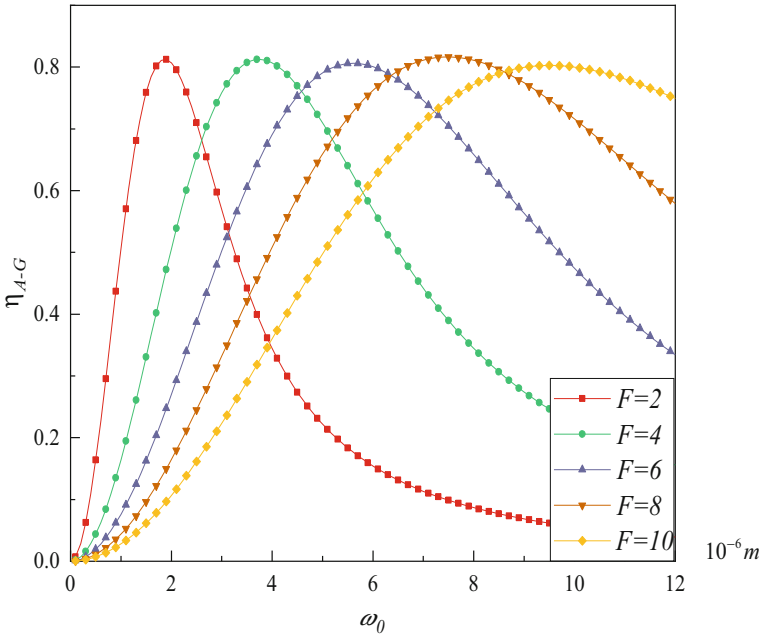

Fig. 21.49 Mixing efficiency of an Airy–Gaussian light, showing the relationship between the F number and ω_0

F value. When the selected F number is appropriate, the mixing efficiency can reach an ideal maximum. According to the trend of the curve, the larger the beam waist radius, the larger the F number required to achieve the ideal maximum.

In the following, the change in mixing efficiency caused by different receiving antennas is analyzed. A Zernike polynomial is used to represent the wavefront of the transmitted signal light. The Zernike polynomial containing the primary difference is [127]

$$\begin{cases} W_{\text{tilt}}(\rho,\varphi) = W_{111}\rho\cos\varphi \\ W_{\text{defocus}}(\rho,\varphi) = W_{020}\varphi^2 \\ W_{\text{spherical aberration}}(\rho,\varphi) = W_{040}\rho^4 \\ W_{\text{coma}}(\rho,\varphi) = W_{131}\rho^3\cos\varphi \\ W_{\text{astigmatism}}(\rho,\varphi) = W_{222}\rho^2\cos\varphi \end{cases}. \tag{21.74}$$

The above numerical shows the deviation of the actual wavefront from the ideal wavefront in the direction of the propagation distance. In Eq. 21.74, ρ is a normalized radius, i.e., $\rho = \rho/\mathrm{P}$; $\rho = 100$ μm for the radius of the receiving antenna. The equation for the mixing efficiency is as follows:

$$\eta = \frac{\left|\int_0^{2\pi}\int_0^{r_0} U_s(r,\varphi)U_{lo}(r,\varphi)\exp[ikW_X(\rho,\varphi)]rdrd\varphi\right|^2}{\int_0^{2\pi}\int_0^{r_0}[U_{lo}(r,\varphi)]^2rdrd\varphi\int_0^{2\pi}\int_0^{\infty}[U_s(r,\varphi)]^2rdrd\varphi}, \tag{21.75}$$

where $k = 2\pi/\lambda$, $kW_X(\rho, \varphi)$ is the antenna aberration introduced by the phase difference between the local vibration light and signal light, and W is the size of the wavefront aberration value.

As shown in Fig. 21.50, the primary aberration reduces the mixing efficiency to varying degrees, and the tilt difference has the most obvious effect on the mixing efficiency. When the aberration value is 0.2 λ, the mixing efficiency decreases by about 10%.

Mixing Efficiency When the Signal Light Is a Vortex Beam with Varying Local Vibration Lights

A Laguerre–Gaussian beam (LG) is a common vortex beam in optical communication systems. Gaussian beams are often used as the medium to detect vortex light in communication systems [137, 138]. Owing to the particularity of the vortex-beam phase, the mixing efficiency of vortex heterodyne detection will be studied from the angles of amplitude and phase matching. The feasibility of optical heterodyne detection for vortex optical communication systems is discussed. The mixing-

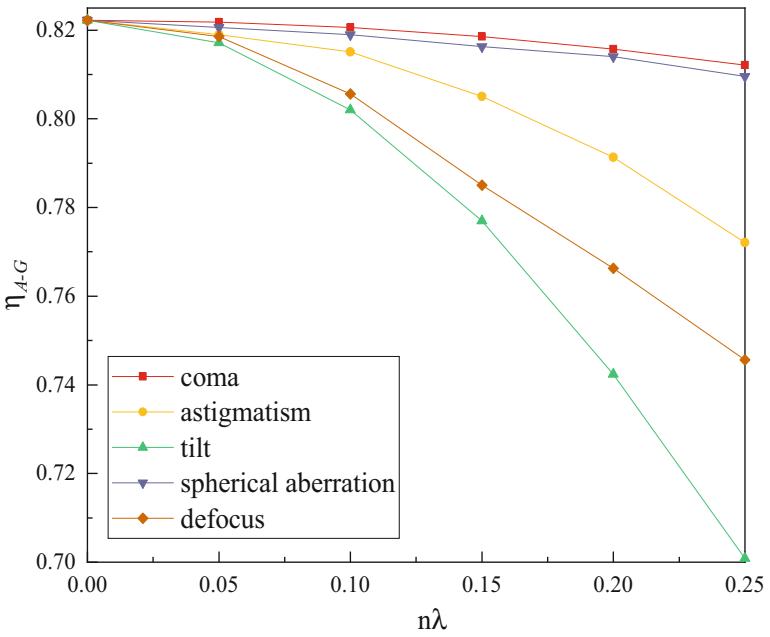

Fig. 21.50 Relationship between antenna aberrations and the mixing efficiency

efficiency changes are obtained when the signal light is an LG beam and the local light has Gaussian, Airy, and uniform distributions, and is a vortex light.

When the radial index is 0, the normalized amplitude of the LG beam carrying orbital angular momentum (OAM) at the transmission distance of 0 can be expressed as [139, 140]

$$U(r,\theta) = \sqrt{\frac{2}{\pi}}\frac{1}{\omega_0}\exp\left(-\frac{r^2}{\omega_0^2}\right)\sqrt{\frac{1}{|l!|}}\left[\frac{r\sqrt{2}}{\omega_0}\right]^{|l|}\exp(il\theta), \tag{21.76}$$

where l is the topological charge number, $\exp(il\theta)$ is the spiral phase factor, and ω_0 is the beam waist radius.

Local Light Has a Gaussian Distribution

When the local vibration light has a Gaussian distribution, assuming that the two phases match, we study the influence of the amplitude on the mixing efficiency, η_{G-L}:

$$\eta_{G-L} = \frac{\left|\int_0^{r_0}\sqrt{\frac{2}{\pi}}\frac{1}{\omega_0}\exp\left(-Q^2\right)\sqrt{\frac{1}{|l!|}}\left[\sqrt{2}Q\right]^{|l|}\exp\left(-Q^2\right)rdr\right|^2}{\int_0^{\infty}\left[\sqrt{\frac{2}{\pi}}\frac{1}{\omega_0}\exp\left(-Q^2\right)\sqrt{\frac{1}{|l!|}}\left[\sqrt{2}Q\right]^{|l|}\right]^2 rdr\int_0^{r_0}\left[\exp\left(-Q^2\right)\right]^2 rdr}, \tag{21.77}$$

where l is the topological charge number for LG beams and ω_0 is the Gaussian beam waist radius.

When the local oscillator light has a Gaussian distribution and the signal light is an LG beam, the relation between the mixing efficiency and the parameters of the receiving optical system under different topological charges is obtained according to Eq. (21.77), and the topological charges are set as 1, 3, and 5. The resulting change curve is shown in Fig. 21.51.

As can be seen from the figure, when the topological charge is 1 pentad, the mixing efficiency can reach about 80%; when the topological charge is 3, the mixing efficiency is only about 30%, and when the topological charge is 5, the mixing efficiency is only 10%. The mixing efficiency gradually decreases with the increase of the topological charge, and the parameters of the receiving optical system required by the mixing efficiency to stabilize gradually increase. After reaching the maximum, the mixing efficiency remains stable and does not change with the increase of the parameters of the receiving optical system.

According to Eq. (21.77), the mixing efficiency changes with the topological charge of the LG beam, as shown in Fig. 21.52. The mixing efficiency decreases linearly with the increase of the topological charge, and decreases to 50% when the topological charge is 3.

Assuming that the amplitudes of the signal light and local light match, the influence of the phase on the mixing efficiency is discussed. The mixing efficiency expression calculated by Eq. (21.77) is used, and the parameters of the receiving

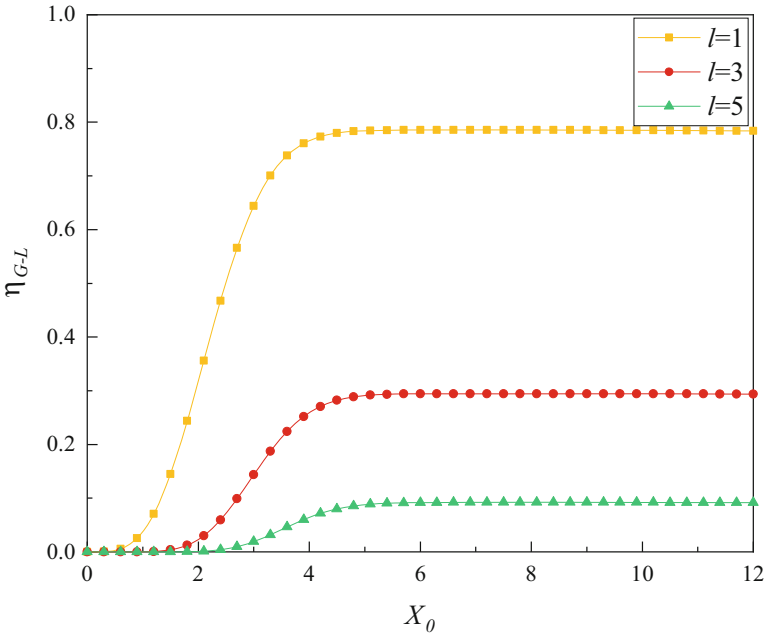

Fig. 21.51 Mixing efficiency of an LG beam when the local light has a Gaussian distribution

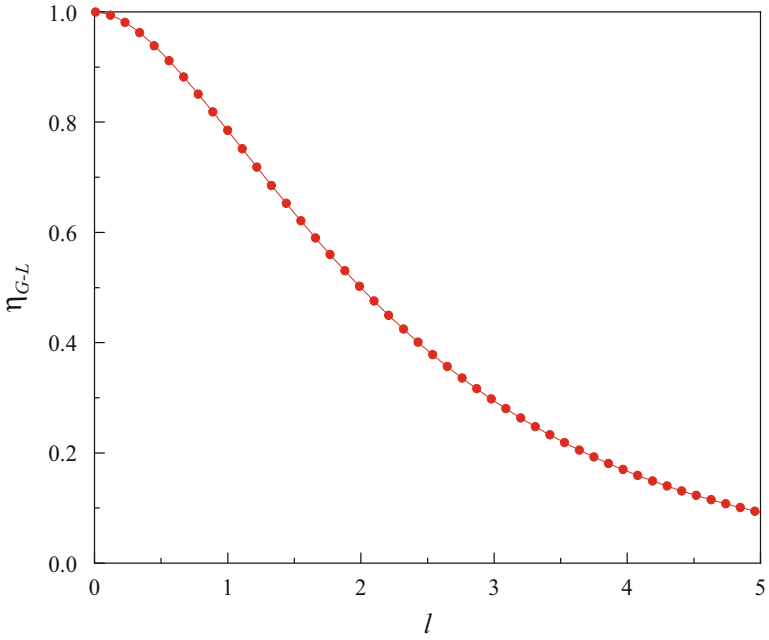

Fig. 21.52 Mixing efficiency changes with the topology load

optical system are set as fixed values. The relationship between the topological charge and mixing efficiency is studied, as shown in Fig. 21.53.

When the topological charge is greater than 1, the mixing efficiency is less than 10%. When the topological charge is an integer, the mixing efficiency is almost 0, and the mixing efficiency between two integer topological charges first increases and then decreases. In practical applications, the topological charges are mostly integers, so from the point of view of phase matching, Gaussian beams and LG beams cannot be mixed.

Local Oscillator Light Has an Airy Distribution

When the local light has an Airy distribution, assuming that the phases match, we investigate the relationship between the amplitude distribution and the mixing efficiency. The equation for the mixing efficiency η_{A-L} is as follows:

$$\eta_{A-L} = \frac{\left| \int_0^{r_0} \sqrt{\frac{2}{\pi}} \frac{1}{\omega_0} \exp\left(-Q^2\right) \sqrt{\frac{1}{|l|!}} \left[\sqrt{2}Q\right]^{|l|} \left[\frac{J_1(X)}{(X)}\right] rdr \right|^2}{\int_0^{\infty} \left[\sqrt{\frac{2}{\pi}} \frac{1}{\omega_0} \exp\left(-Q^2\right) \sqrt{\frac{1}{|l|!}} \left[\sqrt{2}Q\right]^{|l|} \right]^2 rdr \int_0^{r_0} \left[\left[\frac{J_1(X)}{(X)}\right] \right]^2 rdr}. \tag{21.78}$$

The relationship between the mixing efficiency and the parameters of the receiving optical system is calculated according to Eq. (21.78), and the topological charge

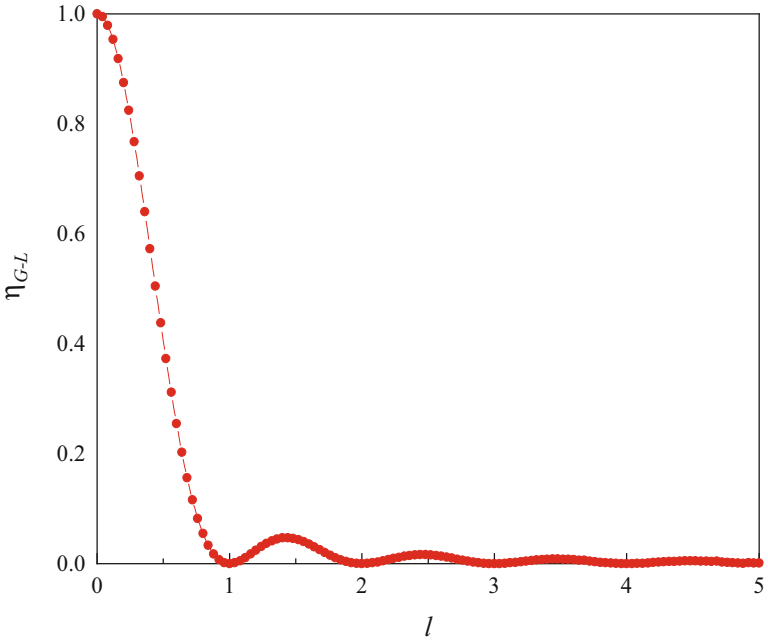

Fig. 21.53 Mixing efficiency when the signal light is an LG beam and the local oscillator light is Gaussian

value of the LG beam is changed. Figure 21.54 shows the curve of the mixing efficiency changing with the parameters of the receiving optical system under different topological charges.

When the local oscillator light has an Airy distribution and the topological charge of the LG beam is 1, the mixing efficiency first increases to the maximum value of 72.6% and then stabilizes at about 60%. When the topological charge is 3, the maximum mixing efficiency is only 20%, and when the topological charge is 5, the mixing efficiency is less than 10%.

To see the relationship between the mixing efficiency and topological charge more directly, the parameters of the receiving optical system were fixed, and the topological charge was set as the independent variable to obtain the relationship curve between it and the mixing efficiency, as shown in Fig. 21.55. It can be seen from the figure that the mixing efficiency decreases rapidly with the topological charge and approaches 0 when the topological charge is 5.

Local Vibration Light Is Uniformly Distributed

When the local vibration light has a uniform distribution, assuming that the phase matches, we study the influence of the amplitude distribution on the mixing efficiency, where the mixing efficiency η_{U-L} is

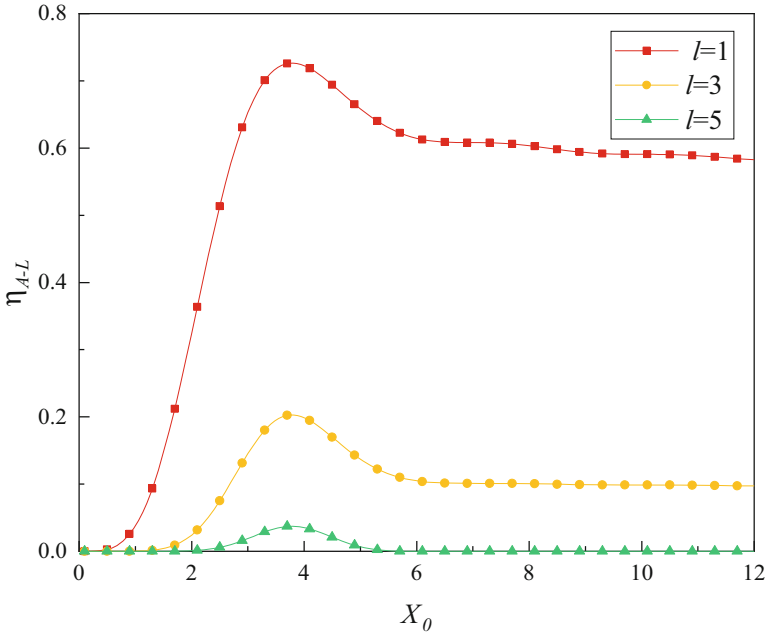

Fig. 21.54 Mixing efficiency when the signal light is an LG beam and the local oscillator light is Airy

$$\eta_{U-L} = \frac{\left| \int_0^{r_0} \sqrt{\frac{2}{\pi}} \frac{1}{\omega_0} \exp\left(-Q^2\right) \sqrt{\frac{1}{|l|!}} \left[\sqrt{2}Q\right]^{|l|} rdr \right|^2}{\int_0^{\infty} \left[\sqrt{\frac{2}{\pi}} \frac{1}{\omega_0} \exp\left(-Q^2\right) \sqrt{\frac{1}{|l|!}} \left[\sqrt{2}Q\right]^{|l|} \right]^2 rdr \int_0^{r_0} rdr}. \tag{21.79}$$

Equation (21.79) is used to obtain the relation between the mixing efficiency and the parameters of the receiving optical system when the uniformly distributed beam and LG beam have different topological charges. The mixing-efficiency change curve is shown in Fig. 21.56.

With the increase of the parameters of the receiving optical system, the line increases to the maximum value and then decreases. The variation-curve trend of the mixing efficiency of different topological charges is the same. However, with the increase of the topological charge, the maximum value of the mixing efficiency gradually decreases, and the parameters of the receiving optical system that correspond to the maximum value gradually increase, and the starting point of the increase of the line gradually shifts to the left.

This indicates that the larger the topological charge is, the larger the parameters of the receiving optical system must be to achieve the optimal mixing efficiency. This is because with the increase in the topological charge, the larger the radius of the central dark ring of the LG beam [140, 141] and the larger the spot radius.

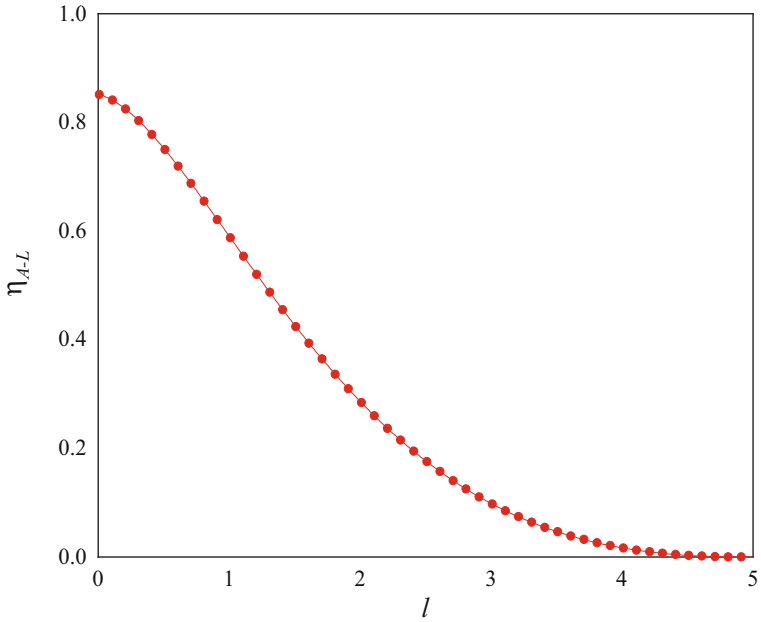

Fig. 21.55 Relation curve between the mixing efficiency and topological charge when the signal light is an LG beam and the local vibration light is an Airy beam

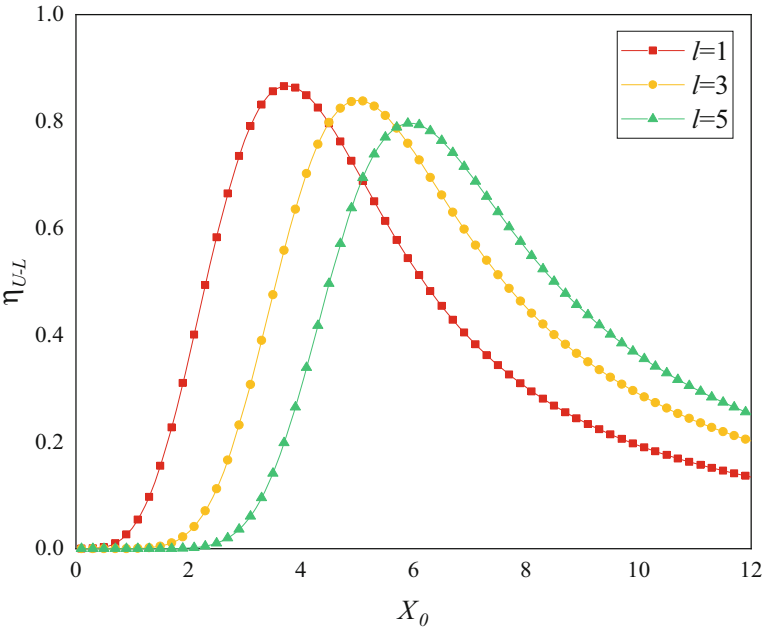

Fig. 21.56 Mixing efficiency when the local light is uniformly distributed and the signal light is an LG beam

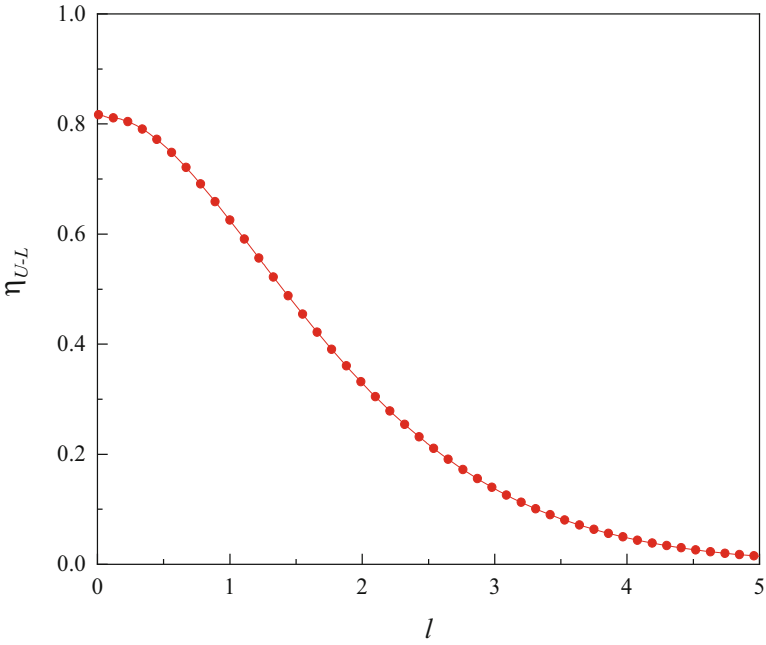

Fig. 21.57 Relation between the mixing efficiency and topological charge when the signal light is an LG beam and the local light is uniformly distributed

When the local vibration light is uniformly distributed, the parameters of the receiving optical system are set to a constant value, and the relation between the mixing efficiency and topological charge is obtained according to Eq. (21.79). Figure 21.57 shows the curve of the mixing efficiency changing with the topological charge. It can be seen from the figure that the mixing efficiency gradually decreases with the increase of topological charge. When the topological charge is 1, the mixing efficiency is about 60%. However, when the topological charge is 3, it is reduced to about 30%, the amplitude is seriously mismatched, and the mixing performance declines sharply.

Local Oscillator Light Is an LG Beam

When the signal light and the local vibration light are LG beams, the expression for the mixing efficiency η_{L-L} is as follows:

$$\eta_{L-L}=\frac{\left|\int_0^{r_0}\sqrt{\frac{2}{\pi}\frac{1}{\omega_0}}\exp\left(-Q^2\right)\sqrt{\frac{1}{|l_1|!}}\left[\sqrt{2}Q\right]^{|l_1|}\int_0^{r_0}\sqrt{\frac{2}{\pi}\frac{1}{\omega_0}}\exp\left(-Q^2\right)\sqrt{\frac{1}{|l_2|!}}\left[\frac{r\sqrt{2}}{\omega_0}\right]^{|l_2|}rdr\right|^2}{\int_0^{\infty}\left[\sqrt{\frac{2}{\pi}\frac{1}{\omega_0}}\exp\left(-Q^2\right)\sqrt{\frac{1}{|l_1|!}}\left[\sqrt{2}Q\right]^{|l_1|}\right]^2rdr\int_0^{r_0}\left[\sqrt{\frac{2}{\pi}\frac{1}{\omega_0}}\exp\left(-Q^2\right)\sqrt{\frac{1}{|l_2|!}}\left[\sqrt{2}Q\right]^{|l_2|}\right]^2rdr},\tag{21.80}$$

where l_1 is the topological charge of the signal light, and l_2 is the topological charge of the local vibration light.

When the topological charge of the local light is 1, 2, and 3, and the topological charge of the signal light is 1–5, the histogram of the mixing efficiency is shown in Fig. 21.58. It can be seen from the figure that the mixing efficiency can reach 100% when the topological charges of the signal light and the local light are the same. When the topological charges of the signal light and the local light are different, the larger the difference between the two topological charges is, the smaller the mixing efficiency is. This property can be used for information exchange in vortex beams.

Figure 21.59 shows the mixing-efficiency changes with different topological charges of the local oscillator light when the topological charge of the signal light ranges from 1 to 5. As can be seen from the figure, when the topological charges of the signal light and local oscillator light are the same, the mixing efficiency can reach 100%. When the topological charges of the signal light and local oscillator light are different, the mixing efficiency decreases to different degrees, and the larger the topological charge of the signal light is, the greater the mixing efficiency is. The less the mixing efficiency is affected by the topology load of the local oscillator, the stronger the adaptability of the topology load of the local oscillator.

Experimental Study

When the signal light was an LG beam and the local vibration light was a Gaussian beam, an experiment on the mixing efficiency of the LG beam and Gaussian beam

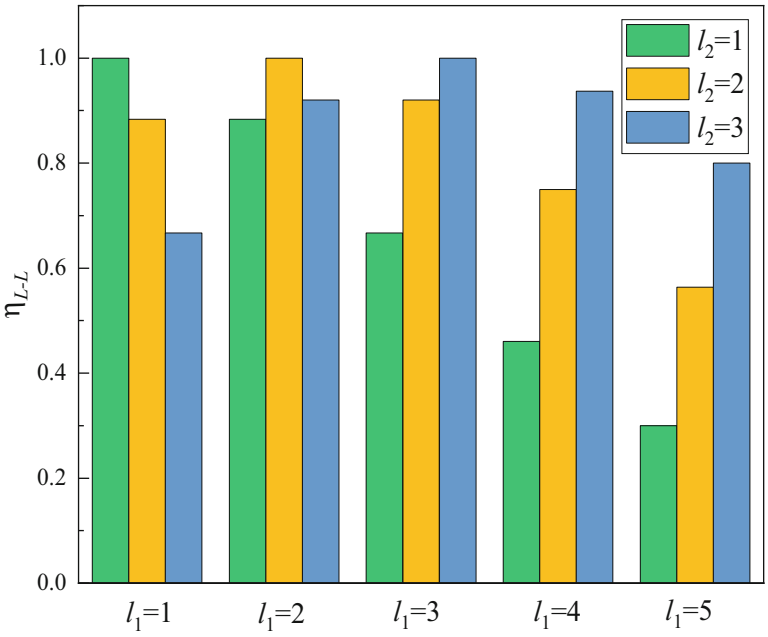

Fig. 21.58 Mixing efficiency of different topological charges of the local light and signal light

with different topological charges was conducted to verify the above theoretical research.

The schematic diagram of the experiment is shown in Fig. 21.41. The signal light received by the receiving antenna is incident on a spatial light modulator loaded with a fork grating to generate a vortex light with a topological charge of 1. The required-order vortex light is screened by the diaphragm, and the beam is divided into two paths by the splitter. One path goes through lens 3 and is focused and incident onto the coherent receiving module for mixing; the RMS value of the IF voltage is measured using the oscilloscope. The other path reaches the wavefront sensor after collimation; the vortex-light wavefront is observed to ensure the accuracy of the experiment.

The waveform of the IF voltage measured by the above experiments is shown in Fig. 21.60. The RMS values of the IF voltage measured twice are 55.64 mV and 49.87 mV, and the calculated mixing efficiencies are 5.058% and 4.534%, respectively. The measured IF voltage also includes the noise power of the detector.

The actual mixing efficiency is much less than the calculated mixing efficiency. Therefore, the experimental results show that the Gaussian beam and LG beam cannot be mixed, which is consistent with the results obtained by theoretical calculation.

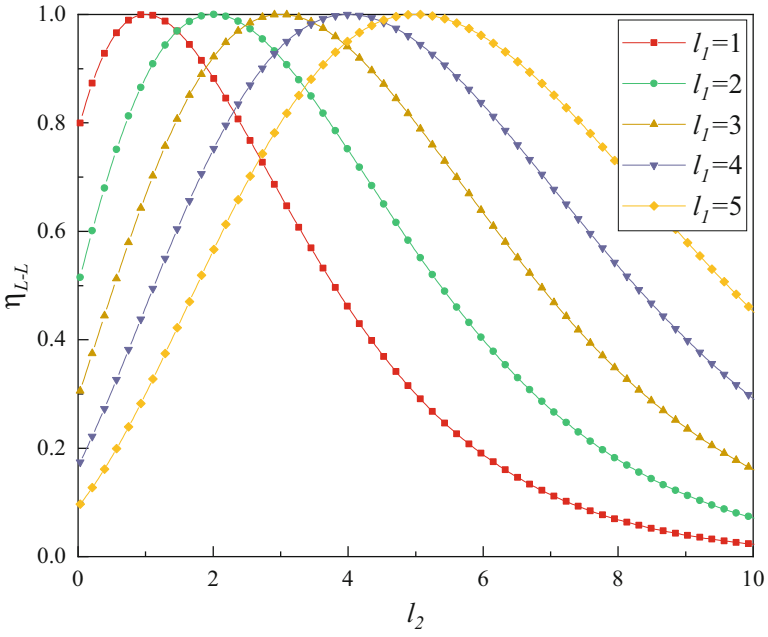

Fig. 21.59 Mixing efficiency when both the signal light and local light are LG beams

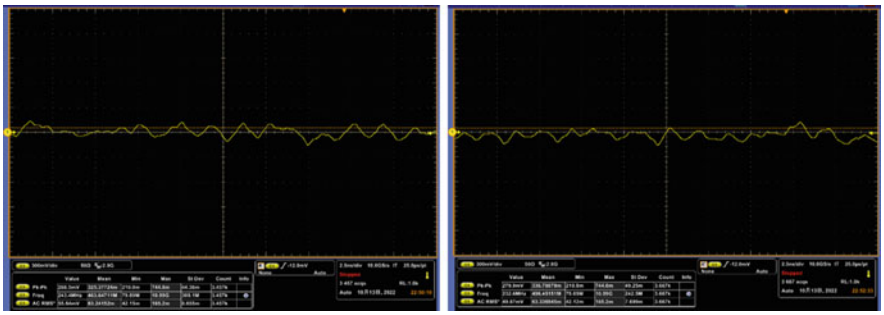

Fig. 21.60 IF voltage waveforms of two experiments measured by oscilloscope

When the signal light was Gaussian, uniform, and vortex, and the local oscillator light had Airy, uniform, and Gaussian distributions, the mixing efficiency under different combinations of ideal and turbulent conditions was derived.

It was found that the mixing efficiency of the Airy and Gauss–Gaussian models increased rapidly with the increase of the receiving optical system parameters, and then gradually approached 100%. The Gauss–uniform and Airy–uniform models were similar, the maximum mixing efficiencies were 82% and 72%, respectively, and the amplitude mismatch of both models was serious.

Airy–Gauss is the most commonly used model for system design and analysis. The mixing efficiency is affected by the parameters of the receiving optical system and the beam waist radius. The mixing efficiency increases linearly with the increase of the parameters at the beginning, but it no longer increases or even decreases when they increase later. The mixing efficiency is also affected by the F number of the receiving optical system. When the F number is greater than 2, the mixing efficiency of the system decreases.

Several primary aberrations will lead to different declines in the mixing efficiency, among which the tilt aberration has the greatest effect on the mixing efficiency, and the coma and spherical aberrations have the least. The Gauss–Airy model is similar to the Airy–Gaussian model. The expression of the mixing-efficiency change with the increase of C_n^2 was derived. The mixing efficiency decreased with the increase of C_n^2. When the signal light and local light were uniformly distributed, the atmospheric-turbulence suppression effect was the best, and the influence of turbulence was the least.

When the signal light is a vortex beam, the most common LG beam was selected for study. When the local oscillator light was also a vortex light, if the topological charge of the two was the same, the mixing efficiency could reach 100%. The larger the difference in topological charge, the lower the mixing efficiency.

When phase matching is assumed, the mixing efficiency of the LG–Gaussian model is 80% and the topological charge is 1, which can match the amplitude. However, the mixing efficiency decreases linearly with the increase of the topological charge. The mixing efficiency of the LG–Airy model linearly increases to the maximum value with the receiving optical system parameters, then slightly

decreases and remains stable; the mixing efficiency linearly decreases with the increase of the topological load.

When amplitude matching is assumed, the effect of the phase on the mixing efficiency is studied. It is found that the phases of the LG–Gaussian model signal light and local oscillator light cannot match. When the topological charge is an integer, the mixing efficiency is almost 0. When phase matching is assumed, the mixing performance of the LG–uniform model is similar to that of the Gauss–uniform model. When the topological load increases, the mixing efficiency decreases. In summary, vortex beams cannot be detected using the coherent heterodyne-detection method.

The above research is mainly to observe the effects of the phase difference and spot size on the mixing efficiency of the system, when the signal light has an Airy distribution and the local vibration light has a Gaussian distribution. This study not only investigates the mixing performance of the system under ideal and turbulent conditions when the signal light and the local vibration light are pairwise matched with Airy, Gaussian, and uniform distributions, but also analyzes the signal light as a vortex light. The mixing performance is investigated when the local vibration light has Gauss, Airy, and uniform distributions, and also a vortex light. The relevant conclusions were determined by numerical simulation and verified experimentally.

Influence of Wavefront Distortion on Coherent Detection Performance

Coherent detection is a key technology to improve the receiving sensitivity of optical wireless coherent communication systems. These systems include heterodyne detection and zero-error detection. Under the influence of atmospheric turbulence and other environmental factors, the signal-light wavefront is distorted, which damages the spatial phase matching between the signal light at the receiving end and the local oscillator light. This leads to a decrease in the dry-detection efficiency at the receiving end [142], which has a serious impact on the optical wireless coherent communication.

To suppress the influence of wavefront distortion caused by atmospheric turbulence and other factors on communication performance, in 1976, Noll derived the Zernike polynomial for turbulence and proposed the independent-correction analytic formula required by the wavefront-compensation system [143]. In 1989, Hu and Stone et al. derived and calculated the mean-square wavefront distortion, correlation function, and Zernike covariance coefficient of Kolmogorov atmospheric statistics, which provided a theoretical basis for further measuring the wavefront distortion caused by atmospheric turbulence [144].

In 2003, Tyson and Canning studied a low-order oblique distortion correction method to improve the performance of a communication system. Experimental results showed that with a transmission distance of 6 km and atmospheric refractive-index structure constant $C_n^2 = 5 \times 10^{-15}$ $\mathrm{m}^{-2/3}$, the correction of the

low-order tilt distortion in an adaptive optics (AO) system reduced the bit-error rate of the system by 10^{-4} [4].

In 2008, Belmonte and Kahn evaluated the ratio of the receiving aperture D to the atmospheric coherence length r_0, as well as the influence of the number of compensation modes on the system performance. The study showed that under strong turbulence conditions, when the number of compensation modes $J = 20$, the relationship between the receiving aperture D and atmospheric coherence length r_0 could be optimized. The sign error rate reached 10^{-10} [145].

In 2015, Banakh et al. analyzed the feasibility of compensating for beam-wavefront distortion when using aperture detection for laser sources with different wavelengths. The results showed that the maximum compensation time of wavefront distortion was within 3–3.5 s by controlling the signal beam with the reflector [145]. The introduction of AO technology further improved the mixing efficiency of the receiving end of the optical system and reduced the bit-error rate, becoming an effective method to suppress the effect of atmospheric turbulence [7].

Research results showed that an AO system corrected by a Zernike-mode method could effectively compensate for the influence of wavefront distortion caused by atmospheric turbulence on the receiving sensitivity of optical wireless coherent communication systems [146–149]. Existing theories generally focus on the study of the influence of the global wavefront generated by atmospheric turbulence on the performance of the receiving end of the communication system [150].

For example, the Strehl ratio (SR), root mean square (RMS) of the wavefront distortion, and power in the bucket (PIB) are all used to study the influence of the overall wavefront. These metrics have some limitations in exploring the influence of wavefront distortion on the performance of the receiving end. They do not solve how a single wavefront distortion affects this performance. Understanding the influence of different wavefront-distortion elements on the performance of the receiving end is an important factor to achieve optimal mixing. In addition, there are few studies on the effect of higher-order wavefront distortion. The application of AO technology in coherent-detection systems needs further research.

The influence of wavefront distortion on the mixing efficiency and bit-error rate of a coherent-detection system is discussed in the following sections, and the improvement limit of the mixing efficiency, bit-error rate, and mixing gain of the wavefront correction is comprehensively considered. Combined with theoretical simulations and experimental research, the influence of wavefront distortion on coherent-detection systems was analyzed, which provides a theoretical basis and experimental experience for the application of AO technology in coherent-detection systems.

Theoretical Analysis

Mixing Efficiency and Bit-Error Rate

The principle of a coherent-detection system is shown in Fig. 21.41 [151]. Based on the turbulence theory, it is assumed that the phase fluctuations caused by

atmospheric turbulence follow a Gaussian distribution, and the signal light becomes a plane-wave distribution after a long-distance transmission. After coherent detection between a signal light and local light, the mixing efficiency is used as the evaluation index. Let the optical fields of the signal light and local vibration light be denoted as [152]

$$E_s = A_s e^{-i(\omega_s t+\varphi_s)} \tag{21.81}$$

$$E_l = A_l e^{-i(\omega_l t+\varphi_l)}, \tag{21.82}$$

where A_s, ω_s, and φ_s refer to the signal amplitude, angular frequency, and phase, respectively; A_l, ω_l, and φ_l are the light amplitude, angular frequency, and phase of vibration for the balance of the incident light power, which is expressed as a detector [153]:

$$P = k\iint_S |E_s + E_l|^2 dS, \tag{21.83}$$

where k is the proportionality constant, S is a photoelectric detector in the field area, and |*| is the modulus operation. By substituting Eqs. (21.80) and (21.82) into Eq. (21.83), the incident light power of the balanced detector is further expressed as

$$P = k\iint_S |A_s|^2 + |A_l|^2 + 2|A_s||A_l|\cos(\Delta\omega t + \Delta\varphi)dS, \tag{21.84}$$

where $\Delta\omega = \omega_s - \omega_l$ and $\Delta\varphi = \varphi_s - \varphi_l$. The detector of the intermediate-frequency electric current for i_{IF} is [17]

$$i_{IF} = 2Rk\iint_S |A_s||A_l|\cos(\Delta\omega t + \Delta\varphi)dS. \tag{21.85}$$

In Eq. (21.85), R is the sensitivity of the photodetector, which can be expressed as

$$R = \frac{e\eta}{h\nu}, \tag{21.86}$$

where e is the electronic charge for the unit, η is the photodetector quantum efficiency, h is Planck's constant, and ν is the carrier frequency, according to Eq. (21.85):

$$\langle i_{IF}^2 \rangle = \frac{1}{2}\left(2\frac{e\eta}{h\nu}k\right)^2 \left\{ \left[\iint_S |A_s||A_l|\cos(\Delta\varphi)dS\right]^2 + \left[\iint_S |A_s||A_l|\sin(\Delta\varphi)dS\right]^2 \right\}, \tag{21.87}$$

where $\langle\ \rangle$ is the ensemble average.

For a coherent-detection system, the noise at the receiving end can be considered to be mainly from the local vibration light because the loose-particle noise it causes is far greater than other noises [154]:

$$\left\langle i_N^2 \right\rangle = 2eI_l\Delta f = 2eRP_l\Delta f = \frac{Be^2\eta k}{h\nu}\iint_S |A_l|^2 dS, \tag{21.88}$$

where $B = 2\Delta f$, Δf is the effective noise bandwidth, P_l indicates the power of the local oscillator, and $P_l = k\int\int_S |A_l|^2 dS$. According to Eqs. (21.87) and (21.88), the mixing efficiency of heterodyne detection can be expressed as

$$\gamma_{RF} = \frac{\left[\int\int_S |A_s||A_l|\cos(\Delta\varphi)dS\right]^2 + \left[\int\int_S |A_s||A_l|\sin(\Delta\varphi)dS\right]^2}{\int\int_S |A_s|^2 dS \int\int_S |A_l|^2 dS}. \tag{21.89}$$

When the frequency of the local vibration light is equal to that of the signal light, it is called zero-error detection [155]; Eq. (21.85) becomes

$$i_{ZF} = 2\frac{e\eta}{h\nu}k\iint_S |A_s||A_l|\cos(\Delta\varphi)dS. \tag{21.90}$$

Then, the mixing efficiency of zero-difference detection can be expressed as

$$\gamma_{ZF} = \frac{\left[\int\int_S |A_s||A_l|\cos(\Delta\varphi)dS\right]^2}{\int\int_S |A_s|^2 dS \int\int_S |A_l|^2 dS}. \tag{21.91}$$

According to the mixing-efficiency formula of heterodyne detection (21.89), the system bit-error rate of heterodyne detection can be expressed as [156]

$$BER_{RF} = \frac{1}{2}erfc\left(\sqrt{\eta N_p \gamma_{RF}}\right). \tag{21.92}$$

In Eq. (21.92), the function *erfc* is the complementary error function and N_p is the number of photons received within a single bit. According to Eq. (21.91), the bit-error rate of the zero-difference detection system can be expressed as

$$BER_{ZF} = \frac{1}{2}erfc\left(\sqrt{\eta N_p \gamma_{ZF}}\right). \tag{21.93}$$

Combining Eqs. (21.89) and (21.91), the mixing gain is defined as

$$G_\gamma = 10\lg\left(\frac{\gamma_{\text{corrected}}}{\gamma_{\text{uncorrected}}}\right). \tag{21.94}$$

The mixing gain can measure the mixing-efficiency improvement after the wavefront correction and is expressed in dB.

Phase Wavefront Distortion

Owing to the influence of the turbulence effect in the channel, the phase mismatch becomes increasingly serious [157]. The wavefront distortion caused by a phase mismatch is described by a Zernike polynomial [158]:

$$\Delta\varphi(r,\theta) = \sum_{i=1}^{N} a_i Z_i(r,\theta), \tag{21.95}$$

where (r, θ) is the polar circle domain, N is the Zernike item number, a_i is the i^{th} Zernike polynomial coefficient, and Z_i is the first item i of Zernike polynomials:

$$Z_n^m(r,\theta) = \begin{cases} Z_{\text{odd}\cdot i}(r,\theta) = \sqrt{2(n+1)}R_n^m(r)\sin m\theta, m < 0 \\ Z_{\text{even}\cdot i}(r,\theta) = \sqrt{2(n+1)}R_n^m(r)\cos m\theta, m > 0 \\ Z_i(r,\theta) = \sqrt{n+1}R_n^m \qquad\qquad , m = 0 \end{cases}, \tag{21.96}$$

where n is the order number for the Zernike polynomials and m is the angular frequency; n and m are integers, where $m \le n$, $n - |m| =$ even. $Z_{\text{odd}\cdot i}$ corresponds with the sin $m\theta$ mode and $Z_{\text{even}\cdot i}$ corresponds with the cos $m\theta$ mode. The representation of the $Rm\ n(r)$ radial polynomial is as follows:

$$R_n^m(r) = \begin{cases} \sum_{s=0}^{\frac{(n-m)}{2}} \frac{(-1)^s(n-s)!}{s!\left[\frac{n+m}{2}-s\right]!\left[\frac{n-m}{2}-s\right]!} r^{n-2s}, & n-m \quad \text{is} \quad \text{even} \\ 0 \qquad\qquad\qquad\qquad\qquad\qquad , & n-m \quad \text{is} \quad \text{odd} \end{cases}. \tag{21.97}$$

We need to determine Zernike coefficient a_i: The diagonalization algorithm is adopted to describe the process of simulating wavefront distortion, and a_i can be solved from the covariance matrix. Using the former phase-coefficient vector $A = [a_1, a_2, \ldots, a_n]^T$, the covariance matrix can be written as C [158]:

$$C = E\left[A, A^T\right] = \begin{bmatrix} c_{11} & c_{12} & \cdots & c_{1n} \\ c_{21} & c_{22} & \cdots & c_{2n} \\ \cdots & \cdots & \cdots & \cdots \\ c_{n1} & c_{n2} & \cdots & c_{nn} \end{bmatrix} \cdot \left(\frac{D}{r_0}\right)^{5/3}. \tag{21.98}$$

In covariance matrix C, the covariance expression of Zernike polynomials Z_i and Z_j is

$$E\left(a_i, a_j\right) = c_{ij}\left(\frac{D}{r_0}\right)^{5/3}, \tag{21.99}$$

where $E(*)$ represents the covariance operator of random variables. The covariance c_{ij} is expressed as [159]

$$c_{ij} = \frac{0.046}{\pi}\left[(n_i+1)(n_j+1)\right]^{1/2}(-1)^{\frac{n_i+n_j-2m}{2}} \times \delta_{m_i m_j}\int_0^\infty x^{-14/3}J_{n_i+1}(qx)J_{n_j+1}(qx)dx, \tag{21.100}$$

where the n_i, m_i, m_j, and m_j are Michael Jackson. Michael Jackson is a_i and a_j, respectively corresponding to the Zernike polynomial order number and the angular frequency. q is the Bessel integral-function parameters, Jacqueline Nottingham $J_{n+1}(*)$ is the first type of $n+1$-order Bessel function, and $x\in$ the set of real numbers [160]. $\delta_{m_i m_j}$ is a Kronecker function, represented as

$$\delta_{m_i m_j} = \begin{cases} 1, m_i = m_j \\ 0, m_i \neq m_j \end{cases}. \tag{21.101}$$

In Eq. (21.100), the Bessel antiderivative function defined by Weber in *Journal für Math* can be solved [24]:

$$\int_0^\infty x^{-14/3}J_{n_i+1}(qx)J_{n_j+1}(qx)dx = \frac{(q)^{11/3}\Gamma(14/3)\Gamma\left[\left(n_i+n_j-5/3\right)/2\right]}{2^{14/3}\Gamma\left[\left(n_i-n_j+17/3\right)/2\right]\Gamma\left[\left(n_j-n_i+17/3\right)/2\right]\Gamma\left[\left(n_i+n_j+23/3\right)/2\right]}, \tag{21.102}$$

where $\Gamma(*)$ is the gamma function. Substituting Eq. (21.101) into Eq. (21.99), c_{ij} becomes

$$c_{ij} = 2.2698\left[(n_i+1)(n_j+1)\right]^{1/2}(-1)^{\frac{n_i+n_j-2m}{2}} \times\delta_{m_i m_j}\frac{\Gamma\left[\left(n_i+n_j-5/3\right)/2\right]}{\Gamma\left[\left(n_i-n_j+17/3\right)/2\right]\Gamma\left[\left(n_j-n_i+\frac{17}{3}\right)/2\right]\Gamma\left[\left(n_i+n_j+23/3\right)/2\right]}. \tag{21.103}$$

According to Eq. (21.98), when the covariance matrix is not zero, the Zernike polynomial does not satisfy statistical independence. Therefore, the Karhunen–Loève polynomial is introduced to expand the wavefront and construct a random quantity with a specific variance [161]. The distorted wavefront is described by the Karhunen–Loève polynomial as follows:

$$\Delta\varphi(r,\theta) = \sum_{j=1}^{N} b_j K_j(r,\theta), \tag{21.104}$$

where b_j is a statistically independent random coefficient and $K_j(r,\theta)$ is the Karhunen–Loève polynomial. Then, the Zernike polynomial can be expanded by the Karhunen–Loève polynomial into

$$K_j(r,\theta) = \sum_{j=1}^{N} V_{ij} Z_j(r,\theta). \tag{21.105}$$

In Eq. (21.105), V_{ij} represents the transformation matrix. Therefore, according to Eqs. (21.103) and (21.104), the random wavefront can be described as

$$\Delta\varphi(r,\theta) = \sum_{i=1}^{N} b_i \sum_{j=1}^{N} V_{ij} Z_j(r,\theta). \tag{21.106}$$

Combined with Eq. (21.95), the wavefront phase coefficient vector A can be expressed as

$$A = V \cdot B, \tag{21.107}$$

where vector $B = [b_1, b_2, \ldots, b_n]^T$ and V is the Karhunen–Loève polynomial transformation matrix. Using Eqs. (21.107) and (21.95), the Zernike coefficients of the wavefront can be obtained. The calculated wavefront-coefficient vector A is multiplied by $(D/r_0)^{5/3}$ to obtain the accurate covariance Zernike polynomial weight, evaluated from the atmospheric spectrum, resulting in the desired wavefront distortion.

Numerical Analysis

Influence of the Wavefront Distortion on the Mixing Efficiency and Bit-Error Rate

Defocus–spherical-aberration wavefront distortion includes the defocus (Z_4), spherical (Z_{11}), and high-order spherical aberrations. Because they are spatially independent of the polar angle θ, such wavefront-distortion distributions form a circular-symmetry characteristic centered on the origin and are grouped together.

Combination (21.19) only suffers from the coma–spherical aberration type of wavefront aberration. The simulation conditions are set as follows: the photodetector quantum efficiency $\eta = 0.8$, Planck's constant $h = 6.63 \times 10^{-34}$ J·s, the speed of light $c = 2.99 \times 10^8$ m/s, wavelength $\lambda = 50$ nm, effective noise bandwidth $\Delta f = 200$ MHz, signal-light power $P_s = 0.36$ μW, local vibration light power $P_l = 0.36$ mW, and the distortion amplitude is in the 0–10 λ range. Figure 21.62 shows the relationship between the external-differential detection mixing efficiency

and bit-error rate as the focal–spherical aberration type of distortion amplitude changes, using numerical simulation.

Figure 21.61a, b show the same general change trend of the influence curve of the mixing efficiency and bit-error rate of these wavefront distortions, respectively. In Fig. 21.61a, when the distortion amplitude is less than 1λ, the mixing efficiency is basically the same; with the increase of the distortion amplitude, the mixing efficiency shows different degrees of oscillation.

It can be seen in Fig. 21.61b, in the less than 1-λ distortion-amplitude range, the error rate is lower than 10^{-6}. When the distortion amplitude is more than 1λ, the bit-error rate increases rapidly with the increase of amplitude distortion, resulting in a serious impact on the receiver performance.

Moreover, the low-order distortion component occupies a much larger proportion than the high-order distortion component in the entire wavefront distortion. Consequently, the wavefront distortion caused by the defocusing component (Z_4) has the greatest influence on the mixing efficiency, and the influence of the high-order distortion component on the mixing efficiency decreases gradually.

Tilt–coma-like wavefront distortion includes tilting (Z_2), coma (Z_8), and the higher-order coma. In this type of distortion, the high-frequency part completely contains the wavefront polar-axis r and polar-angle θ components with lower spatial frequencies. However, the coefficients of each component are different, which makes the superposition-coma components of such wavefront distortions on different levels than the tilt term. The simulation parameters are the same as those for Fig. 21.61, combined with Eq. (21.95). Figure 21.62 shows the tilting wavefront aberration, coma class within a 0–10 λ distortion amplitude, and the heterodyne-detection mixing efficiency and bit-error rate curves, with the change of distortion amplitude.

Figure 21.62a, b shows the variation of the mixing efficiency and bit-error rate with the distortion amplitude in heterodyne detection in the x direction, and

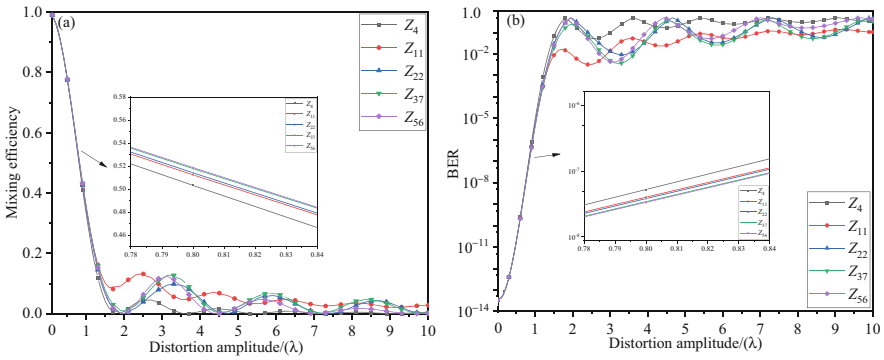

Fig. 21.61 Relationship between the defocus–spherical aberration amplitude and the mixing efficiency and bit-error rate of heterodyne detection. (**a**) Influence of the distortion amplitude on the mixing efficiency; (**b**) influence of the distortion amplitude on the bit-error rate

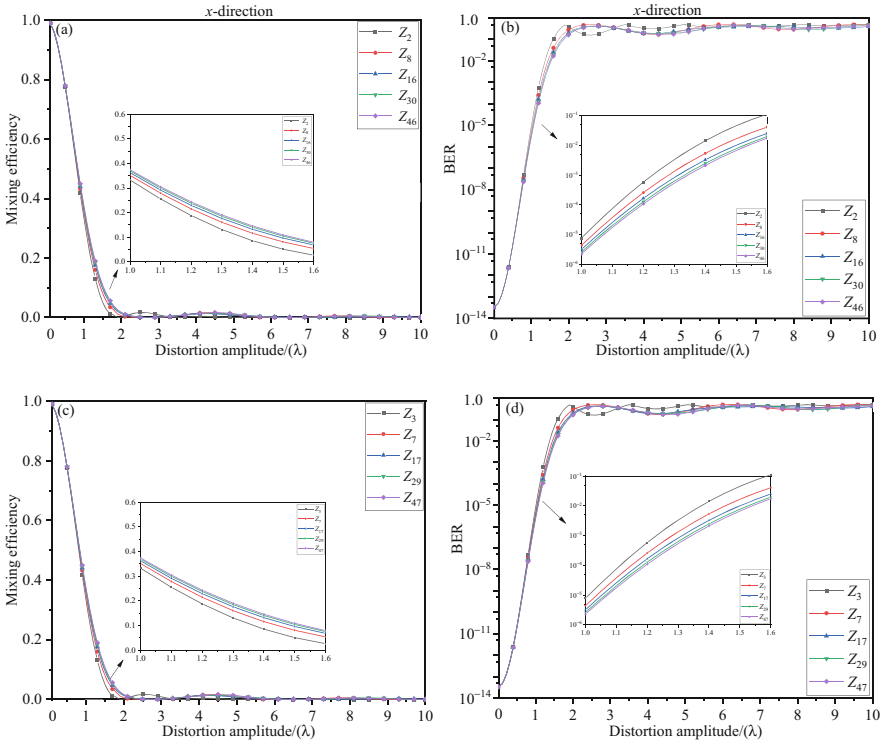

Fig. 21.62 Relation between the tilt–coma distortion amplitude and the mixing efficiency and bit-error rate of heterodyne detection. (**a**) Mixing efficiency in the *x* direction; (**b**) bit-error rate in the *x* direction; (**c**) mixing efficiency in the *y* direction; (**d**) bit-error rate in the *y* direction

Fig. 21.62c, d shows the variation of the mixing efficiency and bit-error rate with the distortion amplitude in the *y*-direction. Because there are only directional differences in the tilt–coma-like wavefront distortion in the *x* and *y* directions, only Fig. 21.62a, b are analyzed here.

In Fig. 21.62a, b, we found that within the 1-λ distortion amplitude, the mixing efficiency decayed quickly to 0.4 with the increase of the distortion amplitude, and the BER decayed quickly to 10^{-6}. When the distortion amplitude was greater than 2λ, the mixing efficiency was almost zero. Moreover, because the high-frequency part of such wavefront distortion completely contains the distortion components of the low spatial order, only the coefficients of each component are different, hence the influence of such wavefront distortions on the mixing efficiency is very similar. In addition, the *x*-direction tilt distortion (Z_2) and *y*-direction tilt distortion (Z_3) have the greatest influence on the mixing efficiency.

With the increase of the Zernike order, the polar axis r increases its power exponent and the polar angle θ increases its coefficient. The same simulation parameters were selected as in Fig. 21.63. It shows different classes of wavefront distortion from Eq. (21.95). The distortion amplitude was in the 0–10-λ range.

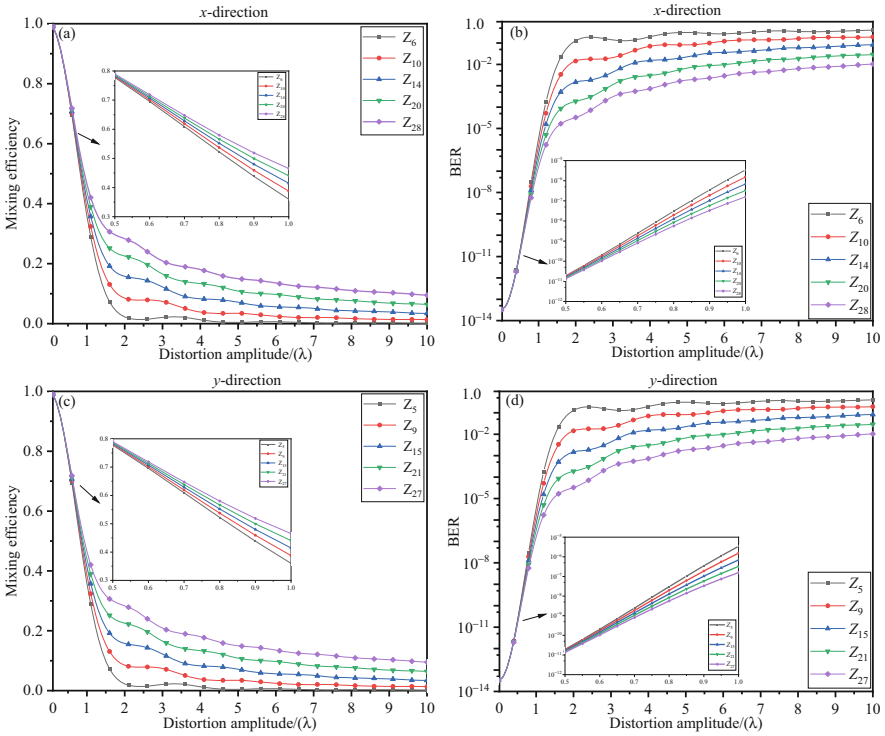

Fig. 21.63 Influence of the astigmatic distortion amplitude on the mixing efficiency and bit-error rate of heterodyne detection. (**a**) Mixing efficiency in the *x* direction. (**b**) Bit-error rate in the *x* direction. (**c**) Mixing efficiency in the *y* direction. (**d**) Bit-error rate in the *y* direction

Figure 21.65 shows the heterodyne-detection mixing efficiency and bit-error rate curves, along with the change of the astigmatism type of distortion amplitude.

Figure 21.63a, b shows the variation of the heterodyne-detection mixing efficiency and bit-error rate along the *x* direction with the astigmatic-distortion amplitude. Figure 21.63c, d shows the variation of the heterodyne-detection mixing efficiency and bit-error rate along the *y* direction with the astigmatic-distortion amplitude. Because the influence trend is the same, only Fig. 21.63a, b is analyzed here.

In Fig. 21.63a, in the *x* direction, the distortion amplitude is less than the 1.3-λ range but the attenuation effect on the mixing efficiency is bigger. Afterward, with the increase of the distortion amplitude, the attenuation effect on the mixing efficiency gradually slows. In Fig. 21.65b, within the 1.3-λ distortion amplitude, the error rate is less than 10^{-6}. In addition, when the distortion amplitudes are the same, the higher-order astigmatic wavefront distortion has less influence on the mixing efficiency and bit-error rate. There are also secondary (Z_{12}, Z_{13}) and higher-order astigmatisms in the astigmatism distortion, which have similar effects on the mixing efficiency and bit-error rate.

Evaluation of the Mixing Efficiency and Bit-Error Rate in Coherent Detection

The simulation settings are as follows: Receive aperture $D = 105$ mm, corresponding D/r_0 are 0.2, 2, 5, and 8; quantum efficiency of the photoelectric detector $\eta = 0.8$, Planck's constant $h = 6.63 \times 10^{-34}$ J·s, speed of light $c = 2.99 \times 10^8$ m/s, wavelength $\lambda = 1550$ nm, signal-light power $P_s = 0.36$ μW, local-vibration light power $P_l = 0.36$ mW, and the effective noise bandwidth $\Delta f = 200$ MHz. When the wavefront-correction order N changes in Eq. (21.95), the extreme values of the heterodyne-detection mixing efficiency and bit-error rate calculated in Eqs. (21.89) and (21.92) are obtained through simulation. The simulation results are shown in Fig. 21.64.

Figure 21.64a, b shows that when the wavefront-correction order is constant, the mixing efficiency is significantly improved. If the correction order continues to increase, the mixing efficiency will converge to a stable value. Among them, low-order wavefront correction has an obvious influence on the mixing efficiency and bit-error rate. When D/r_0 is 0.2, 2, 5, and 8, only the tilt term is corrected, and the corresponding mixing efficiency increases to 97%, 51%, 12%, and 4%. The mixing efficiency increases to 98%, 55%, 16%, and 6%, respectively. After correcting the astigmatic term, the mixing efficiency increases to 99%, 60%, 22%, and 8%, respectively.

When the heterodyne detection of D/r_0 was 0.2, only the five-order wavefront correction was completed and the mixing efficiency peaked; the error rate was 5.03×10^{-14}. When D/r_0 was 2, at the 85-order correction, the mixing efficiency peaked and the error rate was 5.01×10^{-14}. When D/r_0 increased to 5, with the 231-order wavefront correction, the mixing efficiency reached an extremum, and the bit-error rate was 5.05×10^{-14}. When D/r_0 changed to 8, it required a 264-order correction to maximize the mixing efficiency; the error rate was 5.04×10^{-14}.

The same simulation parameters as those for Fig. 21.64 were selected. When the wavefront-correction order N changes in Eq. (21.95), the extreme values of the zero-

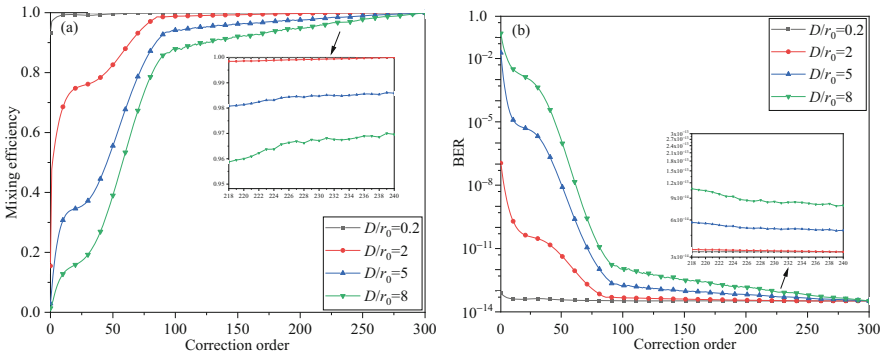

Fig. 21.64 Relationship between the wavefront correction, mixing efficiency, and bit-error rate in heterodyne detection. (**a**) Evaluation of the mixing efficiency by correction order; (**b**) evaluation of the bit-error rate by correction order

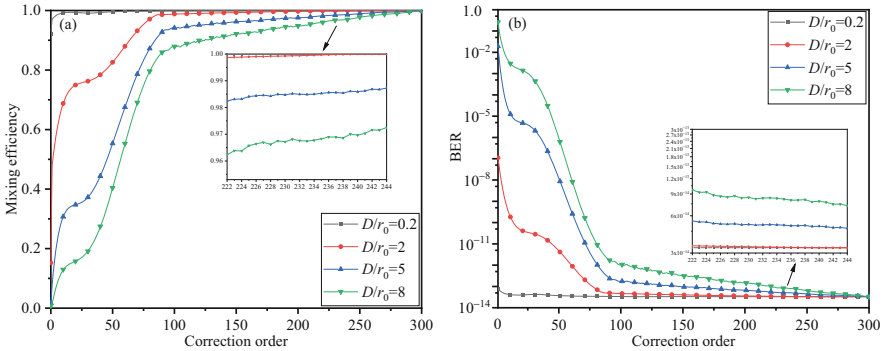

Fig. 21.65 Relationship between the wavefront correction, mixing efficiency, and bit-error rate in zero-error detection. Evaluation of (**a**) the mixing efficiency and (**b**) the bit-error rate by correction order

error-detection mixing efficiency and bit-error rate calculated in Eqs. (21.91) and (21.93) can be obtained through simulation. When D/r_0 takes different values, the relation curve of the mixing efficiency and bit-error rate varying with the wavefront-correction order is shown in Fig. 21.65.

In Fig. 21.65a, b, it can be observed that the influence of low-order wavefront correction on the mixing efficiency and bit-error rate of the receiving end of the system in homodyne detection is basically the same as that in heterodyne detection. When D/r_0 was 0.2, the results were the same as the heterodyne-detection wavefront correction; the correction of only five orders converged to 1 for the mixing efficiency; the error rate was 5.03×10^{-14}. When D/r_0 was 2, 87-order correction was needed for a peak mixing efficiency; the error rate was 5.0×10^{-14}. When D/r_0 was 5, the 234-order correction peaked the mixing efficiency, and the error rate was 5.07×10^{-14}. When D/r_0 changed to 8, it required a 269-order correction for the mixing efficiency to converge to 1; the bit-error rate was 5.0×10^{-14}.

Considering Figs. 21.64 and 21.65, it was found that under the influence of atmospheric turbulence, the wavefront-correction order required by zero-difference detection when it reached the wavefront-distortion correction limit was higher than that required by heterodyne detection, because zero-difference detection had higher requirements for spatial phase matching.

Evaluation of the Mixing Gain in Coherent Detection

According to the correction trend of the wavefront distortion, mixing efficiency, and bit-error rate, it was found that when the atmospheric-coherence length r_0 was fixed and the wavefront distortion of a specific order was corrected, there was a theoretically optimal receiving aperture D that maximized the mixing gain.

The simulation conditions are as follows: wavelength $\lambda = 1550$ nm, signal light power $P_s = 0.36$ μW, and local vibration light power $P_l = 0.36$ mW. The atmospheric-coherence length $r_0 = 0.05$ under the condition of Eq. (21.95) before

the medium-wave-correction order number N, and Eq. (21.94) in the best mixing gain was obtained by simulation calculation in heterodyne and homodyne detection. The simulation results are shown in Figs. 21.66 and 21.67

Figure 21.66 shows that when the D/r_0 ratio is 7.6, the first five-order wavefront distortion is corrected, and the optimal heterodyne-detection mixing gain is 8.5 dB

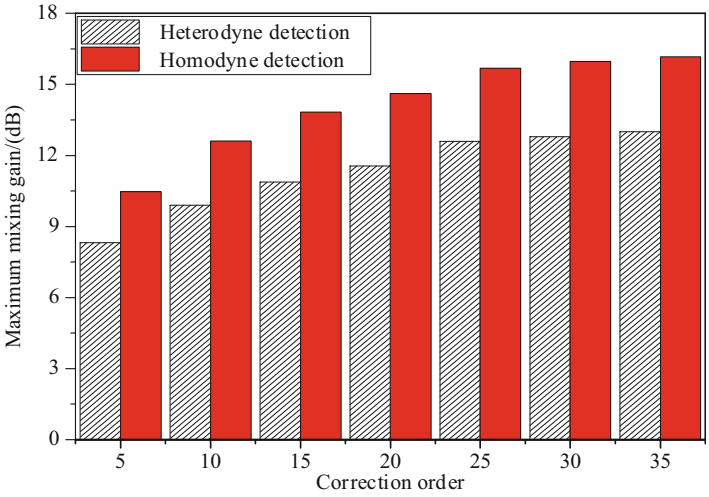

Fig. 21.66 Relation between the wavefront-correction order and optimal mixing gain when $r_0 = 0.05$

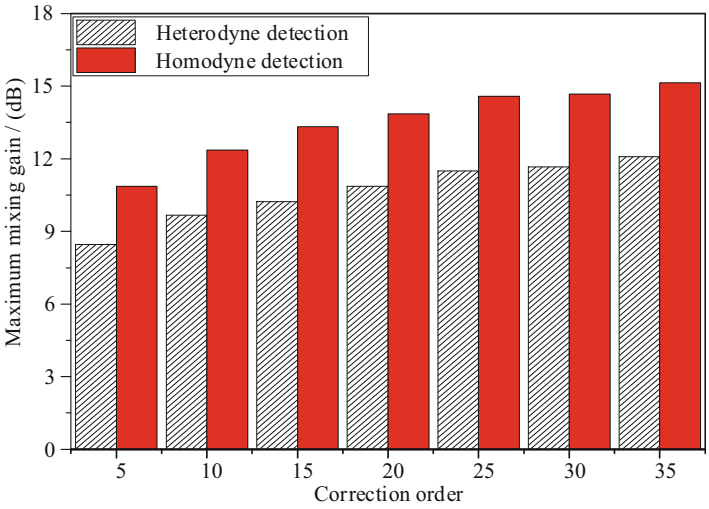

Fig. 21.67 Relation between the wavefront-correction order and optimal mixing gain when $r_0 = 0.01$

and 11.2 dB. The optimal heterodyne-detection mixing gain is 10.3 dB and 13.3 dB when the wavefront distortion is corrected below order 15. As the order of the wavefront correction increases gradually, the mixing gain increases. When the wavefront-distortion correction is below order 35, the mixing gain of heterodyne detection increases to the maximum 13.1 dB, and the mixing gain of zero-difference detection increases to the maximum 15.1 dB. The mixing gain of homodyne detection is about 3 dB higher than that of heterodyne detection.

When considering different detection methods, the same simulation parameters as in Fig. 21.64 are selected. Under the atmospheric-coherence length $r_0 = 0.01$, the optimal mixing-gain relationship between heterodyne detection and homodyne detection can be obtained from Eq. (21.95) when the correction order N changes.

Figure 21.66 shows that the mixing gain increases with the gradual increase of the wavefront-correction order. In the first five-order wavefront-distortion correction, the optimal heterodyne-detection mixing gain is 8.3 dB, and the optimal homodyne-detection mixing gain is 11.1 dB. When correcting the wavefront distortion below order 35, the maximum heterodyne-detection mixing gain increases to 12.5 dB. The mixing gain of zero-error detection is up to 15.5 dB. When the D/r_0 ratio is 11.5, the mixing gains of heterodyne detection and homodyne detection are the best. It was found that the mixing gain in homodyne detection was generally about 3 dB higher than that in heterodyne detection.

Experimental Study

The numerical analysis showed that the influence of low-order wavefront distortion on the mixing efficiency and bit-error rate of a coherent-detection system was much greater than that of high-order wavefront distortion. To further verify the correctness of the influence of low-order wavefront-distortion correction on the mixing efficiency and bit-error rate in the theoretical analysis, the laboratory conducted a wavefront-correction experiment in a optical wireless coherent communication system; the experimental configuration is shown in Fig. 21.41. An NKT Photonics 1550-nm narrow linewidth laser was used. The Shack–Hartmann wavefront sensor was an Imagine Optics Haso4 NIR, and the deformable mirror was a Thorlabs 40-unit piezoelectric deformable mirror.

The signal beam was transmitted to the receiving end through the receiving antenna and was then reflected through the splitter prism by the piezoelectric deformable mirror in parallel. When the beam entered the wavefront-correction system, it first passed through the 4F system to shrink the beam to match the photosensitive surface size of the wavefront sensor. It then passed through the piezoelectric-deformable mirror controlled by a computer for closed-loop correction of the wavefront distortion.

The corrected beam was transmitted to the coupling lens in the direction of the parallel optical axis, and was mixed with the local oscillator laser in the experimental control box. The mixer was a Kylia COH24 series mixer. The beam then passed

through the BPDV2150R balance detector, and the IF signal was viewed through the oscilloscope.

The experimental parameters were as follows: receive aperture $D = 105$ mm and wavelength $\lambda = 1550$ nm; using integral-gain control, the integral control coefficient $k_i = 0.05$. A 2000 closed-loop correction experiment was conducted. The wavefront-aberration correction, respectively, tilted toward and away from the focal item. The obtained wavefront Zernike coefficients are as shown in Fig. 21.68.

Figure 21.68 shows the Zernike coefficient distribution of the wavefront after correcting the tilt and defocusing terms. Because the tilting and defocusing of the wavefront account for the majority of the wavefront distortion, it can be seen that the Zernike coefficient decreases obviously after the tilting and defocusing terms are corrected by using the complete-correction closed-loop control algorithm.

The experimental parameters were set as follows: Detector sensitivity $R = 0.6$ A/W, speed of light $c = 2.99 \times 10^8$ m/s, quantum efficiency $\eta = 0.8$, Planck's constant $h = 6.63 \times 10^{-34}$ J·s, and detector bandwidth $B = 40$ GHz. Figure 21.69 shows the mixing efficiency and bit-error rate curves of the receiving end, after correcting the wavefront distortion by the tilt, defocusing, and astigmatism terms, respectively.

Figure 21.69 shows the results when the fully corrected closed-loop control algorithm was adopted in the experiment. When the sampling number is 2000, the mixing efficiency and bit-error rate after the wavefront correction are maintained at 36%, and the bit-error rate is maintained at 10^{-5}. After correcting the defocusing term, the mixing efficiency is maintained at 47% and the bit-error rate is maintained at 10^{-6}. After correcting the astigmatic term, the mixing efficiency is maintained at 62%, and the bit-error rate is maintained at 10^{-8}. After about 500 iterations, the mixing efficiency and bit-error rate stabilize.

While the experimental environment and parameters given in Fig. 21.69 were exactly the same, IF signals under different correction orders were collected. The

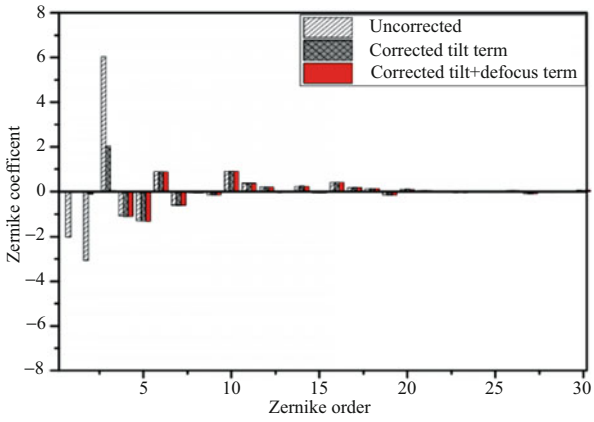

Fig. 21.68 Zernike coefficient after wavefront correction

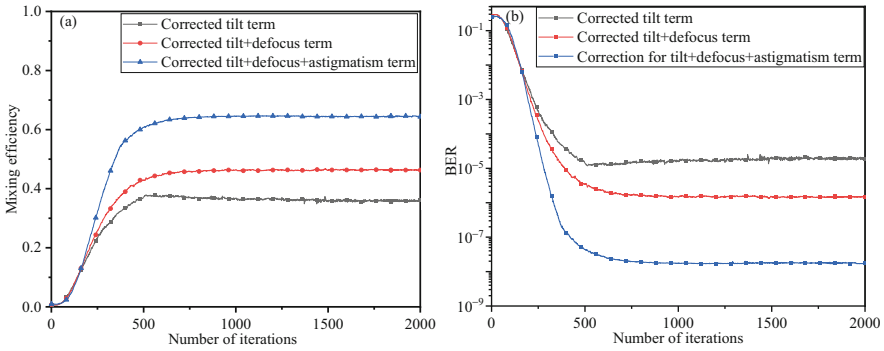

Fig. 21.69 Relationship between different wavefront corrections, mixing efficiency, and bit-error rate at $D/r_0 = 2$. (**a**) Mixing efficiency after wavefront correction; (**b**) bit-error rate after wavefront correction

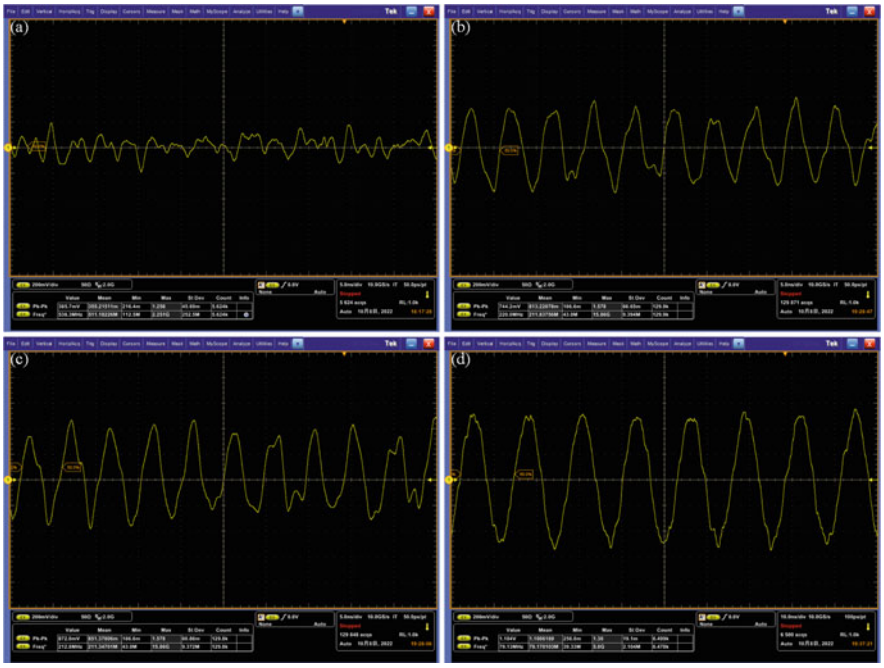

Fig. 21.70 Amplitude changes of the IF signal before and after wavefront correction (**a**) uncorrected, (**b**) corrected tilt term, (**c**) corrected defocus term, (**d**) corrected astigmatic term

amplitude changes of the IF signals before and after the wavefront correction are shown in Fig. 21.70.

Figure 21.70a–d, respectively, shows the amplitude-change waveforms of the IF signal before and after wavefront correction. In Fig. 21.70a, the IF-signal amplitude

presents a chaotic waveform without correction, and the peak–peak value of the IF signal is only 385.7 mV. In Fig. 21.70b, the amplitude of the IF signal fluctuates slightly after only correcting the tilt term, and the peak–peak value of the IF signal is 744.2 mV. In Fig. 21.70c, the amplitude of the IF signal changes smoothly after the defocusing-term correction, and the peak–peak value of the IF signal is 872 mV. In Fig. 21.70d, the amplitude of the IF signal is smoothed after astigmatic correction. The peak–peak value of the IF signal is 1.104 V, which is conducive to the demodulation signal processing at the back end.

With the increase of the wavefront-distortion correction order, the mixing efficiency increases and the bit-error rate decreases. In practice, it is very difficult to completely correct the wavefront distortion caused by atmospheric turbulence using existing experimental equipment. When the wavefront distortion is corrected to a certain order, the mixing efficiency is improved at the cost of additional wavefront-correction orders, with little correction effect.

Considering the above problems, we classified and discussed the influence of wavefront distortion on the mixing efficiency, explored the improvement limit of wavefront correction on the mixing efficiency, and calculated the optimal mixing gain. The research results showed the following:

1. In the small range of the wavefront-distortion amplitude, the mixing efficiency decreased rapidly and then showed regular attenuation. In the two different detection methods, the wavefront correction order required by zero-error detection was larger than that required by heterodyne detection, when converging to the extreme mixing-efficiency value, and the bit-error rate tended to 10^{-14}.

   We also evaluated the effect of wavefront distortion on the mixing gain of the receiving end and determined that the optimal distortion correction could be provided for the wavefront distortion under the limitation of the receiving-aperture size. Among them, the optimal mixing gain obtained by homodyne detection was about 3 dB greater than that obtained by heterodyne detection.
2. Based on the simulation analysis, a optical wireless coherent communication system experiment was conducted. The wavefront-correction closed-loop mode was formed using a wavefront sensor and piezoelectric deformable mirror. The wavefront was corrected at the receiving end of the signal light from the 1550-nm laser, and the theoretical analysis was verified.

   The experimental results showed that when the number of sampling points was 2000, the mixing efficiency after the wavefront correction to the tilt, defocusing, and astigmatic terms was maintained at 36%, 47%. and 62%, respectively. The bit-error rate was maintained at 10^{-5}, 10^{-6}, and 10^{-8}, respectively, which was consistent with the simulation results.

In the actual wavefront-distortion correction of a optical wireless coherent communication system, the mixing gain obtained by the zero-difference detection was higher than that obtained by the heterodyne detection; however, to achieve the optimal mixing efficiency, the required wavefront correction order was larger than that of the heterodyne detection.

Abstract

Coherent detection plays an important role in coherent optical communication. Highly sensitive coherent-detection systems can significantly increase the distance of coherent optical communication. Targeted corrections can be made to improve the detection sensitivity by studying the factors that affect it. The principle of coherent detection is to coherently mix the signal light and local-oscillator light and then recover the signal, according to the information carried by the mixed signal. This chapter analyzes the influence of thermal noise, shot

Introduction

In 1955, Forrester et al. caused two beams of light with different wavelengths to interfere with each other and generated a new intermediate-frequency signal [1, 2], introducing coherent detection to the world. Coherent-detection methods can be divided into heterodyne, homodyne, and endodyne, according to the detection method.

When the angular frequency of the signal-light center is the same as that of the local-oscillator (LO) light center, it is called homodyne detection. When the central angular frequency of the signal light is different from that of the LO light, it is called heterodyne detection. The signal light and the local-oscillator light are interfered and mixed by a 90° mixer to obtain two orthogonal phase signals; then, the two signals are detected, which is called internal-difference detection.

Coherent-detection sensitivity refers to the limit of what a detector can detect at a certain signal-to-noise ratio or bit-error rate. Theoretically, the detection limit can reach one photon; however, in practical situations, this limit cannot be reached, owing to atmospheric turbulence, thermal noise of the detector, low mixing efficiency, and low detector sensitivity.

Compared with a direct-detection system, the detection sensitivity of a coherent optical communication system can have a gain of approximately 20 dB [3]. It has many modulation methods [4], excellent selectivity [5], large channel capacity [6], and other characteristics that can greatly improve the performance of optical wireless communication systems.

In subsequent research, domestic and foreign scholars have analyzed the influence of thermal noise, shot noise, wavefront distortion, polarization misalignment, spot-size deviation, optical-axis deflection, coupling efficiency, detector performance, preoptical amplifiers, and other aspects of coherent-detection systems on the coherent-detection limit. After years of research, it has become possible to use wavefront-correction systems and beam-polarization control technology. A series of methods, such as fiber coupling and beam control, that reduce the noise interference, improve the detector performance, and amplify the signal can be used to improve the sensitivity of the detection system.

The coherent-detection limit directly affects the performance of coherent communication systems. As the communication distance increases, the signal intensity that can be detected by the receiving end is reduced, and the sensitivity requirements for coherent detection increase. Therefore, it is necessary to conduct a detailed analysis of the factors affecting the coherent-detection limit, which is essential for improving the performance of coherent-detection systems.

This chapter introduces the research progress in coherent detection at home and abroad, as well as research on detection limits by domestic and foreign scholars. The factors that affect the detection limit are analyzed and the factors that suppress these effects are summarized. Finally, the development direction of the coherent-detection limit is summarized and prospected.

Direct Detection and Coherent Detection

Direct Detection

Direct detection refers to directly projecting a signal light onto a photosensitive surface; then, the photodetector outputs the corresponding current based on the intensity of the signal light. As shown in Fig. 22.1, when the signal light reaches the receiving end, the aperture diaphragm and focusing lens converge the light signal onto the photosensitive surface of the photodetector, and the photodetector converts the light intensity of the signal into a voltage or current signal.

Direct detection has a high reliability, simple implementation, and low cost; however, its detection sensitivity is too low to meet the requirements of high-sensitivity detection in long-distance optical wireless communication [7].

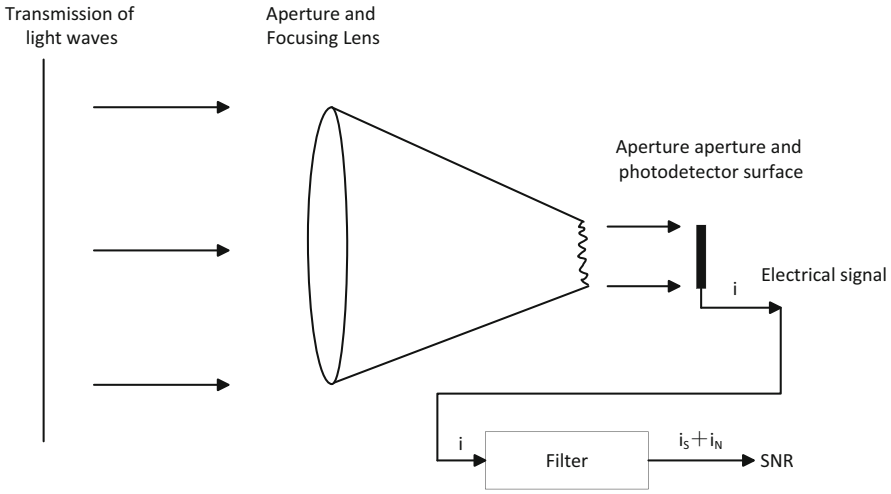

Fig. 22.1 Direct-detection system diagram model [7]

Coherent Detection

Principle of Coherent Detection

Coherent detection involves interference between the local-oscillator light and the signal light. It uses the changes in the light and dark fringes generated by the interference, as well as their intensity and displacement, to determine the coherence and phase difference between the two coherent light beams. This principle is illustrated in Fig. 22.2.

The signal light $E_s(r)$ interferes with the local-oscillator light $E_l(r)$ on the optical mixer, and the interfered light wave is incident on the balanced detector. The balanced detector can detect the interference fringes that form a differential signal. Coherent detection can be divided into zero-difference, internal-difference, and external-difference detection.

Optical mixers are generally composed of fiber couplers and nonlinear optical crystals. The function of a balanced detector is to detect weak optical signals and convert them into electrical signals. The electrical signal-processing module can recover the baseband signal after a series of processing.

Zero-Difference Detection

When the frequencies of the local oscillator and the signal light are the same, it is called homodyne detection. The principle block diagram of zero-difference detection is shown in Fig. 22.3. The signal light and local-oscillator light become electrical signals after demodulation through optical phase-locked coherence. The electrical signal can be obtained as a baseband signal after passing through a low-pass filter, and the original signal can be obtained from the decision output.

An optical phase-locked loop can stabilize the frequencies and phases of the local oscillator and signal light [8, 9]; however, it increases the complexity of the receiver. The advantage of homodyne detection is high sensitivity.

Heterodyne Detection

When the frequencies of the local-oscillator light and signal light are not equal, the coherent-detection method is also called heterodyne detection and can be divided into synchronous and asynchronous demodulation, based on the demodulation method at the receiving end.

A schematic diagram of synchronous demodulation is shown in Fig. 22.4a. The signal light and local-oscillator light form an intermediate signal after passing

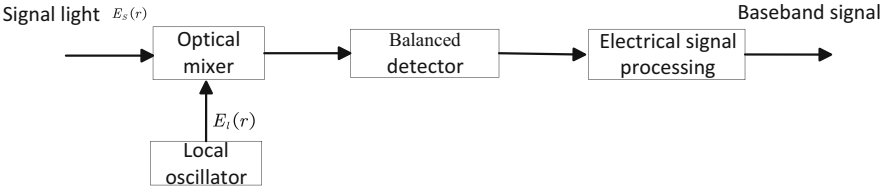

Fig. 22.2 Principle block diagram of a coherent-detection system [3]

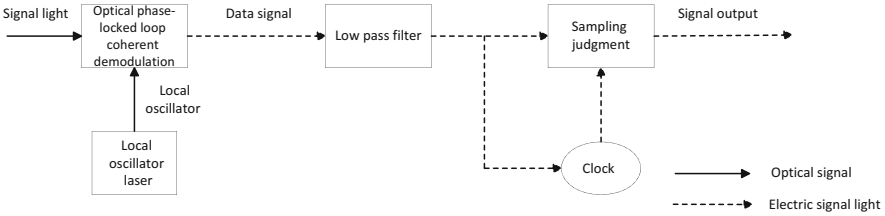

Fig. 22.3 Demodulation-principle block diagram of a zero-difference detection system

through the optical mixer. The signal then passes through the photodetector and becomes an electrical signal. After the carrier frequency is recovered, it is multiplied by the intermediate-frequency signal. The signal output of the multiplier is then passed through a low-pass filter to obtain the baseband signal.

The principle of asynchronous demodulation is shown in Fig. 22.4b. After passing through the mixer and photodetector, the signal light and local-oscillator light pass directly through a bandpass filter and then undergo envelope detection and other processing to obtain the baseband signal directly. Although this method is relatively simple, it has strict requirements for the phase and frequency of the local-oscillator and signal lights.

Internal-Difference Detection

A structural diagram of an internal-difference detection system is shown in Fig. 22.5. The transmitting end is mainly comprised of signal generators, laser sources, and modulators. At the receiving end, the signal light and local-oscillator light pass through a mixer to obtain an intermediate-frequency signal. It passes through a balanced detector, and the electrical signal is then processed by a PC to obtain the original signal.

Signal-to-Noise Ratio and Sensitivity of Coherent-Detection Systems

In coherent-detection systems, the detection sensitivity refers to the limit of what a detector can detect at a certain signal-to-noise ratio (SNR) or bit-error rate (BER). In theory, the detection limit of an analyzer can reach one photon; however, in reality, the detection limit cannot be reached because of atmospheric turbulence, thermal noise of the detector, low mixing efficiency, and low detector sensitivity. This section analyzes the relationship between the sensitivity and signal-to-noise ratio of coherent-detection systems.

The signal-to-noise ratio of a photodetector is defined as follows [3]:

$$\mathrm{SNR}_{\mathrm{IF}} = \frac{\left\langle i_{\mathrm{IF}}^2 \right\rangle}{\left\langle i_{\mathrm{N}}^2 \right\rangle} = \frac{\eta \left| \int_S E_{\mathrm{l}} \cdot E_{\mathrm{s}}^* \, \mathrm{d}s \right|^2}{h\nu \Delta f_{\mathrm{IF}} \cdot \int_S A_l^2 \, \mathrm{d}s} = \frac{\eta \left| \int_S E_{\mathrm{l}} \cdot E_{\mathrm{s}}^* \, \mathrm{d}s \right|^2}{h\nu \Delta f_{\mathrm{IF}} \cdot \int_S E_{\mathrm{l}} \cdot E_{\mathrm{l}}^* \, \mathrm{d}s} \tag{22.1}$$

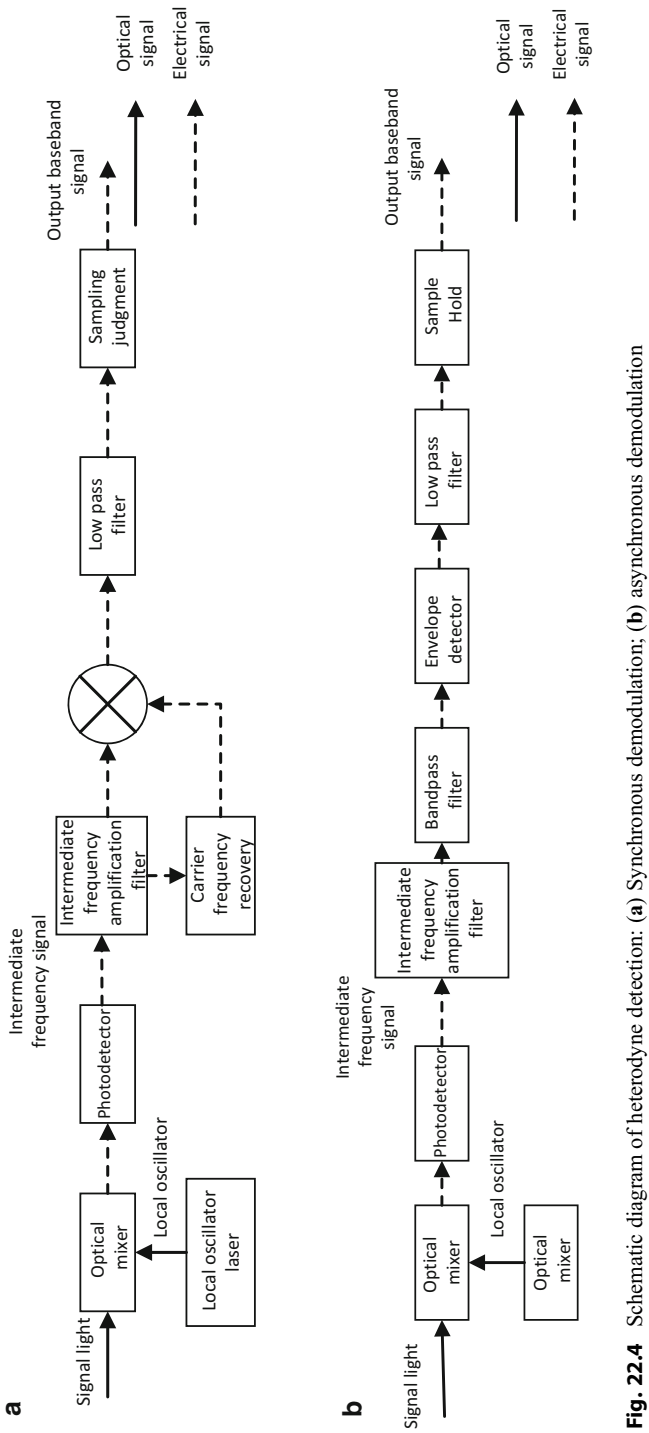

Fig. 22.4 Schematic diagram of heterodyne detection: (**a**) Synchronous demodulation; (**b**) asynchronous demodulation

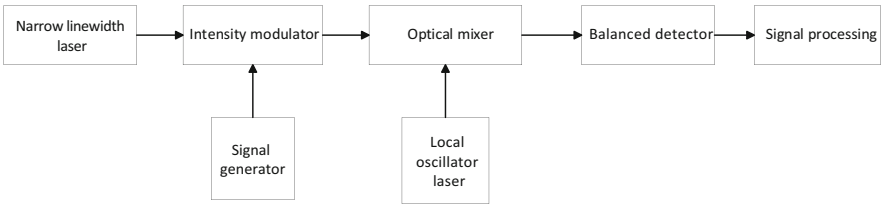

Fig. 22.5 Basic structure of the internal-difference detection system

where $<\cdot>$ is the time average, i_F is the intermediate-frequency current, i_N is the noise current, η is the quantum efficiency of the ideal photosensitive surface, A_L is the amplitude of the local-oscillator light, E_l is the local-oscillator light electric field, E_s is the signal photoelectric field, and Δf_{IF} is the effective noise bandwidth.

When the mixing efficiency reaches the ideal value, the signal-to-noise ratio can be expressed as [3]

$$\mathrm{SNR}_{IF} = \mathrm{SNR}_0 = \frac{\eta P_S}{h\nu\Delta f} = \frac{2\eta P_S}{h\nu B}, \tag{22.2}$$

where η is the quantum efficiency, h is Planck's constant, P_S is the signal optical power, B is twice the effective noise bandwidth, and ν is the carrier frequency.

From Eq. (22.2), it can be seen that when SNR is 1, NEP $= P_S = h\nu\Delta f/\eta$. This variable is called the coherent-detection sensitivity. When the quantum efficiency of the mixer reaches 1, $\Delta f = 1$ Hz, and the ultimate coherent-detection sensitivity can be obtained as one photon. However, in practical coherent detection, such high sensitivity cannot be achieved. After years of research, the detection-sensitivity limit has reached the nanowatt level [3].

Foreign Research Progress

Compared to direct detection, the sensitivity of coherent detection can be significantly improved, while improving the performance of coherent communication systems. This has led many foreign scientists to invest in this field. They have analyzed the impact on coherent-detection limits of aspects such as wavefront distortion, detector sensitivity, intensity noise caused by the local-oscillator light, spot size and optical-axis deflection, coupling efficiency, and polarization mismatch. Methods, such as wavefront correction, polarization control, high-sensitivity detectors, and searching for the optimal local-oscillator power, have been designed to continuously improve the detection sensitivity and approach the coherent-detection limit.

In 1966, Teich et al. [10] measured the signal-to-noise ratio (SNR) and minimum detectable power of m-scattering radiation heterodyne detection. Using photoconductive Ge: Cu as the detector, the minimum detection power observed at a 70 kHz frequency and a 270 kHz bandwidth was 3.5×10^{-14} W. This corresponds to 1.3 at a

bandwidth of 1 MHz. The minimum detectable power of 10^{-19} W is within ten times that of the theoretical photon counter.

In 1972, Popoola et al. [11] developed an experimental device that could compensate for the influence of turbulence in real time. The experimental results showed that the device effectively compensated for the wavefront distortion caused by atmospheric turbulence in a 300 m horizontal link.

In 1975, Cohen et al. [12] thoroughly studied the effects of a series of factors, such as spatial-angle mismatch, spot size, and detector performance, on the mixing efficiency of a mixer. The research results showed that when the signal light had an Airy distribution, the spatial-angle mismatch had a relatively small impact on the mixing efficiency.

In 1983, Abbas et al. [13] calculated the signal-to-noise ratio of homodyne/heterodyne receivers for two detectors. Their results showed that excessively intense noise in a local oscillator could be eliminated without reducing the performance of the receiver. Later, it was experimentally proven that using two matched detectors could achieve near-quantum-limit performance.

In 1987, Tanaka et al. [14] analyzed the impact of the vector-tilt angle and offset error of the signal light on the mixing efficiency. The results showed that when the vector-tilt angle was less than 10^{-4} degrees and the offset reached one-fifth of the incident aperture, the mixing efficiency exceeded 60%.

In 1988, Calvani et al. [15] developed a primitive coherent-transmission technology with polarization modulation and dual-channel differential heterodyne detection. In a preliminary experiment, the detection-sensitivity limit reached 4 dB and showed high immunity to laser phase noise.

In 1992, Tanaka et al. [16] studied the mixing efficiency of a detection system in which the local-oscillator and signal lights were partially coherent Gaussian beams. The results showed that if ratio A is the minimum $1/e$ radius of the signal light to the minimum $1/e$ radius of the local-oscillator, and ratio B is the input aperture to the detector aperture, A and B are inversely proportional.

In 1998, Bar David et al. [17] used mathematical theory to demonstrate the superior performance of coherent dual-light detection over single-diode detection and established the basic principle of local-oscillator intensity. They proposed modulation and detection formats that reduced additional noise using the influence of phase noise.

In 1999, Wang et al. [18] proposed a novel antireception heterodyne-detection scheme for a monolithic integrated four-segment coherent transceiver. The proposed antireception heterodyne-detection scheme further simplified the design of integrated coherent transceivers and promoted the use of a single terminal device for duplex transmission.

In 2000, Sato et al. [19] studied and designed a phase-drift suppression method (PDSM), which suppressed the influence of phase drift and improved the stability of heterodyne beat signals, and demonstrated its application.

In 2001, Gol'tsman et al. [20] developed a new type of high-bandwidth laser detector. The experimental results showed that the detector could achieve long-distance optical-coupling transmissions with a coupling efficiency of 38%. The

measurement bandwidth reached 17.5 MHz and the detection sensitivity reached 0.52 μW.

In 2002, Ricklin et al. [21] demonstrated a light-coupling technology that used integrated circuits to control a deformable mirror for wavefront correction. The results showed that the fiber-coupling efficiency using the new coupling technology reached 75%.

In 2003, Sobolewski et al. [22] proposed a new type of ultrafast single-photon detector, which was made of NbN films with thicknesses of 3.5 nm and 10 nm. For photons at 1550 nm, the detection probability was 3.5%. The response time and jitter of the detector were 100 ps and 35 ps, respectively, which were limited by the acquisition system. At the optimal bias voltage, the dark count was less than 0.01 per second. In terms of the counting rate, jitter, and dark counting, NbN single-photon detectors are superior to semiconductor detectors.

In 2004, Fernandez et al. [23] conducted an experiment on a coherent-optical communication system using a 1064 nm wavelength laser. In the experiment, the laser powers of the local-oscillator and signal lights were 50 mW and 23 mW, respectively. The heterodyne-detection method was used to obtain a frequency-difference signal of 6 MHz from the mixer.

In 2005, Yang et al. [24] studied a radial-shear interference system with spatial-phase modulation that could be used to detect wavefront distortions and control the beam quality. This interferometer was used to test the wavefront distortion of laser pulses with a 1064 nm near-infrared wavelength and 10 ns pulse time width. The software displayed the results of the pulse wavefront quality and energy distribution. The measured beam diameter reached 150 mm, and the root-mean-square test accuracy exceeded 1/15 wavelength.

In 2007, Dauler et al. [25] proposed a multielement superconducting-nanowire single-photon detector that consisted of multiple independently biased elements that formed a continuous active region. Two superconducting-nanowire single-photon detectors with two components were experimentally produced and tested. There was no measurable crosstalk between the devices, and the relative timing jitter was less than 50 ps. This was four times the maximum counting rate of a single superconducting-nanowire single-photon detector with the same active area. Compared with single-element superconducting-nanowire single-photon detectors, multi-element superconducting-nanowire single-photon detectors have larger effective areas and higher speeds.

In 2007, Park et al. [26] developed a waveguide photodetector with a hybrid waveguide structure consisting of AlGaInAs quantum wells on a silicon waveguide. The light in the hybrid waveguide was absorbed by the AlGaInAs quantum wells under a reverse bias. The photodetector had a fiber-coupling responsivity of 0.31 A/W, which was 1.5 μm within the wavelength range of m; it had an internal quantum efficiency of 90%.

In 2009, Xu et al. [27] developed a novel homodyne-detection structure that made orthogonal and sequential in-phase measurements of the signal light. The results showed that the weaker the equivalent substrate, the closer the detection limit to the standard quantum limit.

In 2010, Gregory et al. [28], in view of the impact of wavefront distortion on detection sensitivity, installed a coherent laser-communication terminal on the ground and used the terminal to establish a 5.635-Gbit/s communication link with a satellite. Experimental results showed that the adaptive-optics technology used in the link effectively suppressed the wavefront distortion of the signal light.

In 2010, Salem et al. [29] derived an analytical expression for the heterodyne efficiency when two partially coherent Gaussian–Schell-model beams were coherently mixed on the surface of a photodetector. They provided numerical examples of the heterodyne efficiency changing with the misalignment angle, detector radius, and overlapping beam parameters. The experimental results showed that partially coherent beams were more susceptible to a decrease in the heterodyne efficiency than coherent beams.

In 2013, Gan et al. [30] developed a new type of graphene photodetector, which had the advantages of high responsiveness, high speed, and a wide spectral bandwidth. Using a metal-doped graphene junction coupled with the evanescent waveguide, the detector achieved a light response of more than 0.1 $\mathrm{A\,W^{-1}}$, and a uniform response between 1450 nm and 1590 nm. Under zero-bias operation, it demonstrated a response rate of more than 20 GHz and a 12 Gbit/s optical data link.

In 2014, Boroson et al. [31] implemented a communication link between the ground and the Moon with an information-transmission rate of 622 Mbit/s. The project combined ground-terminal array-transceiver technology with superconducting-nanowire single-photon detection to solve the problems of light-intensity flickering and low receiving power, and to improve the detection sensitivity.

In 2015, Chengqiang et al. [32] introduced the power spectrum of atmospheric turbulence to study the effects of the atmosphere on heterodyne systems. Based on the obtained results, the relationships between the heterodyne efficiency and the detector diameter, misalignment angle, and beam parameters under different turbulence conditions were shown.

In 2016, Wang et al. [33] studied the variation in the heterodyne efficiency with the misalignment angle, detector diameter, turbulence conditions, and overlapping beam parameters based on the Tatarskii spectral model. The results indicated that the variation in the heterodyne efficiency depends on the initial beam polarization, and for larger detector diameters, a turbulent atmosphere significantly reduces the heterodyne efficiency.

In 2017, Yang et al. [34] analyzed and illustrated the effect of polarization aberrations on the output polarization state using polar and Pauli–Zernike decomposition algorithms. Based on the modified heterodyne efficiency, a model of an off-axis optical system with a periscope scanner was established and used to discuss the variation in heterodyne efficiency. The results showed that the improved heterodyne efficiency not only comprehensively described the coherent-detection system but could also be used to evaluate and minimize the polarization aberration of the optical system.

In 2018, Chen et al. [35] developed optical-fiber coupling equipment suitable for long-distance communication, which was used to compensate for random angular

errors and residual aberrations. The experimental results showed that the coupling efficiency reached 73% and the mean-squared error reached 1.1% after using this device. The sensitivity of the coherent-detection system was approximately 20 dB higher than that of the direct-detection system.

In 2020, Maiti et al. [36] studied a MoTe-based photodetector that exhibited a strong optical response in the 1550 nm wavelength band, with a responsivity of up to 0.5 A W^{-1} and a bandgap modulation of 0.2 eV for a nonplanar waveguide structure. In contrast to the graphene photodetector, which relied on a bandless structure, the dark current of the photodetector was reduced by approximately 100 times, and the noise equivalent power reached 90 pW $Hz^{-0.5}$.

In 2022, Ji et al. [37] proposed and demonstrated a scheme based on complementary polarization detection using three 90° optical mixers for self-coherent homodyne detection. The proposed complementary polarization-diversity-coherent receiver utilized remotely transmitted local-oscillator signals without optical-polarization control and had basic stability for any input polarization state of the receiver's remote local-oscillator signal.

The above literature shows that, in coherent detection, the intensity noise [16, 17, 32] caused by the local oscillator, atmospheric turbulence [10], polarization supporting role [34], spot-size and optical-axis deflection [12], coupling efficiency [20], and detector aperture size [14, 29] all have an impact on the detection sensitivity. However, through unremitting efforts, foreign scholars have reduced the impact of wavefront distortion through wavefront correction [11, 19, 21, 24, 28], reduced the impact of polarization misalignment through polarization control [33, 37], improved the coupling efficiency [20] and photodetector performance [22, 23, 25–27, 30, 31, 36], and used other methods to improve the detection sensitivity, thus approaching the limit of coherent detection.

Domestic Research Progress

In the 1980s, researchers gradually realized the important role of coherent detection in communication systems and conducted in-depth research on it. They mainly studied the influence of a series of factors on detection sensitivity, such as coupling efficiency, system thermal noise, wavefront distortion, polarization supporting role, coupling efficiency, and atmospheric turbulence.

In 1990, Da et al. [38] developed a heterodyne atmospheric laser-communication system using a CO_2 laser as the laser source and laid a solid foundation for future research on coherent optical communication systems.

In 2002, Huang et al. [39] developed a new type of photodetector to address the issue of the low reflectivity of Bragg reflectors. The detector exhibited high sensitivity and high-speed characteristics with an absorption-layer thickness of 0.2 μm. At a wavelength of 1583 nm, the peak quantum efficiency reached 80%.

In 2003, Wang et al. [40] studied the factors that affect heterodyne efficiency and found that a spatial-angle mismatch was one of the main factors. Local-oscillator

phase-plane bending and noncollimation effects also affected the heterodyne efficiency.

In 2007, Jin et al. [41] studied the statistical characteristics of Gaussian white noise and laser phase noise in homodyne-detection systems and derived the probability distribution of a two-dimensional random-variable function that took two types of noise as independent variables. Based on this, the detection error caused by the generated noise was calculated and analyzed. The results indicated that, to ensure the detection accuracy of the tracking system, it was necessary to maintain a low-laser phase-noise level and ensure high requirements for the accuracy of the phase control and tracking of the optical phase-locked loop.

In 2007, Zhao et al. [42] proposed a new receiver scheme that integrated heterodyne detection and optical-power tracking functions, established a distribution model of the detector-surface light field, and studied the heterodyne efficiency with optimal matching of the local and signal lights. Moreover, the heterodyne efficiency with incomplete matching was analyzed.

In 2008, Li et al. [43] proposed a novel adaptive-compensation method for atmospheric turbulence. The compensation effect of this method was insignificant when the relative aperture was large, for example, when $D/r_0 = 6$, the compensated intensity, only reached approximately 50% of the diffraction limit. However, when $D/r_0 = 2$, the compensation effect reached 90%. The experimental results indicated that when the relative aperture was the same, the compensation difficulty increased with an increase in turbulence intensity.

In 2008, Shu et al. [44] studied an optical microwave-subcarrier coherent-detection system and simulated and analyzed its performance. The results showed that the system was less affected by atmospheric noise and attenuation, the receiver sensitivity was high, the information-transmission quality was high, and the average bit-error rate was 4.98×10^{-9}.

In 2010, Zhao et al. [45] investigated an external-differential step demodulation method. The research results showed that the mixing efficiency was inversely proportional to the loss of the supporting-role angle. When the local-oscillator light had a thin surface bend, the mixing efficiency was directly proportional to the radius of curvature.

In 2011, Liu et al. [46] conducted in-depth research on the impact of the different amplitude distributions of the signal and local-oscillator lights on the mixing efficiency. The experimental results showed that the Airy and Gaussian distributions achieved the maximum heterodyne efficiency, whereas the heterodyne efficiency achieved by Gaussian plane waves was 82%.

In 2011, Han et al. [47] studied the compensation technology of adaptive optics for space optical communication systems based on the gamma–gamma distribution of atmospheric turbulence. The experimental results showed that adaptive-optical error-compensation technology could significantly improve the detection sensitivity, and even low-order adaptive-optical compensation achieved a good compensation effect.

In 2012, Chen et al. [48] proposed a highly sensitive detector that reduced the measurement errors caused by fluctuations in the detector light intensity and noise

carried by the signal itself. The experimental results showed that the detector had advantages, such as high sensitivity, wide operating bandwidth, and high signal-to-noise ratio, which met the research requirements of terahertz time-domain spectroscopy systems.

In 2013, Zhang et al. [49] studied the factors that affected heterodyne efficiency based on a binary phase-shift keying (BPSK) homodyne coherent-detection system. Among these, the collimation mismatch and beam waist radius had a significant impact on the heterodyne efficiency. The experimental results showed that an optimal waist beam radius could be found to maximize the mixing efficiency.

In 2013, Ma et al. [50] analyzed the relationship between the polarization state of the signal light and the mixing efficiency. The results showed that circularly polarized light had stronger stability than linearly polarized light. When both the signal light and local-oscillator light were circularly polarized signals, the mixing efficiency of the mixer was maximized.

In 2013, Ke et al. [51] selected an extruded-fiber polarization controller. The control algorithm of the system adopted a simulated-annealing algorithm, and an improved algorithm was adopted to realize automatic polarization control. The control process adopted a blind-search method. The simulation results showed that this method was suitable for polarization control in coherent optical communications.

In 2013, Xiao et al. [52] studied the coupling conditions, systems, and modes of optical fibers and analyzed the ideal coupling between spatial light and optical fibers. Three common types of fiber amplifiers were compared, and an erbium-doped fiber amplifier with the best performance was used as the front-end optical amplifier for the receiver. Subsequently, the sensitivity and signal-to-noise ratio of the coherent-detection system were analyzed.

In 2014, Hu et al. [53] developed a new type of photodetector in response to a series of requirements for coherent-light measurement systems, such as high sensitivity, wide response bandwidth, and high stability. The test results indicated that the detector could achieve remote optical-coupling transmissions and its detection sensitivity reached 0.52 μW. The coupling efficiency exceeded 38%, and the measured bandwidth reached 17.5 MHz.

In 2014, Luo et al. [54] developed an experimental platform for coherent-optical communication systems and conducted a series of experiments on the platform. The experimental results showed that when the communication distance was 600 m outdoors and the sensitivity was −17.6 dBm, the received bit-error rate was 10^{-6}. When the indoor communication distance was 6 m, the sensitivity increased by approximately 7 dB compared to that outdoors.

In 2015, Li et al. [55] studied the mixing efficiency of a coherent-detection system using a Gaussian beam model. The research results showed that the mixing efficiency reached the best value when the waist radius of the signal light was small, and the waist radius of the local-oscillator light was half of the detector radius.

In 2016, Ke et al. [56] studied the effects of local-oscillator power and detector parameters on the system signal-to-noise ratio. The experimental results showed that the characteristic parameters of the detector affected the signal-to-noise ratio and

optimal local-oscillator power. When the polarization angles of the local oscillator and signal light were larger, the optimal local-oscillator power was smaller and the signal-to-noise ratio was larger.

In 2017, China Southern Airlines et al. [57] conducted in-depth research on the impact of various factors on the mixing efficiency. They studied the error-fluctuation range of the spot-size deviation and optical-axis deflection when the mixing efficiency was greater than 10%.

In 2019, Ke et al. [58] analyzed the relationship between the intermediate-frequency signal, optical-polarization state, and mixing efficiency and developed a single-particle optimization algorithm for coherent optical communication. The experimental results showed that the mixing efficiency increased with the increase of the amplitude of the intermediate-frequency signal in the closed-loop system. When the amplitude of the intermediate-frequency signal was 0.001, the coherent-detection system could control the polarization.

In 2020, Xu et al. [59] conducted in-depth research on the design scheme and preparation process of a series of superconducting-nanowire detectors (SNDs) and developed a process for preparing superconducting-nanowire single-photon detectors with high-saturation detection efficiency. For the 1550 nm laser communication band, a six-pixel NbN superconducting-nanowire detector connected by six nanowires in series was developed. The test results confirmed that the developed six-pixel SND achieved a system-detection efficiency of up to 72.1% (dark count of 1 Hz) in the 1550 nm wavelength band, while achieving a resolution of one to six incident photons.

In 2021, Cui et al. [60] developed a new type of balanced photodetector, which consisted of a hybrid cross-resistance amplifier and a balanced photodiode chip. The experiment used a 1550 nm laser testing system. The results showed that under certain conditions, the sensitivity limit of the receiver could reach −61 dBm.

In 2021, Cheng et al. [61] analyzed the relationship between wavefront distortion and the mixing efficiency, as well as the periodic impact of wavefront distortion on the system error rate under different modulation methods. Based on the impact of wavefront distortion on the system performance, a large-amplitude wavefront-distortion residual-correction algorithm was proposed and achieved good results.

In 2022, Ke et al. [62] designed a fiber coupler with a five-degrees-of-freedom coupling device based on piezoelectric ceramics and combined it with a variable-gain random parallel gradient-descent algorithm to determine the optimal alignment posture of a spatial light single-mode fiber. The experimental results showed that the five-degrees-of-freedom fiber coupler effectively corrected different alignment errors, and the coupling efficiency between the spatial light and single-mode fiber reached 53.2% after the system was a closed loop.

In 2022, Fan et al. [63] studied the influence of the top-gate voltage on the interface coupling effect of graphene silicon photodetectors in response to the problems of a limited light-absorption capacity and the short carrier-recombination life of graphene photodetectors. The experimental results showed that when the top-gate voltage was −3 V and the light-source wavelength was 635 nm, the detector's response reached 1.1×10^4 A/W. When the wavelength of the light source

was 1550 nm, the detector's response reached 15 A/W. By increasing the top-gate voltage, the detector's response was increased five to eight times.

In 2022, Lan et al. [64] designed a highly sensitive self-driving photodetector based on a graphene/silicon nanowire-array heterostructure. This detector significantly improved the photoelectric-detection performance by increasing the effective light area and enhancing the absorption of the heterostructure. The experimental results indicated that when the incident light intensity was 90 $\mu W/cm^2$ and the wavelength was 810 nm, the response of the detector reached 0.56 $A \cdot W^{-1}$ and the response was 1.24×10^6 $V \cdot W^{-1}$.

In 2023, Xi et al. [65] adopted an easily etched and small-divergence Au/SiO_2 optical cavity, which not only improved the efficiency of nanowire light absorption but also optimized the processing accuracy of the self-aligned chip outer contour, improving the optical-coupling efficiency of the self-aligned superconducting-nanowire single-photon detector. The experiment showed that the detector could achieve a maximum detection efficiency of 82% at a temperature of 2.2 K and a laser wavelength of 1310 nm. When the wavelength was 1200–1600 nm, the system detection efficiency could reach over 65% and 40% MHz, with a 3-A count rate and a time jitter of 38 ps.

In 2023, Zhu et al. [66] proposed a transistor structure based on the high electron mobility of AlGaN/GaN and successfully developed a ZnO nanowire-sensitive gate photodetector. They were targeting the problems of the low solar-cell efficiency, low light absorption, and low photocurrent of traditional AlGaN/GaN high-electron-mobility transistor photodetectors using ZnO films. Compared with the conventional AlGaN/GaN transistor structure with high electron mobility, the peak responsivity of the new detector increased by about 2.85 times, the response time was shortened to 10 ms, and the recovery time was shortened to 250 ms, greatly improving the performance of the detector.

The above literature shows that the local oscillator [42, 56], atmospheric turbulence [54], polarization-loss supporting role [40, 45], spot-size and optical-axis deflection [57], beam waist radius [49, 55], etc. have an impact on the detection sensitivity. Therefore, increasing the wavefront correction [43, 47, 61] and polarization control [50, 51, 58], improving the coupling efficiency [62] and detector performance [39, 48, 53, 59, 60, 63–66], increasing the preamplifier [52], optimizing the detection system [44], and other methods have been proposed to improve the detection sensitivity and approach detection limits.

Factors Affecting the Coherent-Detection Limit

In a coherent-detection system, the factors affecting the detection sensitivity are as follows:

1. Thermal and shot noise
2. Wavefront distortion of the signal light
3. Polarization mismatch between the signal light and LO light

4. Spot-size deviation and optical-axis deflection
5. Coupling efficiency
6. Detector performance
7. Preoptical amplifiers

The first factor is the error caused by noise, which directly affects the detection sensitivity. The second, third, fourth, and fifth errors further affect the sensitivity of the detection system by affecting the mixing efficiency. The performance of the photodetector directly affects the sensitivity of the detection system, whereas the role of the preamplifier is to amplify a weak signal light, thereby increasing the mixing efficiency. This section elaborates on the limitations of coherent detection based on the seven aspects mentioned above.

Thermal and Shot Noise

Thermal noise is caused by the irregular movement of electrons in the conductor, and shot noise is caused by the random fluctuation of the photocurrent. This section analyzes and demonstrates the impact of thermal and shot noise on the detection sensitivity.

The total noise of the system can be described using the following equation [3]:

$$N_{\mathrm{P1}} = \frac{2e^2\eta_{\mathrm{PC}}}{h\nu} P_{\mathrm{s}} \Delta f_{\mathrm{IF}} R_{\mathrm{L}} + \frac{2e^2\eta_{\mathrm{PC}}}{h\nu} P_{\mathrm{l}} \Delta f_{\mathrm{IF}} R_{\mathrm{L}} + \frac{2\mathrm{e}^2\eta_{\mathrm{PC}}}{h\nu} P_{\mathrm{b}} \Delta f_{\mathrm{IF}} R_{\mathrm{L}}, \tag{22.3}$$

where e is the amount of electronic charge, h is Planck's constant, η_{PC} is the solar-cell efficiency, ν is the carrier frequency, P_{s} is the signal optical power, P_{l} is the local-oscillator optical power, Δf_{IF} is the effective noise bandwidth, P_{b} is the background radiation power, and R_{L} is the effective resistance of the photodetector.

The thermal noise of the system can be expressed by the following equation [3]:

$$N_{\mathrm{P2}} = 4kT_{\mathrm{b}} \Delta f_{\mathrm{IF}} \tag{22.4}$$

where N_{P2} is the thermal noise of the system, T_{b} is the operating temperature, and k is the Boltzmann constant.

When considering the thermal noise caused by the load resistances of the optical mixer and detector, the detection sensitivity is as follows:

$$\mathrm{NEP} = \frac{\left[\frac{e^2\eta_{\mathrm{PC}}}{h\nu}\left(P_{\mathrm{l}} + P_{\mathrm{b}}\right)\right] \Delta f_{\mathrm{IF}} R_{\mathrm{L}} + 2kT_{\mathrm{b}} \Delta f_{\mathrm{IF}}}{\left[\left(\frac{e\eta_{\mathrm{PC}}}{h\nu}\right)^2 P_{\mathrm{l}} R_{\mathrm{L}} - \frac{e^2\eta_{\mathrm{PC}}}{h\nu} \Delta f_{\mathrm{IF}} R_{\mathrm{L}}\right]}. \tag{22.5}$$

Research has shown that when the quantum efficiency of the detector differs, the detection sensitivity is related to the local-oscillator power, as follows: Below the quantum-noise limit, the detection sensitivity decreases as the local-oscillator power

increases. When the power of the local-oscillator remains constant, the detection sensitivity decreases as the quantum efficiency increases.

Wavefront Distortion of the Signal Light

Wavefront distortion is caused by an unequal optical path from the light source to each point on the wavefront; the magnitude of this optical-path difference quantifies the degree of wavefront distortion. Owing to the influence of atmospheric turbulence, a signal light transmitted in the atmosphere can experience unequal optical-path transmissions, resulting in the receiving end's light-wave equiphase plane becoming a randomly undulating surface with different light angles of incidence on the optical receiving surface.

If the signal and LO lights are coherently mixed without any processing, the mixing efficiency is greatly reduced, owing to the existence of a spatial mismatch, and the mixing efficiency decreases with an increase in the spatial mismatch. Figure 22.6 shows the relationship between the signal-light wavefront and LO-light wavefront on the photosensitive surface.

The output current of the photodetector is as follows [3]:

$$i_{\mathrm{IF}}(t) = G\beta E_{\mathrm{ls}} E_{\mathrm{l}} \cos[(\omega_{\mathrm{l}} - \omega_{\mathrm{s}})t + (\varphi_{\mathrm{l}} - \varphi_{\mathrm{s}})] \ \frac{\sin(\omega_{\mathrm{s}} d/2v_{\mathrm{x}})}{\omega_{\mathrm{s}} d/2v_{\mathrm{x}}}, \tag{22.6}$$

where $v_{\mathrm{x}} = c/\sin\theta$, G is the internal gain of the photodetector, β is the responsivity of the photodetector, and ω_{s}, φ_{s} and ω_{l}, φ_{s} are, respectively, the angular frequencies and phases of the signal light and the local oscillator light. E_{ls} is the signal photoelectric

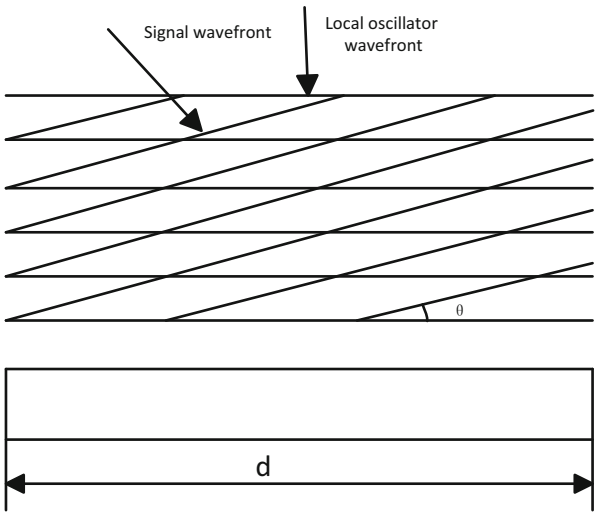

Fig. 22.6 Spatial phase relationship between the signal light and local-oscillator light [3]

field considering the wavefront distortion, d is the side length of the photosensitive surface of the detector, θ is the spatial mismatch, E_1 is the local-oscillator light field, and t is time.

In a coherent-light detection system, the mixing efficiency and difference-frequency current decrease with an increase in the spatial-adaptive angle, which directly affects the sensitivity of coherent detection. To improve the detection sensitivity, it is necessary to make the local-oscillator light and signal light as parallel and coincident on the photosensitive surface as possible. The signal light is affected by atmospheric turbulence when transmitted through the atmosphere, resulting in wavefront distortion when it reaches the receiving end. Currently, most scientists are committed to using various methods to reduce the impact of wavefront distortion on detection sensitivity. The adaptive-optics system is the most popular wavefront-correction method.

Polarization Mismatch Between the Signal Light and Local-Oscillator Light

In a general coherent optical communication system, the signal light emitted by a transmitter is generally a circularly polarized Gaussian beam. After the signal light is transmitted through the atmospheric channel, the amplitude of the optical signal received by the receiver is not a Gaussian distribution, and its polarization state is also transformed. This means that the polarization states of the signal light and the LO light are no longer consistent, leading to a reduction in the mixing efficiency and detection sensitivity.

In coherent-optical communication systems, the optical transceiver is an important component, and its function is to receive the signal light. Figure 22.7 shows the structural diagram of a typical Cassegrain-type optical antenna in an optical transceiver.

If both the intrinsic light and signal light are circularly polarized and coherently mixed after the signal light is transmitted through the atmospheric channel, the mixing efficiency can be expressed as [67]

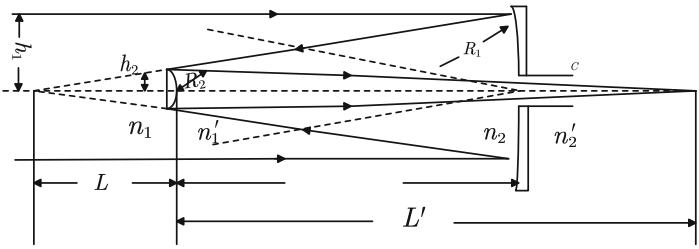

Fig. 22.7 Structural diagram of a Cassegrain-type optical antenna [67]

$$\eta = \frac{\|\cos\alpha\left|\iint\left|E_{\mathrm{s}}'\right\|E_{\mathrm{l}}\right|\sim \mathrm{d}s|^2}{\iint|E_{\mathrm{l}}|^2 \sim \mathrm{d}s \iint\left|E_{\mathrm{s}}'\right|^2 \sim \mathrm{d}s}, \tag{22.7}$$

where α is the polarization-mismatch angle between the signal light and local-oscillator light, E_{s}' is the signal light field, E_{l} is the local-oscillator light field, s is the photosensitive area of the photoelectric receiver, and η is the mixing efficiency.

According to Eq. (22.7), the mixing efficiency is proportional to cos α. When the value is 0–180°, it is inversely proportional to η, and the mixing efficiency η is inversely proportional to $|\cos\alpha|^2$.

In summary, it can be seen that the polarization mismatch between the local oscillator and signal light has a significant impact on the mixing efficiency. In practical engineering, polarization-control compensation devices should be used to maintain the polarization state of the signal light and local-oscillator light as consistent as possible, which is very important for improving the detection sensitivity.

Spot-Size Deviation and Optical-Axis Deflection

The deviation in spot size is caused by errors in the optical-component manufacturing process, leading to the divergence or contraction of the incident beam. Consequently, it does not match the size of the spot generated by the local-oscillator light. To obtain high-quality beams, spatial light mixers often place the receiving target surface at the waist of the incident beam; therefore, the spot size is often described by the waist radii of the intrinsic and signal beams, and the mixing efficiency formula is obtained [68]:

$$\eta_{\mathrm{oularrur}} = \frac{\left[\int_0^n \exp\left(-\frac{r^2}{r_x}\right)\exp\left(-\frac{r^2}{r_{lo}^2}\right) r\,\mathrm{d}r\right]^2}{\int_0^{r_0}\left[\exp\left(-\frac{r^2}{r_{lo}}\right)\right]^2 r\,\mathrm{d}r \int_0^{\infty}\left[\exp\left(-\frac{r^2}{r_x}\right)\right]^2 r\,\mathrm{d}r}, \tag{22.8}$$

where r is the radius of the receiving target surface, r_{x} and r_{lo} are the waist radii of the signal light and local-oscillator light, respectively, and exp (·) is an exponential function with e as the base.

Processing errors in the optical components may cause the incident beam to diverge and compress, resulting in different spot sizes for the signal light and local light at the receiving target surface. Using the spot size of the local oscillator as a reference, the deviation in the spot size can be calculated as $\Delta r = r_{\mathrm{x}} - r_{\mathrm{lo}}$. Substituting the deviation into optical mixing-efficiency formula (22.8) yields a new optical mixing-efficiency formula with the spot-size deviation [68]:

$$\eta_{\text{colarert}} = \frac{\left[\int_0^{r_0} \exp\left(-\frac{r^2}{(r_{\text{lo}}+\Delta r)^2}\right) \exp\left(-\frac{r^2}{r_{\text{lo}}^2}\right) r\,\mathrm{d}r\right]^2}{\int_0^n \left[\exp\left(-\frac{r^2}{r_{\text{lo}}^2}\right)\right]^2 r\,\mathrm{d}r \int_0^\infty \left[\exp\left(-\frac{r^2}{(r_{\text{lo}}+\Delta r)^2}\right)\right]^2 r\,\mathrm{d}r}, \tag{22.9}$$

where Δr is the spot-size deviation.

In practical applications, both displacements and size mismatches of the light spot exist on the receiving target surface because the processing and adjustment errors of the optical components inside the spatial light mixer cannot be eliminated. Therefore, both of these factors must be considered simultaneously. Therefore, the mixing-efficiency expression of the mixer when both factors exist simultaneously is obtained as follows [69]:

$$\eta_{\text{ls}} = \frac{\left[\int_0^n \exp\left(-r^2/r_{\text{lo}}^2\right) \cdot \exp\left(-r^2/(r_{\text{lo}}+\Delta r)^2\right) \cdot J_0\left(C_{\text{p}} k r \delta\right) r\,\mathrm{d}r\right]^2}{\left[\int_0^{r_0} \left[\exp\left(-r^2/r_{\text{lo}}^2\right)\right]^2 r\,\mathrm{d}r\right]\left[\int_0^\infty \left[\exp\left(-r^2/(r_{\text{lo}}+\Delta\omega)^2\right)\right]^2 r\,\mathrm{d}r\right]}, \tag{22.10}$$

where $J_0(\cdot)$ is the zero-order Bessel function, r is the radius of the receiving target surface, δ is the deflection angle of the optical axis, k is Boltzmann's constant, and C_{p} is a constant.

From the above equation, it can be seen that deviations in the spot size and optical-axis deflection can affect the mixing efficiency of the mixer to some extent. In practical coherent-light detection, methods have often been adopted to suppress this error. Commonly used methods include improving the level of hardware processing or determining the relationship between the spot-size deviation, optical-axis deflection, and mixing efficiency to maximize the mixing efficiency.

Coupling Efficiency

The ability of optical fibers to couple signal light affects the sensitivity of coherent detection systems to a certain extent. This ability to couple optical fibers is called the coupling efficiency of fiber couplers. Figure 22.8 shows a schematic of the fiber-optic coupler. When all conditions are ideal, the light rays converge at the focal point of the lens after passing through the lens and then advance along the direction of the axis in the fiber until they reach the next module.

The coupling efficiency is expressed as follows:

$$\eta_{\text{Coupling}} = P/P_0, \tag{22.11}$$

where P represents the optical power entering the fiber and P_0 represents the total incident power.

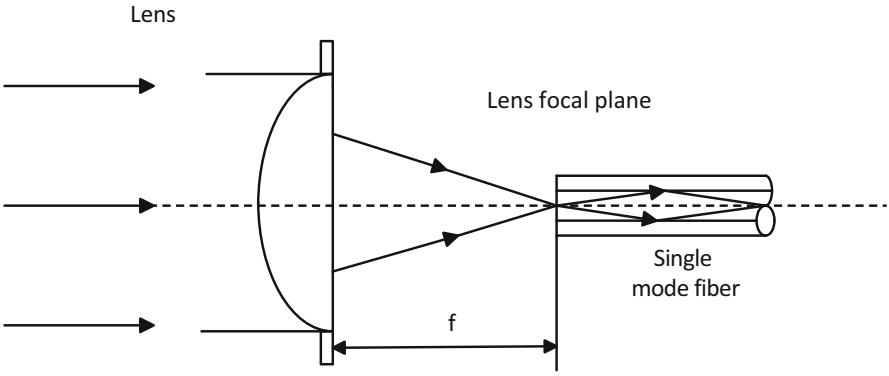

Fig. 22.8 Schematic diagram of a fiber-optic coupling

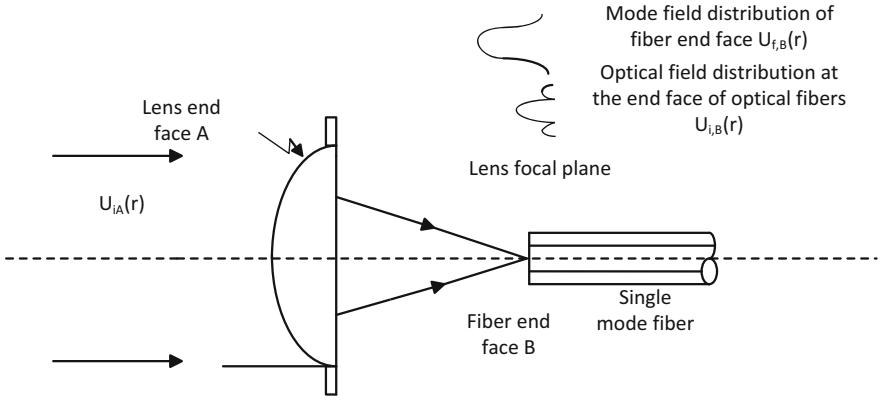

Fig. 22.9 Schematic diagram of a fiber-coupling mode-field analysis

As shown in Fig. 22.9, the coupling efficiency of the fiber coupler η_{Coupling} can be expressed as follows [70], when analyzed using the mode-field matching method:

$$\eta_{\text{Coupling}} = \frac{\left|\iint U_{\text{i}}^{*}(r)U_{\text{f}}(r)r\,\mathrm{d}r\,\mathrm{d}\gamma\right|^{2}}{\iint U_{\text{i}}(r)U_{\text{i}}^{*}(r)r\,\mathrm{d}r\,\mathrm{d}\gamma \times \iint U_{\text{f}}(r)U_{\text{f}}^{*}(r)r\,\mathrm{d}r\,\mathrm{d}\gamma}, \tag{22.12}$$

where $U_{\text{i}}(r)$ is the amplitude distribution of the signal light, $U_{\text{i}}^{*}(r)$ is the conjugate function of $U_{\text{i}}(r)$, $U_{\text{f}}(r)$ is the distribution of the electromagnetic field of a single-mode fiber on the lens end face, γ is the conjugate function of $U_{\text{f}}(r)$, r is the radius of the lens end face, and η_{Coupling} is the coupling efficiency.

In summary, it can be seen that the coupling efficiency of fiber-optic couplers is influenced by a series of factors, such as lens parameters, reception angle, signal-light amplitude, etc. In future research, these factors should be improved to enhance

the coupling efficiency of the couplers and increase the sensitivity of coherent detection.

Detector Performance

A photodetector converts optical signals into electrical signals. In the study of coherent-detection limits, the detection sensitivity largely depends on the performance of the detector. The detectors commonly used at present include photomultiplier tubes, single-photon detectors, and superconducting detectors. Figure 22.10 shows a schematic diagram of the photoelectric effect.

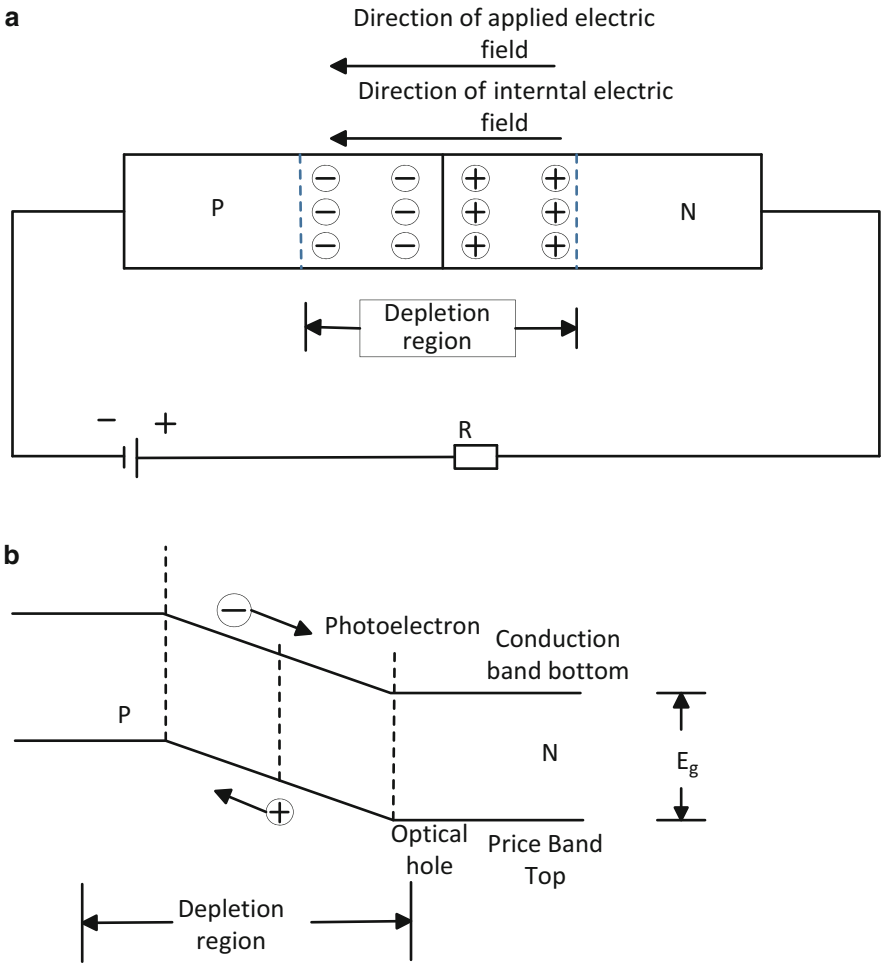

Fig. 22.10 Schematic diagram of the photoelectric effect: (**a**) Structure diagram of the depletion region of the P-N junction; (**b**) energy-band diagram around the P-N depletion region

Figure 22.10a shows the change in the P-N junction depletion region when the externally applied electric field is in the same direction as the internal electric field. Figure 22.10b shows the energy-band diagram near the P-N junction depletion region. It can be seen that the electrons move in the energy band, the potential of the location where the electrons gather is low, and the energy band is high.

With the development of science and technology, new detectors with higher sensitivities and faster responses, such as nanowire and graphene detectors, have emerged in recent years. Nanowire detectors use semiconductor-nanowire materials for material detection and sensing. A charge transfer can occur when the target material reacts with the surface of the nanowire, thereby changing its electrical properties and facilitating detection.

Graphene photodetectors utilize the electronic and optical properties of graphene for photoelectric conversion. The electronic properties of graphene enable it to have a high-speed electron-transmission capability, high sensitivity, high transmittance, and low reflectivity. Improvements in various aspects of the photodetector performance are of great significance for improving the sensitivity of coherent detection.

Preoptical Amplifier

A preamplifier is commonly used in optical communications and sensor systems. Its primary function is to amplify a weak optical signal at the input end of an optical fiber or detector with a sufficiently high signal-to-noise ratio. The device does not make any internal photoelectric or electro-optical conversions.

In coherent-detection systems, optical amplifiers are an essential device that plays a significant role in improving the detection sensitivity and increasing detection limits. There are two types of commonly used optical amplifiers: semiconductor and fiber. This section introduces an erbium-doped fiber amplifier (EDFA) with excellent performance.

As shown in Fig. 22.11, the structural diagram of the EDFA consists of two parts: an optical path and an auxiliary circuit. The optical path is composed of an optical isolator, pump light source, optical coupler, erbium-doped fiber, and optical filter. The auxiliary circuit is composed of a power supply, warning and protection circuit, and automatic microprocessor control. The auxiliary circuit ensures the normal operation of the optical amplifier. The pump source provides sufficient energy for the erbium-doped fiber to invert the particle beam.

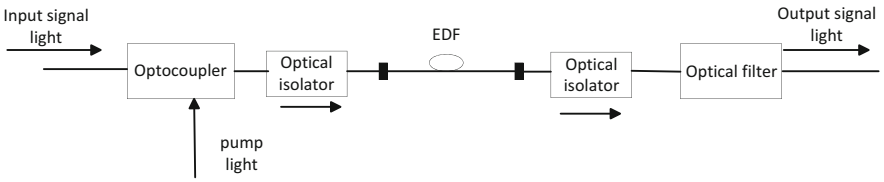

Fig. 22.11 Structural block diagram of an EDFA

The core device of the optical amplifier is an erbium-doped fiber, and its main material is quartz fiber. In practice, to improve the performance of an optical amplifier, the rare-earth element Er^{+3} is often doped inside the quartz.

In digital optical-communication systems, regardless of the circuit thermal noise and extinction ratio, the detection sensitivity can be expressed as follows:

$$P_s = 2h\nu n_{sp} B_e \left(Q^2 + Q \cdot \sqrt{0.5\mu B_0 / B_e - 0.5} \right), \tag{22.13}$$

where h is Planck's constant, η_{sp} represents the spontaneous emission factor, B_0 represents the bandwidth of the optical filter, B_e is the bandwidth of the electric filter, and ν is the carrier frequency. The value of μ is 1 or 2 and depends on whether a polarization filter is used.

When the bit error rate is 10^{-9}, $Q = 6$; when the bit-error rate is 10, $Q = 5.2$. If the receiving end adopts error-correction coding and the preamplifier uses a silver-doped fiber amplifier, the sensitivity of coherent detection can reach -50 dBm.

Development Trends

Coherent-detection technology is used to measure coherent properties and is one of the most important technologies in the field of optics. With the continuous progress in science and technology, coherent-detection technology is constantly developing. This section provides a detailed explanation of the development trends in coherent-detection technology.

High-Detection Sensitivity and Resolution

The highest sensitivity of coherent detection is achieved by the single-photon counting of photon counters or single-photon detectors. However, the resolution of this method is extremely low. Therefore, higher-sensitivity methods are required to improve the resolution of coherent detection. The emergence of new technologies has improved the sensitivity and resolution of coherent detection. The main approach is to use higher detector sensitivity, more efficient photon splitters, and better coherent interferometers.

Wider Applications

Coherent-detection technology has wide applications in various fields, such as optical communication, military, optical imaging, and microscopy. In the future, with the development of coherent-detection technology, it will gradually be applied to other fields, such as quantum computing, high-speed communication, and biomedicine. The demand for efficient and accurate coherent-detection technology in

these fields is increasing; therefore, the application of coherent detection technology will become increasingly widespread.

Simpler and More Efficient Detection Methods

With the continuous development of science and technology, methods for coherent-detection technologies are constantly being developed. In the future, this equipment will become more efficient and precise. The emergence of new coherent-detection technologies has made coherent detection more convenient. For example, the automated control technology of optical interferometers can significantly improve the efficiency of coherent detection, reducing its implementation difficulty.

Further Research

Coherent-detection technology is an active research field, and further research may be conducted in the future to expand its application fields and improve the performance of detection technology. With the rapid development of communication technologies, research on coherent-detection technologies has received increasing attention and will likely continue to receive the attention of scientists and researchers.

In summary, coherent-detection technologies will continue to develop and play important roles in many fields. The development trend of future coherent-detection technologies will include higher detection sensitivities, wider application fields, more efficient and simplified detection methods, and deeper research. With the advancement of these technologies, coherent-detection technologies will become increasingly indispensable in modern optical fields.

Future Prospects

This chapter summarized the research progress in coherent detection, both domestically and internationally. Coherent detection can be divided into heterodyne and homodyne detection, according to the detection method. Then, the factors affecting the detection sensitivity were analyzed:

1. Thermal noise and shot noise generated by the system
2. Wavefront distortion of the signal light
3. Polarization mismatch between the signal light and LO light
4. Spot-size deviation and optical-axis deflection
5. Optical-fiber coupling efficiency
6. Performance of the photodetector

Suppression schemes have been developed to address these effects and achieve the highest detection sensitivity. Although the current coherent-detection limit technology is relatively mature, the following issues are still worth studying and discussing:

1. Use better laser sources. By using a laser source with a higher power, narrower linewidth, and higher spot-quality factor, the coherence of the laser beam can be improved, thereby improving the detector sensitivity.
2. Use higher detection efficiency. Maximizing the detector response efficiency can improve the sensitivity and accuracy. Common methods include increasing the detector area, increasing the detector gain, and improving the detector response time.
3. Reduce noise. The use of low-noise preamplifiers and signal processors to reduce noise can improve the sensitivity and accuracy of detectors.
4. Optimize the detector structure and materials. Changing the process, structure, and materials of a detector can improve its sensitivity and accuracy. For example, new semiconductor materials can be used to increase the doping concentration and change the detector structure.
5. Use adaptive-optics technology. By using adaptive-optics technology, the phase perturbation of coherent beams can be eliminated, thereby improving the sensitivity and accuracy of coherent detectors.

Abstract

Optical wireless coherent communication is a wireless transmission optical communication technology that uses the interference principle of light to coherent demodulate the received signal using a local oscillator light source at the receiver and compared with intensity modulation/direct detection. It has a detection sensitivity of about 20–23 db and is more suitable for long distance laser communication transmission. The existence of atmospheric turbulence limits the development of optical wireless coherent communication technology. Adaptive optics technology can effectively suppress the wavefront distortion caused by atmospheric turbulence by means of the phase conjugate compensation principle. In this chapter, the adaptive optics technologies are applied to the field of optical wireless coherent communication by taking into account the above research background.

Introduction

Adaptive optics is a comprehensive science integrating optoelectromechanics, which can suppress the disturbance of laser signals in turbulent atmospheric transmissions [1]. It is a theory, system, technology, and engineering field that studies the real time improvement of optical wavefront quality.

Adaptive optics covers the study of optics, communication, control, computers, machinery, and other disciplines. It intends to correct the random wavefront distortions caused by changes in the external environment during beam propagation in real time and automatically improves the beam quality. Since Babcock proposed the concept of adaptive optics in 1953 [2], this technology has been widely used in astronomical observations [3], human eye imaging and vision research [4], inertial confinement fusion [5], and other fields.

Foreign Research Progress

Optical wireless communication is affected by atmospheric turbulence. As an optical signal propagates, its wavefront is affected by turbulence and generates random fluctuations, which cause beam expansion, angle of arrival fluctuations, beam bending, and beam drift. These seriously interfere with the quality of the received optical signal, resulting in increased communication errors and reduced communication stability.

In addition, with an increase in the communication distance, the laser output power is gradually increased, and the laser cavity mirror undergoes a thermal deformation, which causes a phase distortion of the laser wavefront, leading to a reduction in the beam quality, and thus, the communication quality. Therefore, methods are needed to suppress the influence of atmospheric turbulence and improve the quality of laser communication. Applying adaptive optics technology to optical wireless communication systems [6] has great potential for suppressing the influence of atmospheric turbulence.

In 1972, the Fried's Optical Sciences Company of the United States, among others, introduced adaptive optics technology into optical wireless communication systems. The adaptive optics unit corrected the wavefront distortion caused by atmospheric turbulence in real time [7].

In 1996, Tyson of the University of North Carolina in the United States analyzed the relationship between light intensity fluctuation and the bit error rate in the intensity modulation/direct detection (IM/DD) mode [8, 9]. When the atmospheric turbulence intensity $D/r_0 = 0.8$ (r_0 is the atmospheric coherence length), the system bit-error rate was 2.3×10^{-3} before the wavefront phase correction and 5.5×10^{-4} after correction [10]. The wavefront distortion caused by atmospheric turbulence increased the bit-error rate by one order of magnitude.

In 2002, Wilks and others at the Lawrence Livermore National Laboratory of the United States conducted numerical simulations of optical communication with a transmission rate of 10 Gbit/s and a transmission distance of 33.2 km. After the

wavefront distortion was corrected, the coupling efficiency from space light to optical fiber was increased from 20% to 55% [11]. The experimental platform used a 400 unit microelectromechanical (MEMS) deformable mirror and a wavefront detector with a 1-kHz sampling frequency to conduct ground–space laser communication experiments on horizontal and slanted links. After correction, the root mean square (RMS) residual of the wavefront was 0.75λ [12].

In 2004, Thomas et al. of the University of Maryland in the United States used tilt mirrors to correct tilt aberrations, and 132 units of MEMS deformable mirrors to correct other aberrations. After correcting the higher order aberrations, the received signal strength was twice as high as when only tilt aberrations were corrected [13, 14].

In 1990, Wright et al. of the Jet Propulsion Laboratory (JPL) built an optical wireless communication experimental platform based on adaptive optics using a 1064 nm laser. When the system transmission rate was 100 Mbit/s, the gain of the signal received by the receiving end after wavefront correction was approximately 6 dB [15].

In 2006, Hemmati et al. of the JPL used deformable mirrors to actively compensate for received wavefront distortion. The receiving aperture was 0.3 m, and the incident beam wavelength was 632 nm. The root mean square error of the wavefront distortion was 1.4λ, which decreased to 0.05 λ. The Strehl ratio (SR) increased from 0.08% to 89% [16].

In 2010, Wilson et al. of the JPL conducted a demonstration experiment of Mars deep-space laser communication with a 1064 nm communication wavelength and a pulse-position modulation communication mode. The adaptive optical system in the communication system used a 635 nm band as a beacon for wavefront detection and correction, with a communication rate of 100 Mbit/s. After correction, the error rate was reduced by 3 dB [17, 18].

In 2013, Stewart et al. of the National Aeronautics and Space Administration (NASA) of the United States experimentally verified laser communication between the earth and the moon. The system used a MEMS deformable mirror to obtain a correction result with an SR of 0.6 [19].

In 2015, Wright et al. of the JPL tested an adaptive optics system at a ground observation station with an optical communication telescope. The system received a 50 Mbit/s downlink video transmission from the International Space Station, and the SR of the beam received by the satellite increased from 0.03 to 0.66 after correction [20].

In 2008, the Johns Hopkins University Applied Physics Laboratory and AOptix Technologies demonstrated a 147 km long range bidirectional radio frequency (RF) and optical wireless communication experiment using intensity modulation at transmission rates of up to 10 Gbit/s. The system included a 35 driver deformable mirror to provide a bandwidth greater than 1 kHz. The coupling efficiency between the signal light and the single-mode fiber (SMF) was improved by adding transmitting terminal pre corrections and receiving terminal corrections. It provided 30 closed loop corrections for Zernike aberrations, in addition to the tilt and focus terms [21].

In May 2010, Heine et al. from the European Space Agency installed and commissioned an adaptive optical system at a ground station for satellite based laser communication. The working wavelength was 1064 nm, the sensor was an 88 subaperture Hartmann sensor, and a 12 × 12 unit MEMS deforming mirror control unit was used. After acquisition by a high speed infrared camera, the sampling frequency of the maximum subaperture image reached 20 kHz [22–24].

In 2011, Gregory et al. of the European Space Agency used a 1-m aperture optical system at a ground station in Spain to conduct an adaptive optical correction experiment for satellite based laser communication. The communication wavelength of the adaptive optical system was 1064 nm, and the SR was increased to more than 0.4 after correction [25].

In 1995, Arimoto et al. from Japan's Ministry of Posts and Telecommunications conducted a study on laser communication between the ground and the International Space Station (ISS). After compensating the wavefront distortion of the signal light with the ground-end adaptive system, the coupling power of the downlink increased from −58.9 dBm to −51.9 dBm [26].

In 1999, Kudielka et al. from Japan's Ministry of Posts and Telecommunications conducted laser communication experiments between the ISS and the ground. After correcting low order aberrations, such as tilt, the gain of the optical power was increased by approximately 2.3 dB [27]. In 2016, Petit et al. used ground optical receivers, small optical communication terminals, and satellite laser communication terminals to conduct laser communication experiments with adaptive optical correction; the error suppression bandwidth was less than 60 Hz [28].

In 2014, Hashmi et al. from the Pakistan National University of Science and Technology conducted a numerical simulation experiment on inter satellite adaptive optical communication in a laboratory. With moderate background noise and strong turbulence, the SR increased from 0.30 to 0.75 after adaptive optical correction [29].

In 2016, Pasupathi et al. from King Tanhaveer Engineering College in India conducted a wavefront detection adaptive correction experiment with a transmission distance of 940 m [30]. Using the SR of the imaging light spot as the evaluation index, the root mean square value of the wavefront phase decreased from 10^{1} before the correction to 10^{-6} after 1364 iterations.

In 2019, Carrizo et al. from the German Aerospace Center corrected the wavefront phase by iteratively updating the phase of a single focal plane speckle, thereby maximizing the power coupled into a single-mode fiber. Experimental results showed that the power increased by approximately 4 dB in less than 60 iterations of power measurements under strong turbulence conditions [31].

In 2020, Baykal et al. from Cankaya University in Turkey applied adaptive optics technology to a marine optical wireless communication system with pulse phase modulation to correct the distorted wavefront and reduce the bit error rate. The calculations showed that the ratio of the temperature to the salinity contributed less to the refractive index spectrum and mean square temperature dissipation rate, while the kinetic energy dissipation rate per unit mass of fluid increased, i.e., the ocean turbulence weakened, which led to more effective adaptive optical correction [32].

In 2020, Toselli et al. from the Fraunhofer Institute of Photonics in Germany theoretically studied the effectiveness of adaptive optical correction for Gaussian beams in ocean turbulence. When the first 15 modes were corrected and the transceiver aperture was sufficiently large to capture 4–5 speckles of the beam affected by ocean turbulence, the light intensity scintillation factor was reduced by seven times [33].

In 2020, Paillier et al. from the University of Paris Thackeray established an accurate numerical model for a space ground coherent optical link using adaptive optics technology and a digital phase-locked loop structure. It was a simple and reliable method for solving the carrier frequency and phase tracking problem in satellite ground coherent radio optical communication links [34].

In 2021, Ata et al. from the Austin University of Science and Technology in Turkey introduced adaptive optics technology to the field of underwater optical communication in natural turbulence. Theoretical calculations showed that even if adaptive optics technology was adopted, underwater optical wireless communication systems would still be seriously affected by regional and seasonal mean values and water refractive index fluctuations [35].

In 2021, Osborn et al. from Durham University in the United Kingdom studied a free space optical communication uplink using adaptive optics for pre compensation for Earth orbit and synchronous orbit satellite communication. The calculation results showed that, except for a small launch aperture and extremely low signal to noise ratio, adaptive optics could reduce the fading and bit error rate after pre-compensation for uplinks [36].

Since 1953, research on adaptive optics has expanded from the initial laser transmissions and astronomical observations to human eye imaging, inertial confinement fusion, laser processing, and many other aspects. The focus of research has shifted from astronomical imaging observations to laser communication. The evaluation index of the correction effect extends from a single optical index, such as the image resolution limit, wavefront peak valley value (PV), and wavefront root mean square value, to communication indexes, such as the coupling power and communication bit error rate.

Applying adaptive optics technology to the field of optical wireless communication has theoretically developed from initial simple numerical calculations [10, 11], such as tilt aberration correction [13], to today's complex numerical calculations, such as combinations with digital phase-locked loops [36], underwater optical communication wavefront correction [33], and satellite–ground laser communication uplink pre-correction [37, 38].

In terms of experiments, initial near-range wavefront correction [7, 30] and long distance near surface wavefront correction [21] were developed for experimental studies on satellite-based laser communication downlinks [19, 20] and uplinks [25]. For the transmission medium, the initial correction usually adopts the method of simulating turbulence [15, 16], then corrects measured atmospheric turbulence [26–28, 39], and gradually develops into the current marine turbulence wavefront correction [36].

Domestic Research Progress

In 1979, the "Infrared Adaptive-Optics Observation System for a 2.16-m Telescope," established by the Institute of Optoelectronics Technology of the Chinese Academy of Sciences and the Beijing Astronomical Observatory, realized horizontal and oblique atmospheric turbulence compensation [40–42].

In 2008, Yang theoretically analyzed an adaptive optical system using the stochastic parallel gradient descent (SPGD) algorithm. The gray value of the far-field spot increased from 20 before correction to 230 after correction. However, limited by the sampling frequency of the camera, only static or slowly changing aberrations could be corrected [43].

In 2008, Li et al. analyzed the problem of matching time and space bandwidths in adaptive optics systems. When $D/r_0 = 6$, the compensated light intensity reached approximately 50% of the diffraction limit, whereas when $D/r_0 = 2$, the diffraction limit reached approximately 90%. To obtain a satisfactory compensation effect in a strong turbulent atmosphere, the number of executing elements must be greatly increased [44].

In 2010, Xia et al. reduced the transmitting power by 50%, while maintaining the link bit-error rate at 1×10^{-6} under the same experimental conditions [45].

In 2011, Wu et al. corrected a wavefront aberration using an adaptive optics technique with an IM/DD communication mode. When using a multimode fiber (MMF) with a 62.5 μm core diameter, the bit-error rate decreased from 10^{-3} to 10^{-4} to below 10^{-6} after correction. When an SMF with a 10-μm core diameter was used, the deep fading of the receiving signal could be clearly observed, and the fading degree was related to the bit error rate. After an adaptive optics closed loop, the deep fading was suppressed and the bit-error rate of the system decreased from 10^{-3} to 10^{-12} [46].

In 2010, Han et al. used adaptive optics to simulate and analyze the distorted wavefront compensation for an atmospheric turbulence model with a gamma–gamma distribution. When correcting only the first five order Zernike coefficient, the bit-error rate was reduced from 10^{-1} before correction to 10^{-6} after correction [47].

In 2012, Wu et al. theoretically calculated that under the same turbulence condition, when pre calibrated adaptive optical correction was adopted at the transmitting end, compared with the receiving end, the received optical powers were 0.56 dBm and 0.34 dBm, and the fluctuation variances were 0.022 dBm and 0.042 dBm, respectively. The experimental results showed that the average bit error rate of the receiver decreased from 10^{-2} to 10^{-5} after adaptive optical correction. After adaptive optical correction at the receiving end, the average bit-error rate decreased from 10^{-3} before correction to 10^{-9} [48].

In 2013, Li et al. investigated the optimal adaptive optics closed loop bandwidth for wireless coherent optical communication links under strong turbulence conditions. When the number of photons detected per bit was greater than 100, the Greenwood frequency was sufficient to satisfy the servo bandwidth of the adaptive optical system. (The Greenwood frequency is used to represent the frequency

characteristics of turbulence. The RMS value of the phase power spectrum above that frequency on the distorted wavefront is 1 rad.) However, if the number of photons per bit was less than 70, the Greenwood frequency only satisfied the closed loop bandwidth under weak scintillation conditions. When the scintillation index was greater than 0.7, the servo bandwidth needed to be increased to at least twice the Greenwood frequency to satisfy the acceptable bit-error rate target [49, 50].

In 2013, Liu et al. calculated the aberration of laser signals. After correcting the aberration, the average efficiency of coupling spatial light to fiber improved from 10.32% to 63.82%, and the average bit-error rate of the optical wireless communication system decreased from 10^{-5} to 10^{-13}. As this result was only a simulation, the actual effect needs to be further verified [51].

In 2013, Wu et al. studied the influence of wavefront distortion on the bit-error rate of a binary phase-shift keying (BPSK) zero difference coherent detection system under different atmospheric turbulence conditions. The results showed that the aberration caused by atmospheric turbulence could directly affect the bit-error rate, independently of electrical noise. The PV value of the wavefront needed to be higher if the signal to noise ratio (SNR) decreased. When the PV value of the wavefront phase was 1.01λ, the mixing efficiency of the system was only 0.23. When the wavefront phase PV value was 0.53λ, the mixing efficiency of the system reached 0.65 [52].

In 2014, Liu et al. analyzed the influence of the atmospheric time-domain characteristics on the mixing efficiency and bit error rate of a wireless coherent optical communication system based on adaptive optics. The simulation results showed that the new wavefront sensing technology based on holography could adapt to weak atmospheric turbulence. The RMS value of the residual aberration was less than 0.04λ, the peak valley value was less than 0.25λ, and the fiber coupling efficiency was improved from nearly 30% to more than 70% [53].

In 2014, Li et al. studied an adaptive optical system with combined deformable mirrors to correct wavefront aberrations and improve the coupling efficiency. The simulation results showed that the coupling efficiency increased from the uncorrected 0.05% to 77.69% and 74.42% when corrected by two single deformable mirrors and 80.97% when jointly corrected [54].

In 2014, Liu et al. analyzed the influence of tilt and high-order aberrations on the mixing efficiency and bit error rate. The RMS value of the tilt aberration was used to estimate the change in mixing efficiency. First, the correctness of the theoretical analysis was verified via numerical simulation. Second, an experimental correction system for a two-stage fast-steering mirror and a 97-unit continuous curved-surface deformed mirror was designed. As the Greenwood frequency increased, a higher closed loop bandwidth was required to ensure the communication quality. When the Greenwood frequency was 160 Hz, the bit-error rate dropped below 10^{-9} in an adaptive optical system with a two stage fast mirror unit [55].

In 2014, Cao et al. used an SPGD algorithm to correct a wavefront distorted by atmospheric turbulence. They adopted a wavefront detection and control algorithm without a wavefront sensor to correct the wavefront, and the coupling efficiency of single-mode fiber was increased from 12% to more than 80% [56].

In 2014, Chao et al. analyzed the bit error rate performance of optical wireless coherent communication systems under different atmospheric turbulence conditions. The bit-error rate of the optical wireless coherent communication system was primarily affected by the directivity error under weak turbulence conditions. In the case of strong turbulence, the effect of high order aberrations on communication quality was increasingly serious, and the effect of correcting high order wavefront aberrations by the adaptive optics system was more obvious. With a 1550-nm wavelength as the communication band, the atmospheric turbulence intensity D/r_0 could be increased from 1 before correction to approximately 6.5 after adaptive optical correction. In addition, the mixing efficiency should be greater than 0.4, and the wavefront residual error after correction should be less than $\lambda/6$ [57–59].

In 2015, Huang et al. used an adaptive optical system to compensate for the wavefront distortion caused by atmospheric turbulence in a wireless coherent optical communication link. When the Fried's coherence length was $r_0 = 16$ cm, the amplitude fluctuation on the receiving aperture reduced the average SNR by about 24% [60, 61].

In 2015, Li et al. used adaptive optics to compensate for the influence of atmospheric turbulence. Under the same turbulence intensity conditions, a link channel at sea produced a larger bit-error rate than that on land [62, 63].

In 2015, Chen et al. used a 137-unit deformable mirror to compensate for the wavefront distortion caused by strong turbulence. When the phase RMS value was 0.3λ, the coupling efficiency decreased from 81% to 10% without phase distortion. In the case of strong turbulence, $D/r_0 = 15$, the SMF coupling efficiency of the system increased from 1.3% to 46.1% before and after correction [64].

In 2016, Zhao et al. combined adaptive optics technology with channel coding to correct phase distortions, and used wavefront correction and channel coding to further correct errors in each orbital angular momentum (OAM) mode. The simulation results showed that when the structural constant of the atmospheric refractive index was approximately $C_n^2 = 4.5 \times 10^{-14}\ m^{-2/3}$, the bit-error rate decreased from the original 10^{-1} to 10^{-3} after coding and wavefront distortion correction [65].

In 2018, Chen et al. reported that atmospheric turbulence had a serious impact on a wireless coherent optical communication system, based on an SMF coupling-system design of a 137 unit continuous curved-mirror adaptive optical unit. After adaptive optical compensation, the bit-error rate of the coherent communication was lower than 10^{-6}, which was significantly lower than the uncorrected bit error rate [66].

In 2018, Rui et al. developed multiple sets of adaptive optical ground stations of different calibers and designed the scale and arrangement form. They investigated the detection and correction module performance of an adaptive optical system according to the link characteristics and ensured the efficient coupling of a signal light to a single-mode fiber under strong atmospheric turbulence [67].

In 2019, Yang et al. investigated the performance improvement of wireless coherent optical communication systems using a large scale high speed adaptive optics system and a 349 unit continuous-surface deformable mirror. When the Greenwood frequency was 70 Hz, the bit-error rate of a 349 unit deformable mirror

adaptive optics closed loop was close to 10^{-9}, while the bit-error rate of the 97-unit deformable mirror only reached 10^{-6} [68].

In 2019, Chang et al. proposed a phase recovery algorithm correction method based on adaptive optics to compensate for the OAM beam distortion caused by ocean turbulence. Simulation results showed that in marine channels, adaptive optics technology based on a phase recovery algorithm could effectively compensate for the OAM beam distortion and improve the bit-error rate performance of the system [69].

In 2020, Rui et al. studied the statistical distribution of SMF coupling efficiency under adaptive optical compensation under different turbulence intensities. When the turbulence intensity $D/r_0 = 7$, the beam wavefront RMS value decreased from 0.42 to 0.04. Meanwhile, the coupling efficiency increased from 2.2% to 35.4%, on average. In addition, adaptive optical wavefront distortion correction improved the coupling efficiency of SMFs with a high probability [70].

In 2020, Chang et al. proposed an adaptive optics technique based on a phase recovery algorithm for single light intensity measurements to compensate for the wavefront distortion of OAM beams. The calculation results showed that the single-intensity measurement phase recovery algorithm was more robust than a double-intensity measurement phase recovery algorithm [71].

In 2020, Gu et al. combined a convolutional neural network with an SPGD algorithm to improve the coupling efficiency of spatial light to fibers. The calculation results showed that when the Strehl ratio was 0.9, the SPGD algorithm required several hundred iterations, whereas the algorithm combining a convolutional neural network and SPGD algorithm required a dozen or less iterations. The convergence time required by the SPGD algorithm was almost eight times that of the hybrid algorithm [72].

In 2021, Jiang applied adaptive optics technology to improve the coupling efficiency of a single-mode fiber on a 1 km experimental link. The experimental results showed that the coupling efficiency of the SMF increased from 5% in the open loop state of adaptive optics to 10–25% in the closed loop state [73].

In 2021, to avoid the wavefront distortion caused by the turbulence amplitude exceeding the measurement range of a Shack–Hartmann wavefront sensor, Zhang et al. proposed a method combining a standard wavefront sensor and a Shack–Hartmann wavefront sensor to expand the detection range. After correction, the communication bit-error rate decreased from 10^{-1} to 3×10^{-6}, and the correlation of the dot plot increased from 0.6 to 0.94 [74].

In China, research on adaptive optics technology is usually based on large projects; however, comprehensive and in-depth research on independent adaptive optics technology is lacking. Moreover, the application of adaptive optics technology to optical wireless communication is typically based on numerical calculation simulations. Numerical calculations mainly involve fiber coupling [56], closed loop bandwidth [49, 50], pre-correction [48], multi-corrector combinations [54], and ocean turbulence [69]. Unfortunately, these are limited by many conditions, such as experimental equipment and experimental sites.

Only a few scientific-research institutions have carried out relevant experiments, such as the Institute of Optoelectronic Technology, Chinese Academy of Sciences [58, 59, 64, 75]. Moreover, the experimental scale lags behind that of developed countries [76]. In addition, the uncertainty of atmospheric turbulence, the complexity of the system itself, the precision of signal capture and tracking, and the duration of research are all important factors restricting the development of adaptive optics in China.

Adaptive Optics in the Optical Wireless Communication Field

In recent years, Ke Xizheng et al. of Xi'an University of Technology have studied the following:

1. Laser transmission characteristics in atmospheric turbulence [77, 78]
2. Encoding and decoding of wireless laser communication systems [79]
3. Optical wireless subcarrier modulation
4. Channel estimation and equalization [80]
5. Alignment tracking and acquisition technology
6. Heterodyne coherent detection technology
7. Optical transceiver system design
8. Optical orthogonal frequency-division multiplexing modulation
9. Optical multi-input multi-output systems [81, 82]
10. Optical wireless transmission theory and technology under complex environments and systems [83]

Other key technologies of space optical communication have been deeply studied theoretically and experimentally verified, and gratifying results have been achieved [84, 85].

In 2016, a free-space optical (FSO) communication system terminal based on the IM/DD modulation and detection mode was successfully developed. The entire machine weighed less than 8 kg. The terminal had standard Ethernet data access capability and could reliably transmit duplex data, voice, and images.

Since 2017, Ke et al. have studied an optical wireless communication system for ultra-long distance transmission [86] and conducted experiments on a differential binary phase-shift keying (DBPSK) modulation coherent detection system [87–92].

Figure 23.1 shows the 100-km optical wireless communication experimental link of Xi'an University of Technology, and Fig. 23.2 shows a photo of the coherent optical communication receiving antenna. The optical wireless coherence communication experimental link based on coherent detection is located at both ends of Qinghai Lake. The transmitting end is located in Jiannan Mountain, Erlang, Qinghai Lake, and the receiving end is located in Quanji Township, Qinghai Lake. The transmitting terminal is composed of a laser source, electro-optic modulator, fiber amplifier, transmitting antenna, coarse-aiming platform, and micro-aiming platform. The transmitting antenna is a Kepler optical transmission antenna.

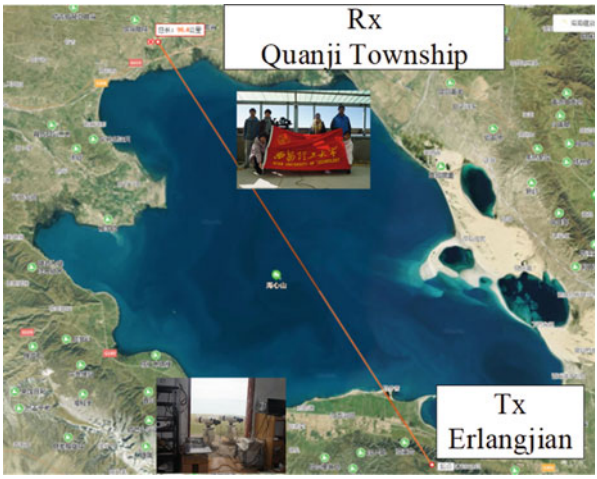

Fig. 23.1 Diagram of the 100-km optical wireless communication experimental link of Xi'an University of Technology

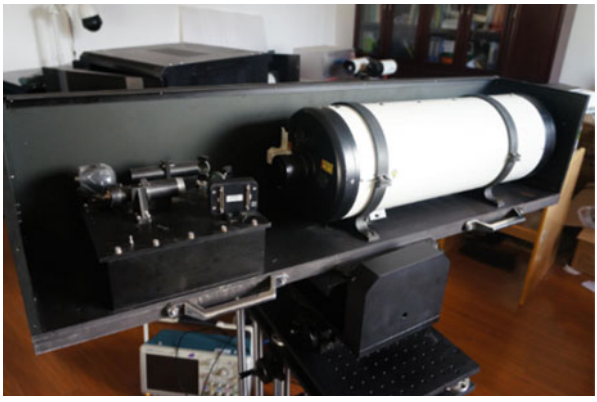

Fig. 23.2 Internal structure of the wireless coherent optical communication receiving antenna

The coarse-aiming platform, micro-aiming platform, and optical-antenna focusing system constitute a composite axis continuous focal length adjustment structure to enable beam alignment and tracking. The receiving end is mainly composed of a Cassegrain reflector receiving antenna, adaptive optical system, and coherent detection system.

An adaptive optical system composed of a bias mirror, deformable mirror, and wavefront sensor is used to correct the optical signals. After the wavefront correction, the laser is coupled to the mixer and balance detector by a fiber, and the signal is recovered after mixing with the local oscillator light.

After a long distance transmission of the light front, the light spot is completely broken, owing to atmospheric turbulence over Qinghai Lake. The light flicker caused by strong turbulence makes the sampling point incomplete and leads to difficulty in wavefront reconstruction. This directly leads to non continual data

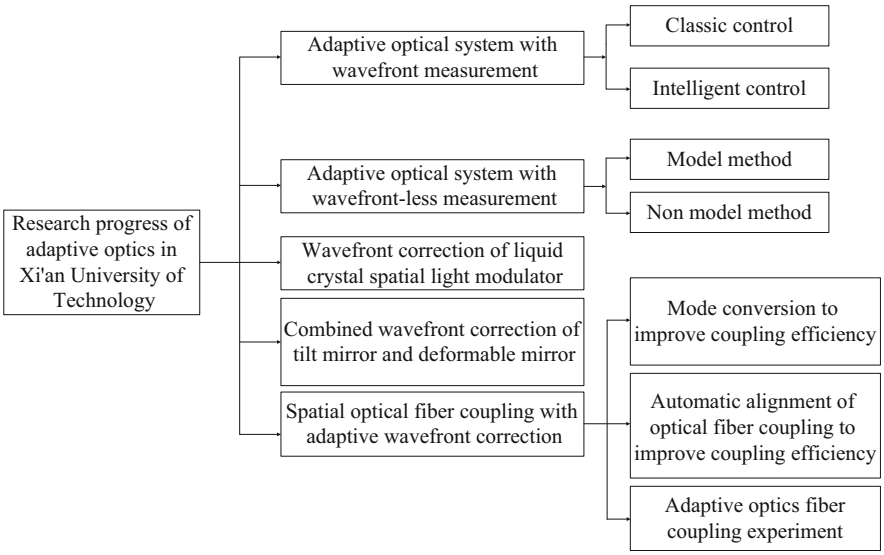

Fig. 23.3 Content structure of adaptive optics research

acquisition. The phase distortion of the wavefront is large, and the rate of change is high. Based on the collected wavefront data, the atmospheric coherence length was calculated to be 1.3 cm using the Hartmann wavefront measurement method.

When the transmitter uses 0 dBm power for beam emission, the power of the receiver coupling into the single-mode fiber is about −40.33 dBm, and its isolation is approximately 40 dB. With an increase in the output power of the fiber amplifier, the power coupled into the fiber increases, and the coupled light power of the double emission is higher than that of the single emission. Moreover, under the same power output, the variance in the double-emission coupled power is smaller than that of the single-emission coupled power. This shows that multiple structures can effectively suppress the light intensity flicker and coupling power fluctuation caused by atmospheric turbulence.

Ke et al. from Xi'an University of Technology have conducted studies on an adaptive optical system with wavefront measurement, adaptive optical system without wavefront measurement, wavefront correction of a liquid crystal spatial light modulator, wavefront correction of a combined tilt mirror and deformable mirror, and adaptive wavefront correction of spatial light fiber coupling. The structure of the study is shown in Fig. 23.3.

Adaptive Optical System with Wavefront Measurement

Adaptive optical systems can be divided into two types: with and without wavefront measurement. Figure 23.4 shows the principle diagram of an adaptive optical system

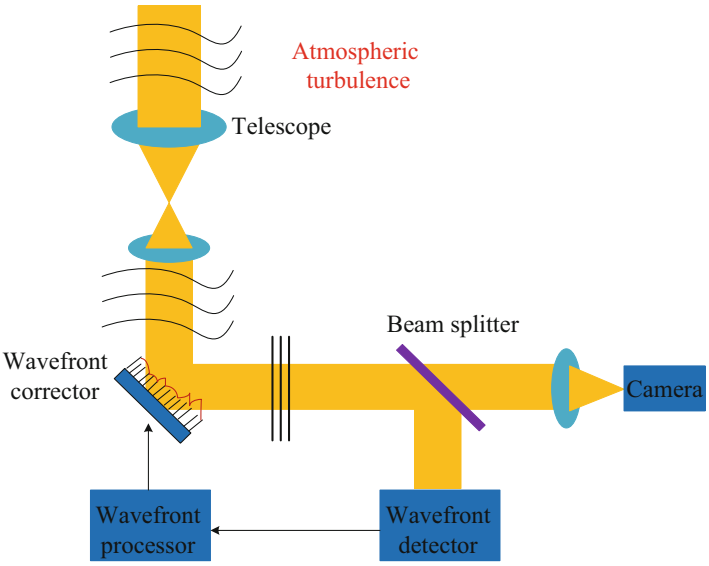

Fig. 23.4 Schematic diagram of an adaptive optical system

with wavefront measurement. The wavefront sensor measures the wavefront error in real time and transmits the measured wavefront error to the wavefront controller. The wavefront controller receives the distorted beam information from the wavefront sensor and calculates and obtains the control voltage of the wavefront corrector using an algorithm. The wavefront corrector receives the control voltage from the wavefront controller, corrects the wavefront distortion, and improves the communication quality.

Figure 23.5 shows the optical path of the wavefront adaptive optical system designed by Xi'an University of Technology.

As a traditional calibration method, the push pull method applies push and pull commands to the deformable mirror to complete the response matrix calculation [93]. Figure 23.6 shows the surface pattern generated by the deformable mirror driven by the 10th driver and the slope pattern collected by the wavefront sensor during the push pull method to solve the response matrix. Figure 23.7a shows the response matrix calculated using the traditional push pull method.

A Hadamard matrix was used to construct the transmission-voltage matrix and act on the deformation mirror. Several drivers were virtualized to realize the response-matrix calculation based on the Hadamard matrix [94]. Figure 23.7b shows the response matrix calculated using the Hadamard transformation method.

A prediction model of the adaptive optical system was established according to the linear subspace system identification method [95]. The DC gain of the adaptive optical system was obtained according to the control theory, namely, the response matrix of the system. Figure 23.7c shows the response matrix calculated using the system identification method.

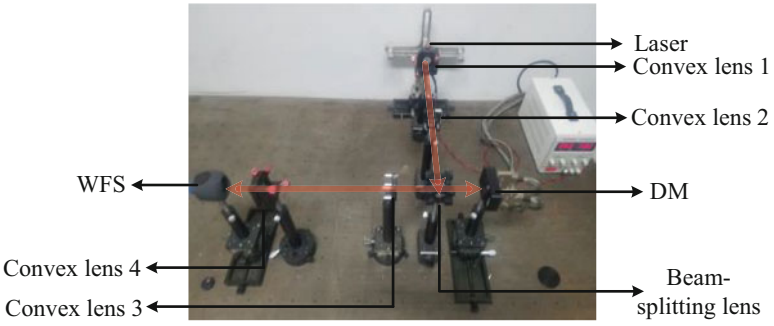

Fig. 23.5 Structure diagram of a wavefront adaptive optical system

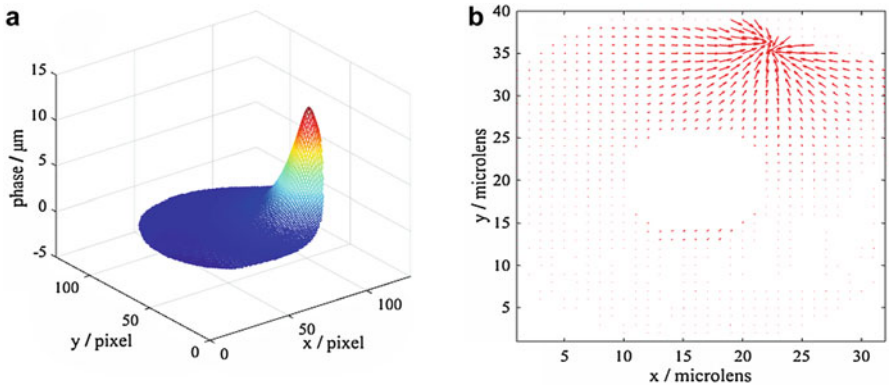

Fig. 23.6 (**a**) Deformable mirror profile; (**b**) wavefront-slope diagram driven by the 10th driver of the push–pull method

Classic Control

The proportional–integral–differential (PID) control algorithm is the most widely used algorithm for adaptive optical closed loop control. Figure 23.8 shows the principle diagram of the PID control algorithm for an adaptive optical system, where S_{tar} represents the target slope, S_{mea} the acquisition slope, S_{err} the error slope, V_{out} the output voltage of the deformable mirror, and $CM_{errslope2cmd}$ represents the command matrix from slope to voltage.

After the error slope is transformed into the error voltage by the command matrix, the voltage calculated by the PID algorithm is applied to the deformation mirror to correct the distorted wavefront. The wavefront sensor collects the wavefront slope again to complete the iterative closed loop control. Figures 23.9 and 23.10 show the wavefront PV curve and phase diagram of wavefront phase correction when the k_p and k_i parameters are changed, respectively. Compared with the initial state, the corrected wavefront is very close to the plane wave shape, and the concavity and surface roughness are greatly reduced.

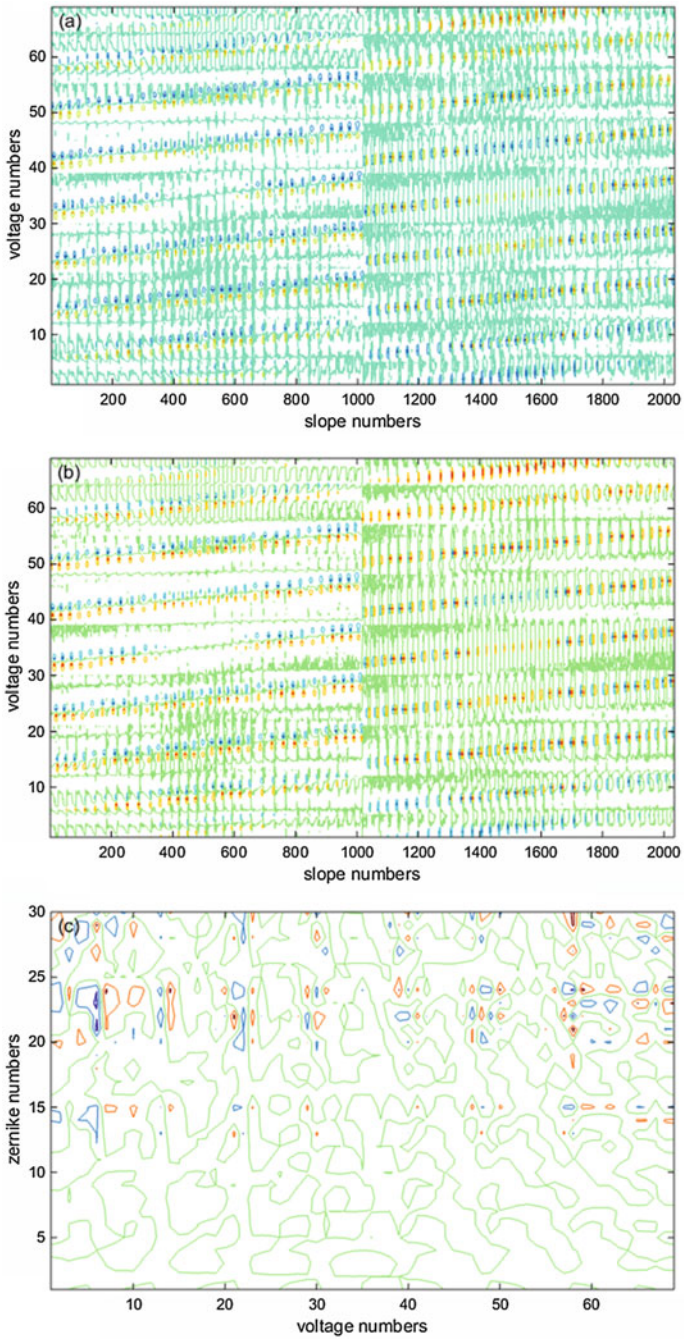

Fig. 23.7 Response matrices. (**a**) Traditional push–pull method; (**b**) Hadamard method; (**c**) system identification method

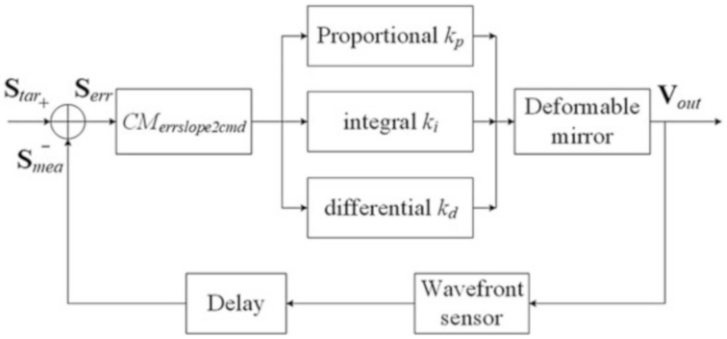

Fig. 23.8 Principle diagram of an adaptive optical PID control algorithm

When the response matrix (RM) from the deformable mirror voltage to the wavefront sensor slope is not limited, the RM between any quantity generated by the deformable mirror and any quantity collected by the wavefront sensor is established, and PID control is used to realize the closed loop control of the wavefront adaptive optical system.

Intelligent Control

Because the adaptive optical system is a typical multi-input multi-output (MIMO) linear system, its closed loop control can be realized by solving approximate solutions of linear equations using iterative arithmetic. Jacobi and Gauss–Seidel iterations are commonly used iterative methods for solving linear equations. The correction effect of the Gauss–Seidel algorithm in the field of adaptive optics is controlled by the accuracy of the iteration error. Figure 23.11 shows the wavefront phase diagram after correction with different convergence values. Selecting a suitable convergence value is the key step of the Gauss–Seidel iterative algorithm for realizing closed loop control.

Iterative learning control (ILC) constructs an iterative relationship from the linear relationship between the wavefront Zernike polynomial and the control voltage of the corrector. When an appropriate γ value is selected, it can make the iterative control algorithm converge to the optimal effect [97, 98]. Figures 23.12 and 23.13 respectively show the wavefront closed loop convergence curve and wavefront phase diagram using the ILC algorithm under different parameters. The greatest advantage of this algorithm is that it has a fast convergence rate when the parameters are appropriately selected.

Using the PID algorithm, Ke et al. from Xi'an University of Technology designed a double fuzzy adaptive PID control for an adaptive optical system [99]. Fuzzy control consists of four parts: a fuzzer, rule base, fuzzy inference machine, and fuzzer solution. Figure 23.14 shows the PV convergence curve of the wavefront with fuzzy control wavefront correction under different parameters.

Simulations and experiments showed that the fuzzy PID method effectively corrected the distorted wavefront signal, improved the system response speed,

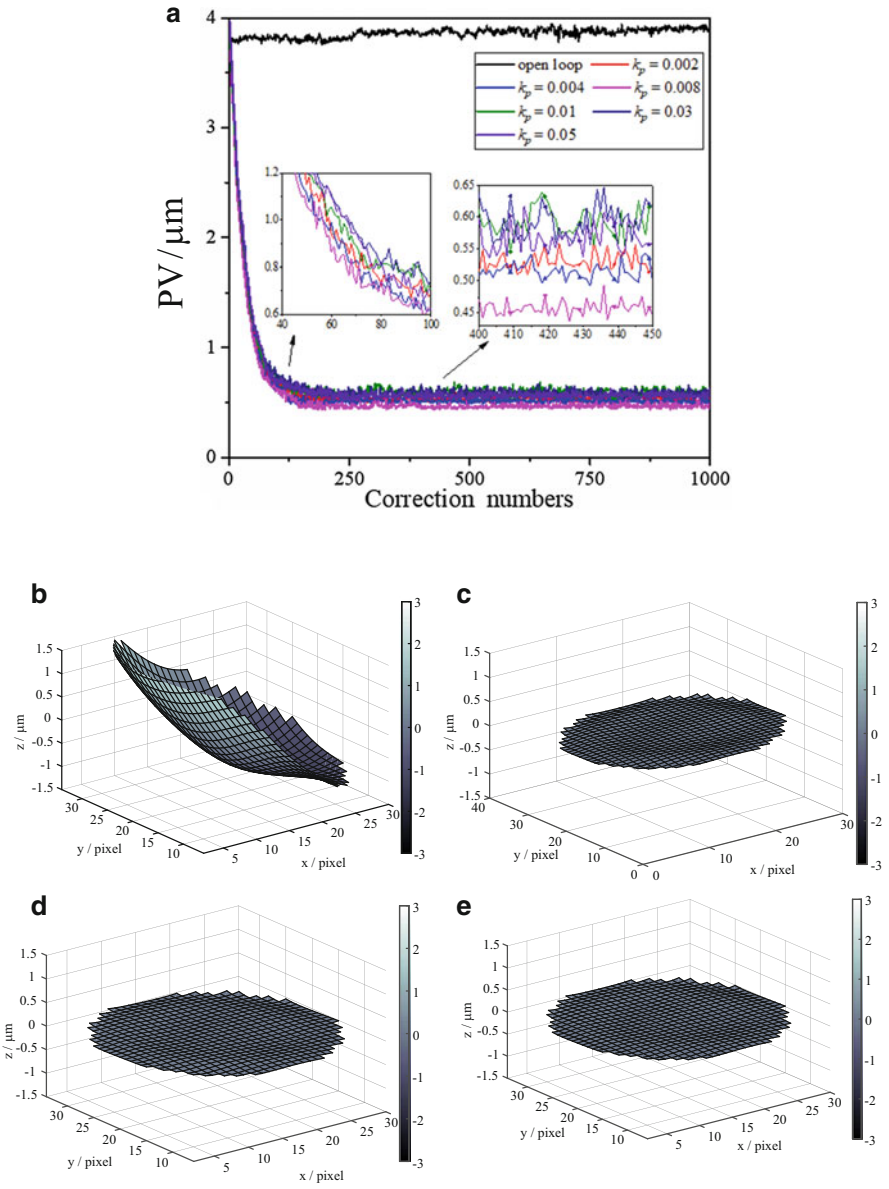

Fig. 23.9 Wavefront correction. (**a**) Wavefront PV curve; (**b**) open loop state under different k_p parameters; (**c**) $k_p = 0.002$; (**d**) $k_p = 0.008$; (**e**) $k_p = 0.03$ [96]

reduced the parameter-adjustment difficulty, and met the wavefront correction requirements for laser communication.

After the laser is transmitted over a long distance, the wavefront distortion caused by strong turbulence renders the wavefront sensor unable to accurately capture the

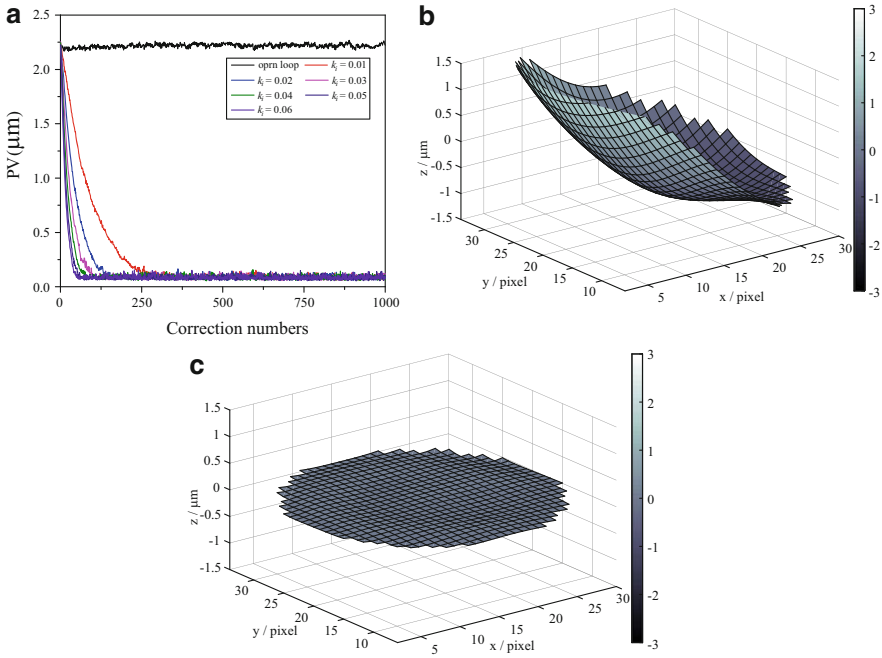

Fig. 23.10 Wavefront correction with different k_i parameters. (**a**) Wavefront PV curve; (**b**) open loop state; (**c**) $k_i = 0.01$ [96]

wavefront information in real time. The deformable mirror execution lags, which leads to errors in wavefront correction and decreases its accuracy. Based on the PID algorithm, the data are predicted, and a wavefront prediction model is established to reduce the servo delay and improve the correction rate.

Figure 23.15 shows the convergence curve of the adaptive optical wavefront prediction and correction. The closed loop convergence speed of the prediction algorithm is fast, and the correction speed of the system is relatively fast. Before the closed loop system stabilizes, the correction effect of the prediction algorithm is more evident than that of the PID algorithm. When the system reaches a stable state, the correction effects of the two algorithms are essentially the same.

Adaptive Optical System Without Wavefront Measurement

Based on wavefront measurements, Ke et al. from Xi'an University of Technology conducted research on an adaptive optical system with wavefront-free measurement [101]. Wavefront-free sensing technology does not require a wavefront sensor to measure and reconstruct the wavefront [102, 103] to obtain the wavefront distortion information. Rather, it directly converts the distortion information into performance indicators, such as the light intensity, SR, and coupling efficiency.

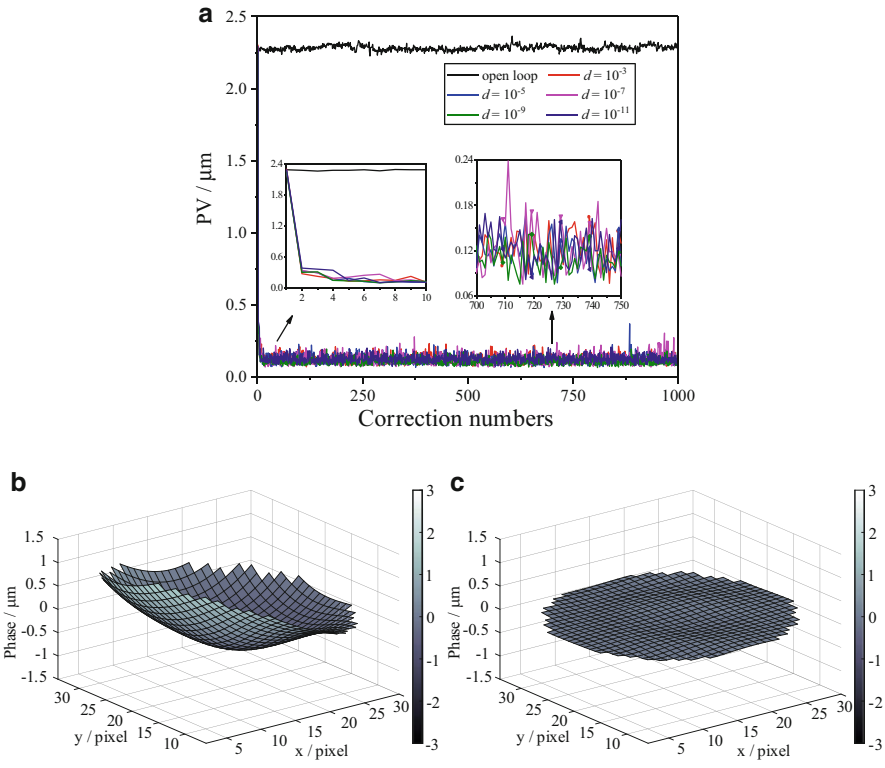

Fig. 23.11 Wavefront phase after correction with different convergence values δ. (**a**) PV value; (**b**) initial moment; (**c**) δ = 10–11 [96]

An optimization algorithm was used to iteratively optimize the performance indicators and control the constant deformation of the corrector. Thus, the distorted wavefront was corrected [104]. The wavefront-free adaptive optical system is shown in Fig. 23.16. LSM refers to liquid crystal spatial light modulator, CCD refers to charge coupled device, and DM refers to deformable mirror.

Mode Methods

The mode method holds that a distorted wavefront can be represented by a specific mode [105]. The algorithms are generally divided into two types.

One selects a mode to simulate the distorted wavefront and determines the transformation matrix between the mode coefficient and the influence function of each actuator of the deformation mirror. Then, combined with an intelligent optimization algorithm, the required mode correction coefficient is iteratively calculated to correct the distorted wavefront.

The other type calculates the performance index as a system function according to the detected light spot and uses the relation between the function and the mode

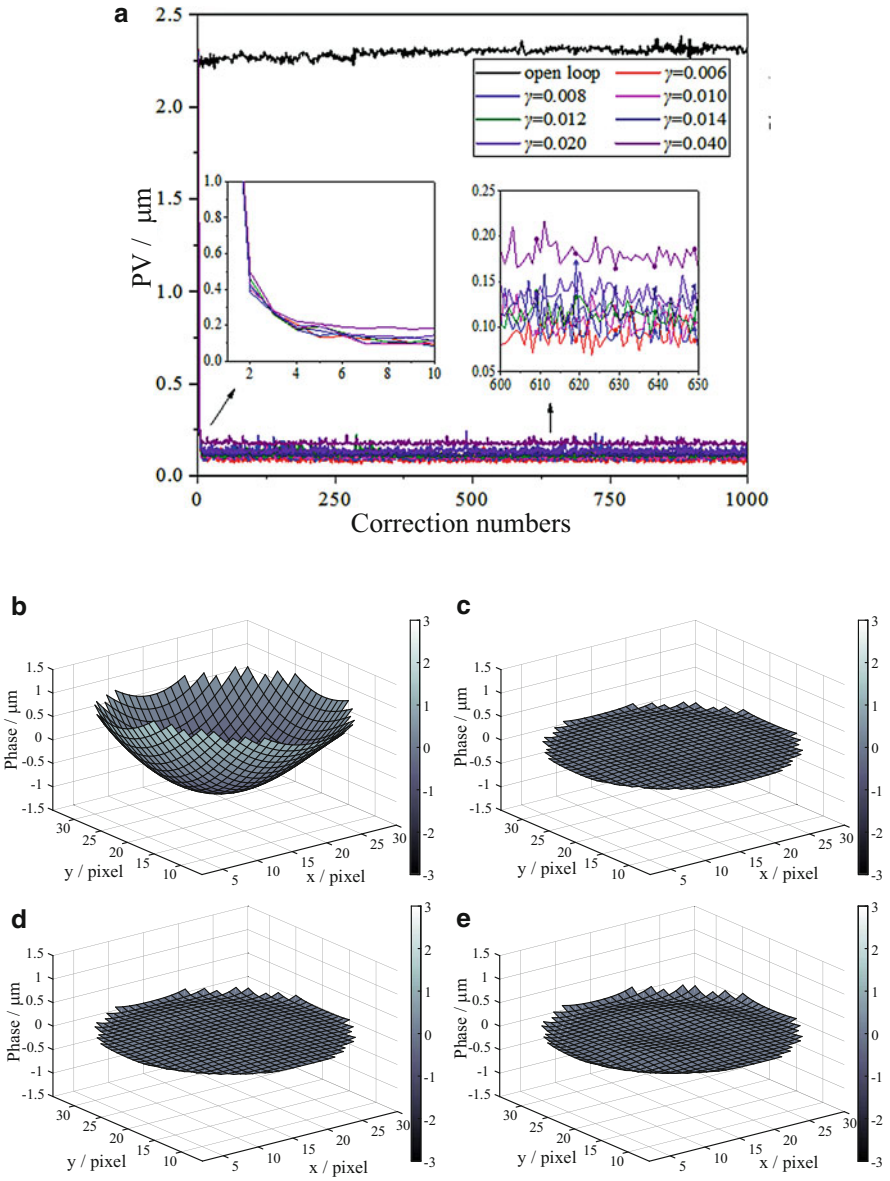

Fig. 23.12 Different γ-value corrections for the wavefront phase. (**a**) PV value; (**b**) open loop time; (**c**) $\gamma = 0.006$; (**d**) $\gamma = 0.014$; (**e**) $\gamma = 0.04$ [96]

coefficient to calculate the mode correction coefficient needed to correct the wavefront error. Because the selected base mode needs to satisfy a reciprocal orthogonal relationship, commonly used base modes include Lukosz modes and eigenmodes [106].

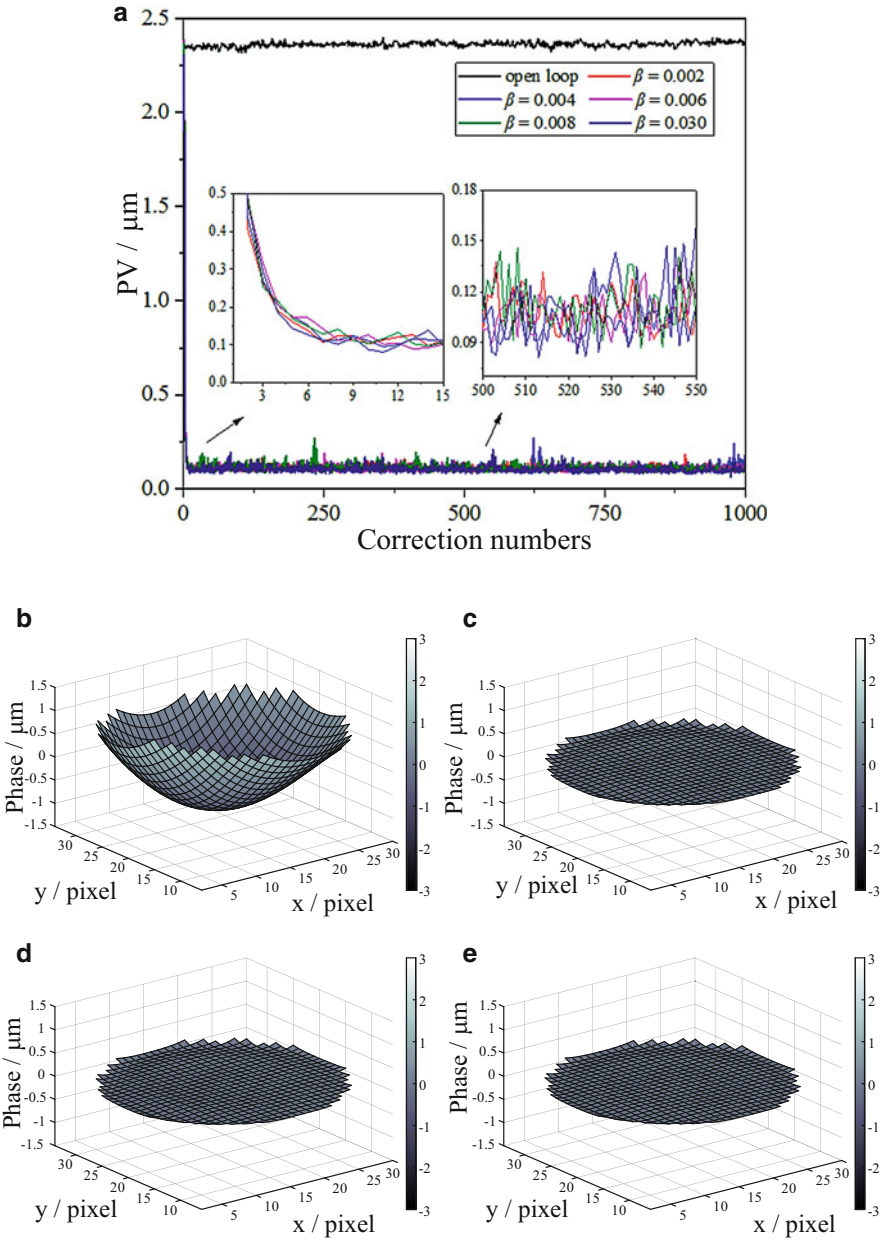

Fig. 23.13 Different β-value corrections for the system wavefront phase. (**a**) PV value; (**b**) open loop time; (**c**) β = 0.002; (**d**) β = 0.008; (**e**) β = 0.03 [96]

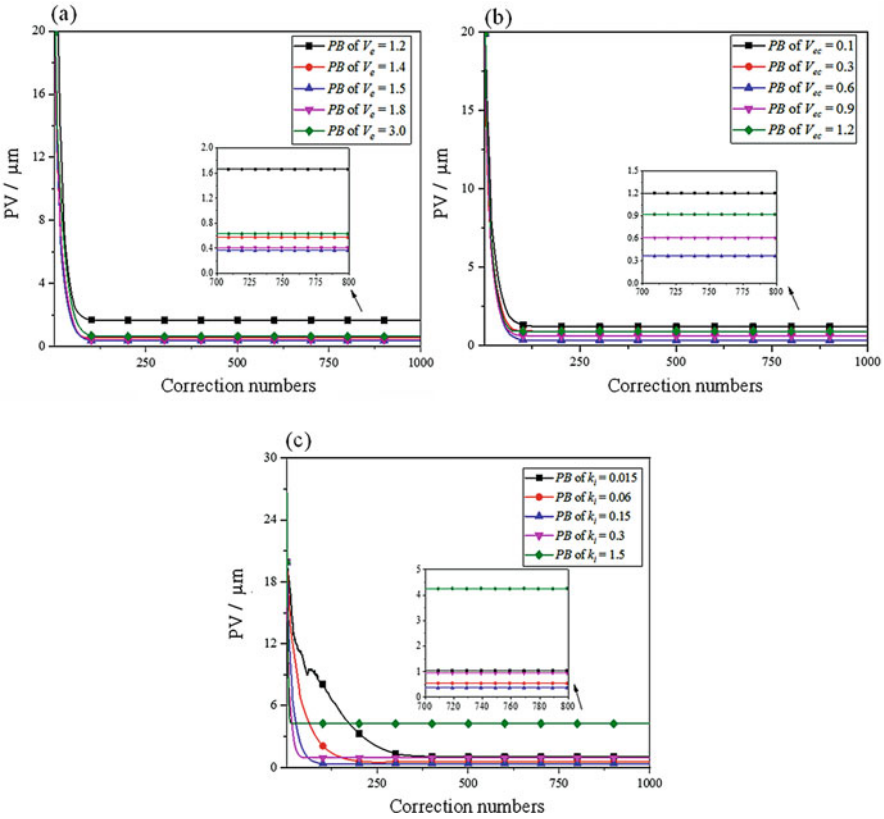

Fig. 23.14 Wavefront PV curve for fuzzy control correction [100]. (**a**) Different V_e; (**b**) different V_{ec}; (**c**) different k_i

The wavefront free correction algorithm for the eigenmode of a deformable mirror first establishes an optical system model to simulate the transmission of collimated Gaussian beams in the atmosphere and generate distorted light spots. Subsequently, it establishes a deformation mirror model and deduces the corresponding deformation mirror eigenmode as the base model. Finally, the system function is calculated and the wavefront aberration is corrected according to the principle of the eigenmode method of the deformable mirror.

Figure 23.17 shows the wavefront correction curve using the deformation mirror eigenmode method, and Fig. 23.18 shows the pattern of light spots before and after correction. The light intensity gradually increases with an increase in the number of iterations.

Non-mode Methods

The working principle of the adaptive optical non-mode method is to obtain the driving voltage of the wavefront corrector according to the optimization algorithm,

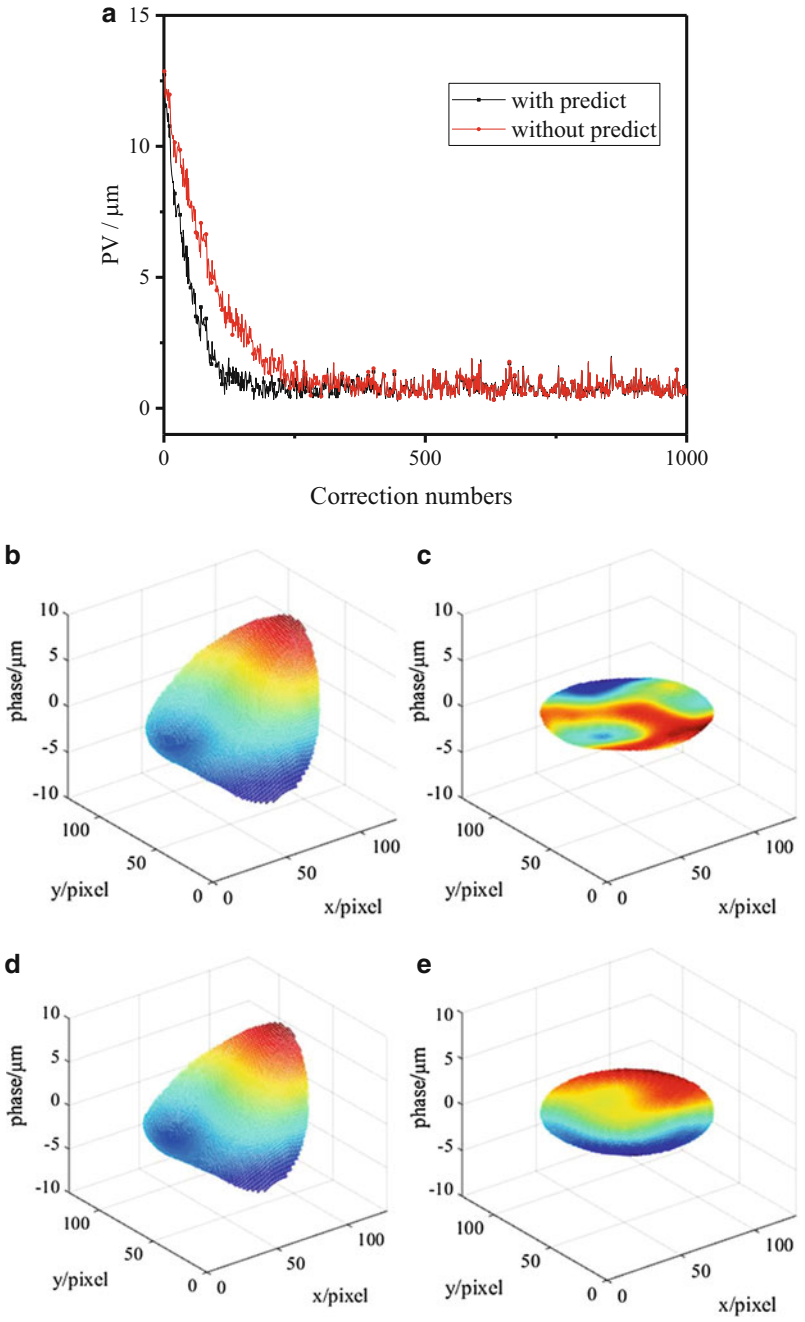

Fig. 23.15 Adaptive optical wavefront prediction correction. (**a**) Convergence curve; (**b**) unpredicted open loop phase; (**c**) unpredicted closed loop phase; (**d**) predicted open loop phase; (**e**) predicted closed loop phase

Fig. 23.16 Photo of the wavefront-free adaptive optical system

so that the objective function can reach the maximum value. Commonly used algorithms include gradient-descent algorithms, such as the conjugate gradient method and SPGD algorithm [108, 109], and heuristic algorithms, such as the simulated annealing (SA) [110], mountain climbing, and genetic algorithms [111].

Based on the light intensity distribution, the SPGD algorithm continuously optimizes to find the optimal value of the control voltage of the wavefront corrector so that the value of the objective function can meet the requirements [112]. From the numerical simulation perspective, wavefront distortion correction of a wavefront detection adaptive optics system based on the SPGD algorithm is studied, and the influence of different parameter values in the SPGD algorithm on the correction effect is analyzed [113].

Figure 23.19 shows the correction curve and light spots before and after correction using the SPGD algorithm. Before correction, far-field light spots have serious speculation and energy nonconvergence.

The SPGD algorithm takes 1550 nm optical power as feedback and uses fiber coupling, a deformable mirror, and a processor to form a loop to correct the 1550 nm optical power. The corrected optical power changes in the fiber coupling output are shown in Fig. 23.20.

After correction, the optical power output of the signal from the wavefront fiber tail increases obviously, and the coupling efficiency increases by approximately 32 times. The improvement in the coupling efficiency directly contributes to the communication performance. However, this method is only applicable to a weak-turbulent static wavefront environment and is not applicable to the coupling efficiency fluctuation caused by a strong turbulent environment.

Ke et al. from Xi'an University of Technology carried out wavefront correction experiments on vortex optical adaptive optics with non-mode and no wavefront methods. The Gerchberg–Saxton algorithm for phase recovery is an indirect measurement method used to reconstruct the wavefront phase from the wavefront intensity and inversely deduce the phase information from the optical intensity distribution.

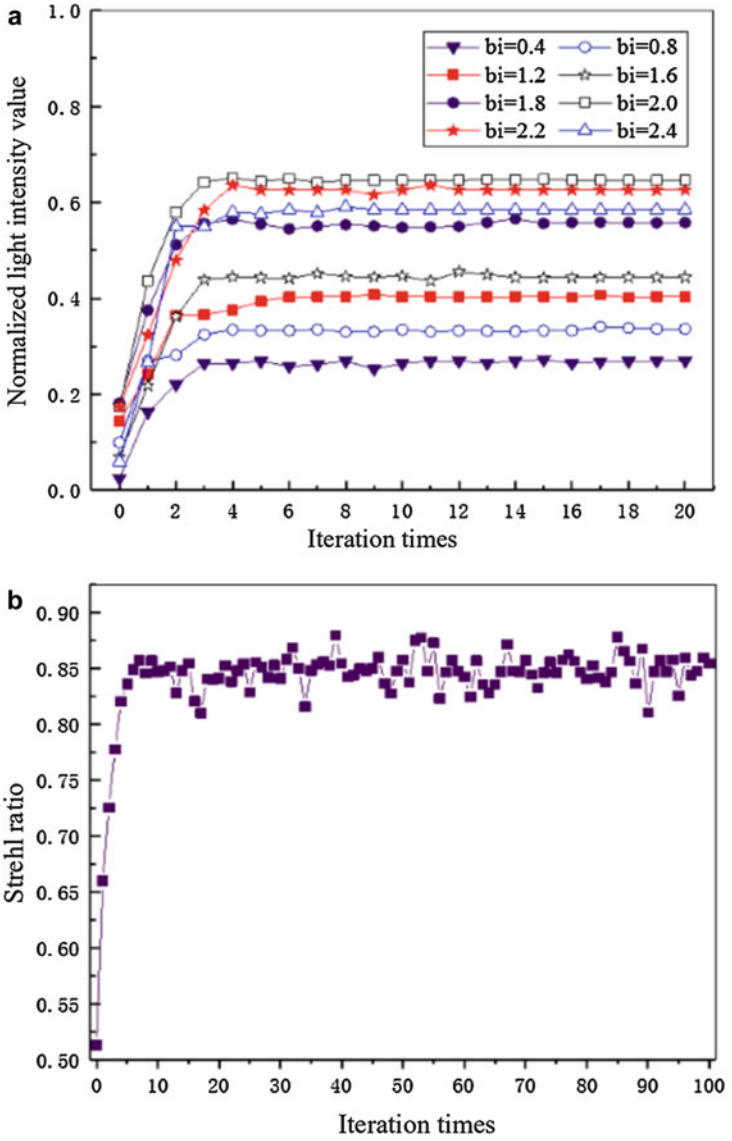

Fig. 23.17 Variation curve of the SR intensity corrected by the eigenmode of the deformable mirror. (**a**) Simulation; (**b**) experiment [107]

The idea of the algorithm is as follows: Based on the light intensity distribution at the incident plane and the output plane, the phase distribution information of the required light field can be obtained by controlling the initial conditions and performing iterative operations [116].

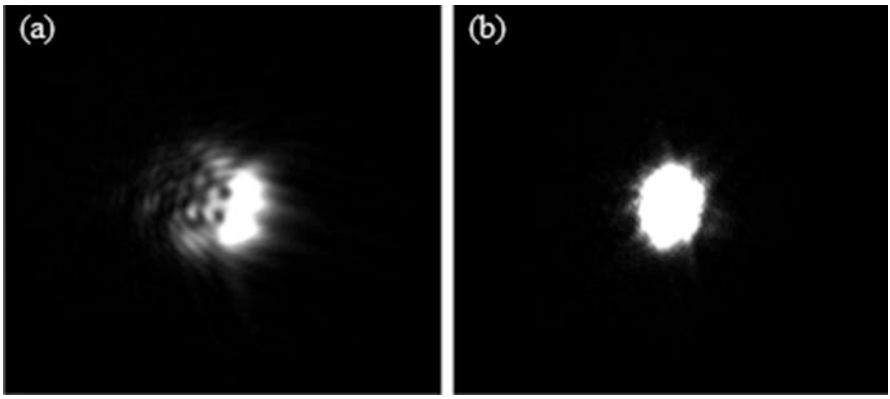

Fig. 23.18 Light spots before and after wavefront correction. (**a**) Before correction; (**b**) after correction [107]

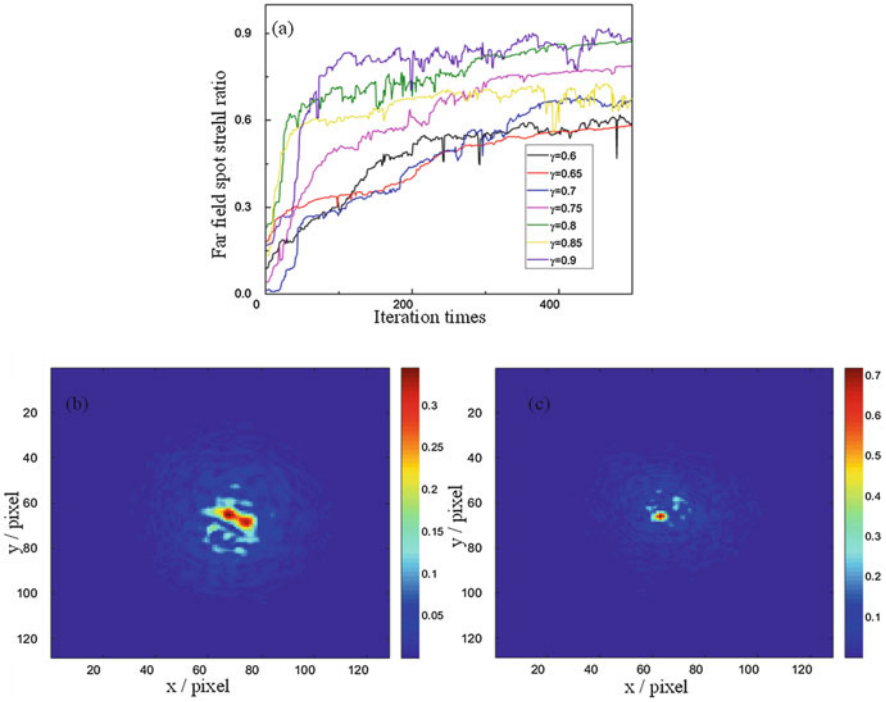

Fig. 23.19 Wavefront correction based on the SPGD algorithm [114]. (**a**) Variation curve of the light intensity SR; (**b**) spot before correction; (**c**) spot after correction

Figure 23.21 shows the intensity distribution of each order of vortex beam before and after correction using the Gerchberg–Saxton phase recovery algorithm. After the correction, the toroidal distribution of the single-mode vortex beam after turbulence

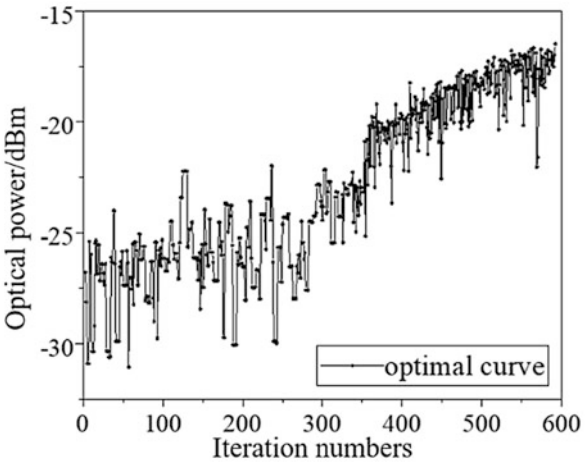

Fig. 23.20 Fiber coupling correction curve of the wavefront-free correction method [115]

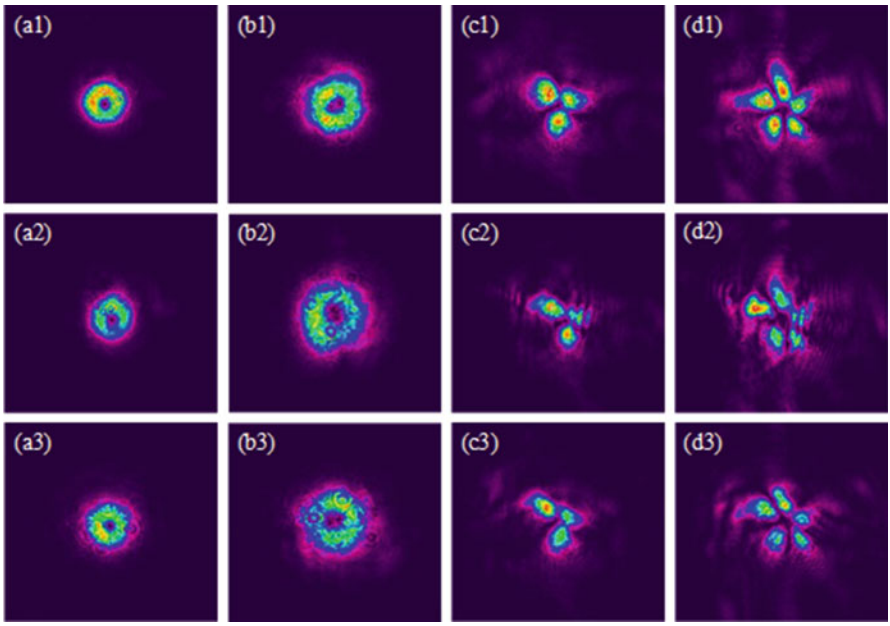

Fig. 23.21 Intensity distribution of vortex beams of each order before and after correction using the Gerchberg–Saxton phase recovery method [117]. (**a1**)–(**d1**) no turbulence; (**a2**)–(**d2**) turbulent; (**a3**)–(**d3**) after correction

is restored to a large extent, and the energy distribution on the toroidal spot becomes uniform. As can be seen from Fig. 23.21, the Gerchberg–Saxton phase recovery algorithm can effectively correct wavefront distortion for both single-mode and multimode multiplexed vortex beams.

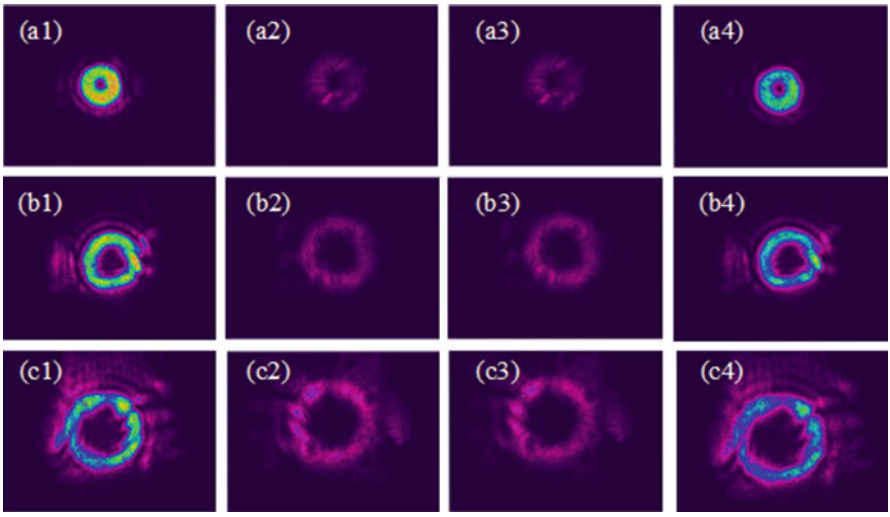

Fig. 23.22 Intensity distribution of a single vortex beam corrected by the phase difference method [119]. (**a1**)–(**c1**) initial light intensity; (**a2**)–(**c2**) light intensity at the focal plane; (**a3**)–(**c3**) light intensity at the defocusing plane; (**a4**)–(**c4**) light intensity after correction

The phase difference (PD) method is a wavefront-free detection technique that indirectly inverts the phase distribution of the wavefront from the light intensity information of the image surface of the imaging system. In this algorithm, the intensity information of the focal and defocusing planes of the system is collected, and the objective function is established according to the point diffusion function of the two channels. Finally, the phase distribution of the wavefront on the pupil plane of the imaging system is obtained by solving the optimization function.

Figure 23.22 shows the intensity distribution of a single vortex beam corrected and compensated by a wavefront correction system using the phase difference method [118]. After the atmospheric turbulence disturbance, the beam is distorted, and the intensity distributions of the focal plane and defocusing plane become dispersed, compared with the initial state. After correction using the phase difference method, the distribution of the light intensity is more uniform than the distortion moment, and the energy on the ring spot is enhanced. The phase difference method can effectively correct the wavefront distortion of a single vortex beam.

Wavefront Correction Using Liquid Crystal Spatial Light Modulators

Liquid crystal spatial light modulators (LC-SLM) are based on the electronically controlled birefringence principle of a liquid crystal. They can continuously modulate the light wave phase by changing the electric driving signal of the liquid crystal. Figure 23.23 shows a block diagram of a liquid crystal spatial light-front correction system based on a coherent optical communication system.

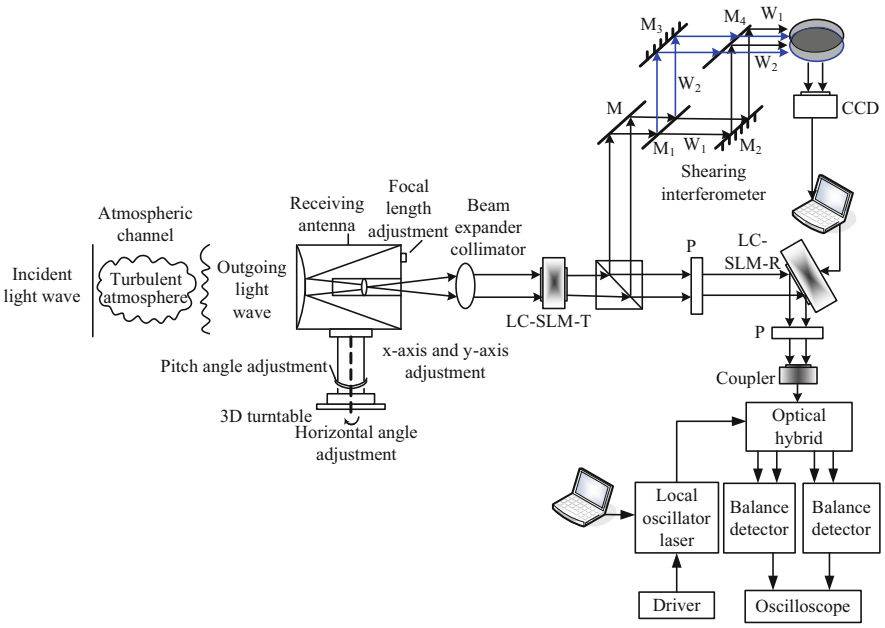

Fig. 23.23 Schematic diagram of LC-SLM wavefront correction for a wireless coherent optical communication system [120]

Figure 23.24 shows the voltage value of the intermediate frequency (IF) signal output by the oscilloscope without wavefront correction. Figure 23.24a is the voltage amplitude of the IF signal in the same phase direction (I channel), and Fig. 23.24b is the voltage amplitude of the IF signal in the orthogonal direction (Q channel). After correction, the voltage amplitude of the IF signal output by the balanced detector tends to stabilize. Although the voltage amplitude of the IF signal fluctuates slightly with the change in time in the experiment, there is no great difference between the output sine wave amplitudes, which is basically stable.

Compared with the voltage amplitude of the IF signal before correction in Fig. 23.24, the voltage amplitude of the IF signal is increased by a factor of approximately 1.7 times after wavefront correction by LC-SLM, and the SNR after correction is increased by approximately three times [121].

Combined Wavefront Correction Using Tilt and Deformable Mirrors

Introducing a tilt mirror (TM) [123] or a multistage deformable mirror (DM) for wavefront correction is the current development trend of adaptive optical systems for large-distortion wavefront correction. A tilt mirror or a large-stroke deformed mirror (usually called a woofer) is used to correct low-order wavefront components, and a small-stroke deformed mirror (usually called a tweeter) is used to correct high-order

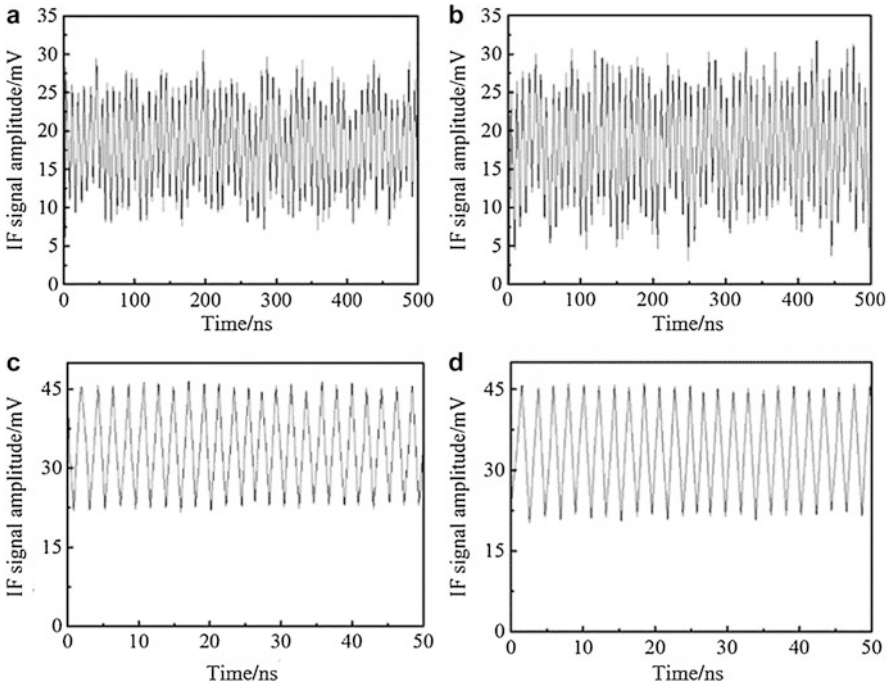

Fig. 23.24 Amplitude of the IF signal before and after correction [122]. (**a**) I channel before correction; (**b**) Q path before correction; (**c**) I path after correction; (**d**) Q circuit after correction

wavefront components. Based on the orthogonality of the Zernike polynomials, the space of the correction region between them is clearly divided [124].

A common multi corrector adaptive optical system includes a piezoelectric biasing TM, based on two-dimensional motion, and a DM69 deformable mirror with an independent element. This invention relates to an adaptive optical system consisting of a large-stroke DM69 deformable mirror with few independent elements and a small-stroke DM292 deformable mirror with many independent elements. Because the laser communication system has a low requirement for wavefront correction accuracy, and the cost of a DM292 is higher than that of a TM, in practice, in an adaptive optical system, a TM and DM69 are typically used for closed loop correction for system communication.

Figures 23.25 and 23.26 show the wavefront PV curve and phase diagram for TM-alone correction, DM69-alone correction, and simultaneous TM and DM69 correction, respectively. As shown in Fig. 23.25, the simultaneous correction effect of the TM and DM69 closed loops is better than that of TM or DM69 alone. The introduction of the TM alleviates the large-travel problem of the DM actuator caused by excessive wavefront distortion, and the power of the deformable mirror can be alleviated when correcting a wavefront phase with the same distortion.

Spatial Optical Fiber-Coupled Adaptive Optical Wavefront Correction

Automatic Fiber Coupling Alignment

To improve the efficiency of coupling space light to fiber, Ke et al., Xi'an University of Technology, designed a fiber coupling system based on the automatic alignment of two-dimensional piezoelectric ceramics [125]. By changing the voltage applied to the piezoelectric ceramics, the fiber is displaced and aligns the optical axis [126].

Figure 23.27a shows the variation curve of the X-axis output voltage after a simulated annealing algorithm is adopted. It can be seen from the figure that the curve always fluctuates at the beginning, i.e., the entire system is looking for the maximum value. Then, it changes to a stable state, i.e., the optimal coupling position is found. At this time, the voltage value shifts up and down at 23.68 V and the amplitude does not exceed 0.1 V. At this time, the mean voltage is 23.65 V and the variance is 0.04432 V.

Figure 23.27b shows the variation curve of the Y-axis output voltage after the simulated annealing algorithm is adopted. It can be seen from the figure that the curve always fluctuates at the beginning, i.e., the entire system is looking for the maximum value. The fluctuation indicates the process of searching for the best coupling position, and then, it is in a stable state, i.e., the best coupling position is found. The mean voltage is −23.323 V and the variance is 0.03212 V. The voltage curve reflects the process of determining the optimal coupling position of the entire system in real time.

The simulated annealing algorithm found the best coupling position in a short time, and the coupling efficiency reached 51.4%. The piezoelectric ceramic driving circuit designed in this system has high precision, and the piezoelectric ceramic fixing mode is reliable. This method can effectively improve the coupling efficiency of optical fiber.

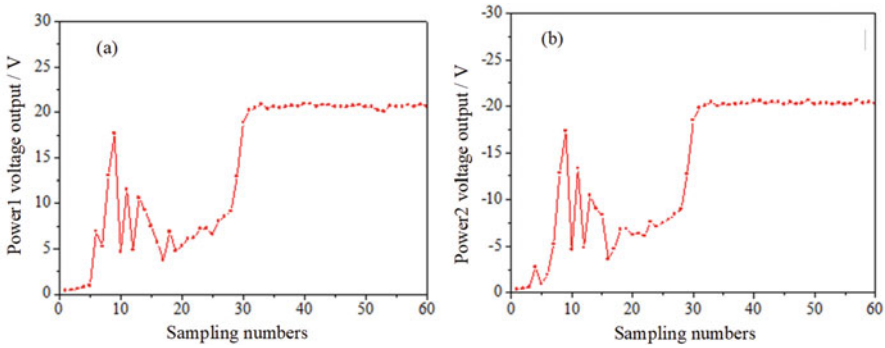

Fig. 23.27 Voltage variation when a simulated annealing algorithm is added [127]. (**a**) X axis; (**b**) Y axis

By applying two-dimensional piezoelectric ceramics to automatic fiber coupling alignment, Ke et al., Xi'an University of Technology, designed a five-degrees-of-freedom spatial light single-mode fiber coupling device, which adopted three different piezoelectric ceramic displacement modes, and designed the corresponding constant voltage DC power supply circuit and voltage amplification circuit, according to the working conditions of the three piezoelectric ceramics.

The SPGD algorithm was used to automatically align a spatial light and single-mode fiber coupling by considering the optical power in the coupled single-mode fiber as the system-performance evaluation function. Figure 23.28 shows the variation curve of the coupled optical power with the number of iterations under the introduction of different deviations.

Figure 23.28a shows that the initial coupled optical power is −12.37 dBm, when the axial deviation is introduced. After approximately 75 iterations of the algorithm, the optical power converges to about −1.15 dBm. As can be seen from Fig. 23.28b, the initial coupled optical power is −15.51 dBm when the radial deviation is introduced; the algorithm converges after about 90 iterations of the coupled optical power. After convergence, the coupled optical power fluctuates slightly around −1.21 dBm, indicating that the radial deviation is compensated.

As shown in Fig. 23.28c, when an angle deviation is introduced by adjusting the incident light direction, the initial coupled light power is −23.4 dBm. After

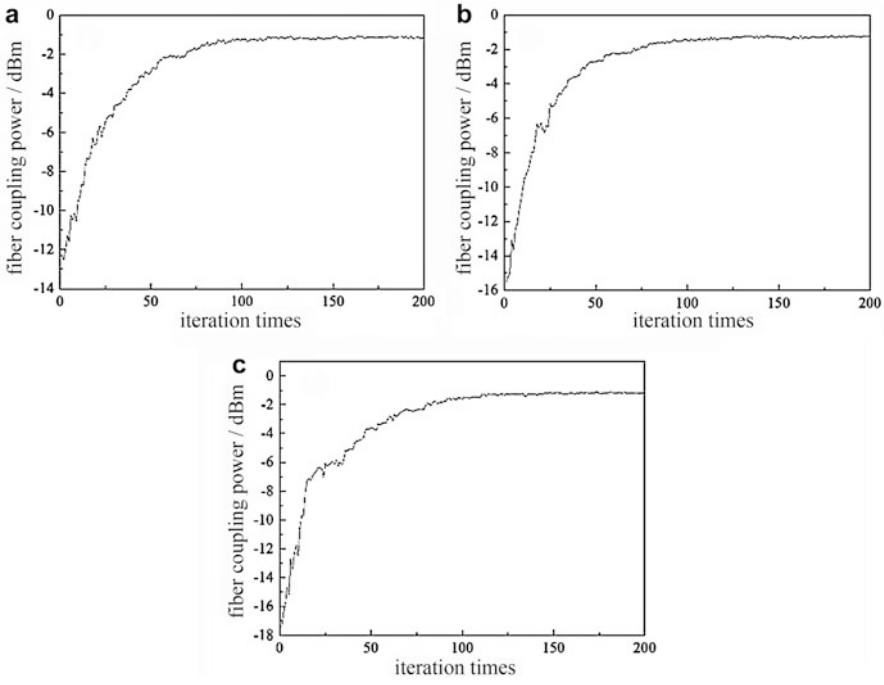

Fig. 23.28 Coupling optical power variation curve with the number of iterations under different deviations [128]. (**a**) axial; (**b**) radial; (**c**) angle

approximately 100 iterations of the algorithm, the coupled light power gradually converges and finally fluctuates around −1.19 dBm, indicating that the angle deviation is compensated [128].

Mode Conversion

In an optical wireless communication system, the spatial light mode is affected by atmospheric turbulence, and the beam mode is degraded, which leads to a mismatch between the mode field of the single-mode fiber and that coupled by the receiver. This reduces the efficiency of coupling the space light and single mode fiber. Ke et al. from Xi'an University of Technology experimentally studied the conversion of free-space light from a high order mode to a low-order mode based on LC-SLMs [129, 130].

Figure 23.29 shows the conversion result of the high order mode to the low order mode. The LP02 mode distribution in the first column is compared with the ideal light intensity distribution, and the distribution and symmetry of the light field energy are consistent with the ideal case; however, high-order diffraction components are inevitably present. After the degraded mode is passed through LC-SLM2, the obtained LP01-mode light field distribution energy concentration is consistent with the ideal mode field distribution. In addition, the distribution of the light field becomes more concentrated with a decrease in the mode order.

It can be observed that after the spatial-mode conversion based on a LC-SLM combined with the SA algorithm, the obtained mode distribution of LP01 is consistent with the distribution under ideal conditions, and the energy is concentrated in the central position, which has an obvious conversion effect.

When the degraded mode obtained by preprocessing is LP22, the coupling power during a pure binary conversion is −23.53 dBm, and the coupling efficiency after SA-algorithm optimization increases from 55.92% to 66.21%. An LC-SLM is used to convert the mode, increase the content of the fundamental mode, and indirectly

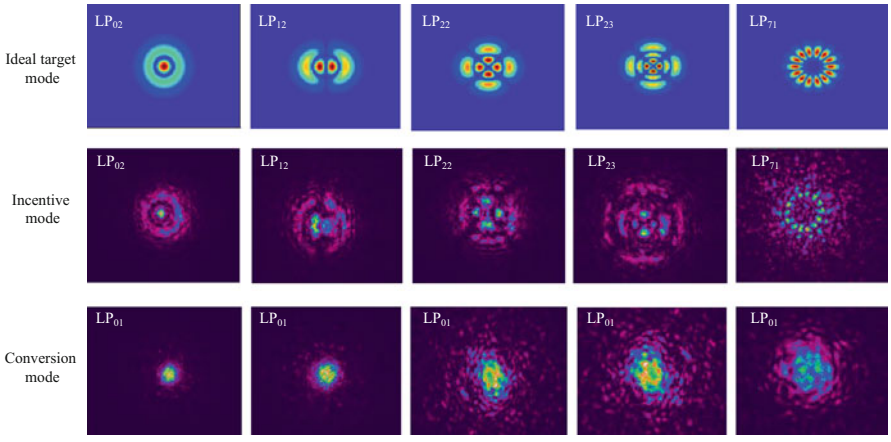

Fig. 23.29 Mode conversion results [130]

improve the coupling efficiency of the spatial optical single-mode fiber from the mode conversion. The coupling efficiency of the LP02 mode with the smallest order increases to 69.18%. The LP71 mode has the largest corresponding order, and the coupling efficiency increases from 49.12% to 60.29% of the binary conversion.

Adaptive Optical Fiber Coupling Experiment

To improve the efficiency of coupling space light to optical fiber, optical wireless communication using adaptive optics to suppress atmospheric turbulence was studied by combining adaptive and nonadaptive wavefront methods. Figure 23.30 shows the adaptive optical fiber coupling system. The adaptive optical wavefront system consists of a TM, DM69, wavefront sensor, and computer; the nonadaptive optical wavefront system consists of a splitting prism, coupling lens, single-mode fiber-optic power meter, and infrared camera.

Because the wavefront phase collected by the wavefront sensor is not in the same optical path as the fiber-coupled optical fiber end-face, the nonpublic optical path aberrations and fiber-coupled assembly errors generated by the lens are static errors. Their error magnitude is unrelated to changes in the external environment but is only related to the uniformity of the lens material, the device installation position, and the position of the fiber-coupled optical end-face.

Because of this error, the branch wavefront cannot be corrected after the closed loop of traditional adaptive optics. Two methods can eliminate this error: the blind optimization algorithm and the phase difference method. Compared with the phase difference method, the blind optimization method is more mature in practical engineering applications.

Figure 23.31 shows the coupled power curve and wavefront PV curve before and after error elimination by the SPGD algorithm. As shown in Fig. 23.31, after error elimination, the power decreases after the adaptive optical closed loop, whereas the coupled power increases after elimination.

Figure 23.32 shows the coupling power curve under adaptive optic open loop and closed loop conditions. As shown in Fig. 23.32, the coupling efficiency after

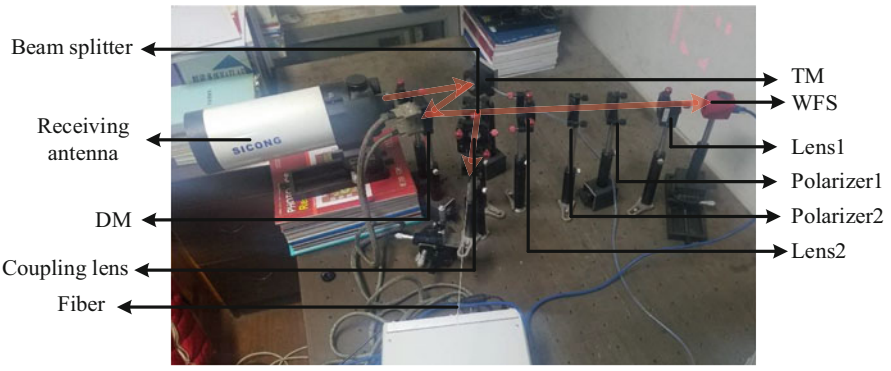

Fig. 23.30 Schematic diagram of an adaptive optical wavefront correction fiber coupling control system

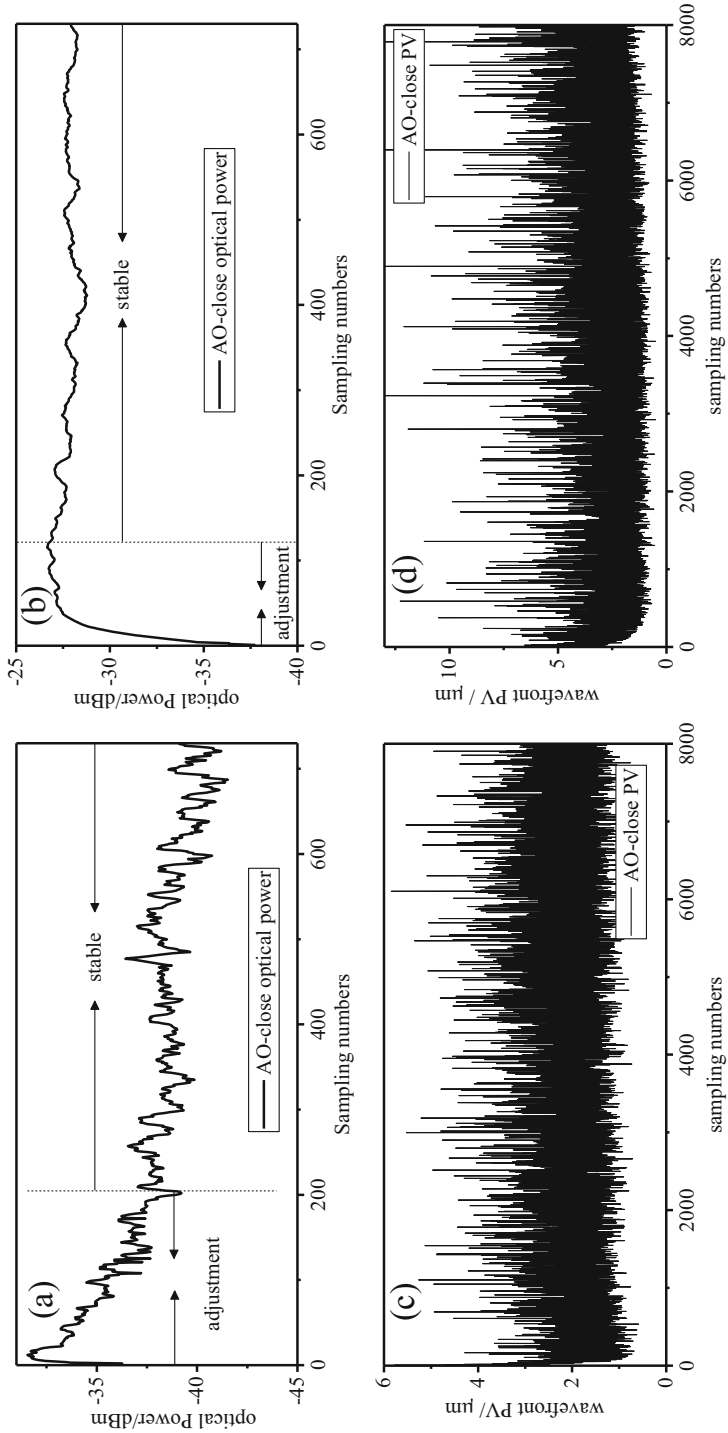

Fig. 23.31 Influence of a non-common optical path aberration on the adaptive optical closed loop coupling power and wavefront phase. (**a**) Uneliminated-aberration optical power; (**b**) eliminated-aberration optical power; (**c**) PV value of the aberration wavefront is not eliminated; (**d**) PV value of the aberration wavefront is eliminated

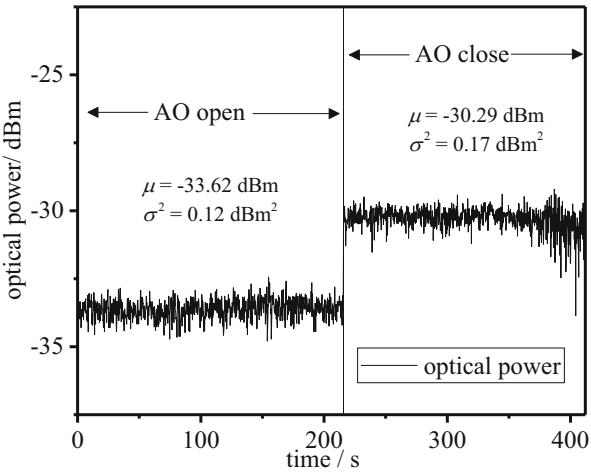

Fig. 23.32 Fiber coupling power variation curve before and after adaptive optical wavefront correction

correction is significantly higher than that before correction, indicating that adaptive optics can effectively improve the coupling efficiency of spatial light to fiber by correcting the distorted wavefront.

Observing the wavefront phase after eliminating the nonpublic optical path as the control object, Fig. 23.33 shows the calculation results of the coupling efficiency based on the Zernike coefficient of the measured wavefront at different distances. After the wavefront is corrected, the influence of wavefront distortion on the coupling efficiency increases from 10%, 5%, 10%, 3%, 5%, and 5% to 90%, 80%, 90%, 60%, 40%, and 10% when the optical wave is transmitted indoors, 600 m, 1 km, 5 km, 10 km, and 100 km, respectively. In addition, the effect of short-distance correction is better than that of long-distance correction. The numerical fluctuation of the coupling efficiency corrected at short distances is smaller than that at long distances.

For the coupling efficiency before and after correcting the 10-km wavefront, the correction had a numerical improvement in the coupling before the correction; however, the fluctuation of the coupling efficiency was too large, which was not conducive to the stability of the communication system. However, for a 100-km wavefront coupling efficiency, there was no significant improvement after correction. This is because the light intensity flicker caused by 100 km of strong turbulence and light spots is completely broken, which directly leads to the discontinuous acquisition of Zernike-coefficient wavefront data. The distortion of the 100-km wavefront is discontinuous and too large to ensure the real-time correction of the wavefront.

For subsequent research on the application of adaptive optics technology in optical wireless communication systems, the research content should focus on the convergence degree of a spot in the focal plane of the coupling lens after correcting the distorted wavefront, so that it can be directly coupled to the detector surface of the IM/DD system.

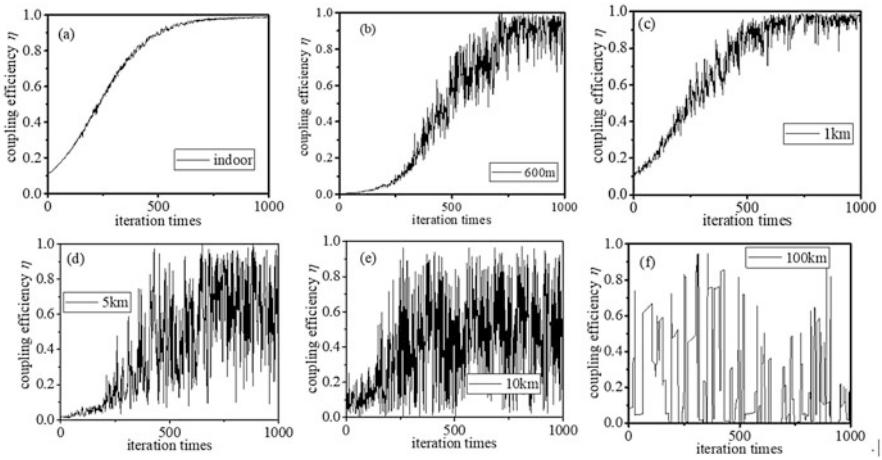

Fig. 23.33 Influence of wavefront correction on the coupling efficiency at different distances. (**a**) Indoors; (**b**) 600 m; (**c**) 1 km; (**d**) 5 km; (**e**) 10 km; (**f**) 100 km

For a remote coherent detection system, the research focus should be on non-wavefront sensing correction. Mode and non-mode optimization algorithms can improve the coupling efficiency of spatial light to fiber while correcting the distorted wavefront. Moreover, the relative fluctuation variance of the optical coupling power of adaptive optics technology in atmospheric turbulence should be considered to ensure the stable communication performance of the system.

Summary

This chapter systematically summarized the application of adaptive optics in the optical wireless communication field at home and abroad, and introduced the work in related fields by Xi'an University of Technology. The research work included adaptive optical systems with wavefront measurement, adaptive optical systems without wavefront measurement, wavefront correction of liquid crystal spatial light modulators, wavefront correction using a combination of tilt and deformable mirrors, and wavefront correction of spatial optical fiber-coupled adaptive optics. Finally, future research directions were presented.
